Abstract
We describe a superconducting Casimir apparatus inspired by a recently proposed setup involving magnetic surfaces (Bimonte G 2014 Phys. Rev. Lett. 112 240401). The present setup consists of a superconducting Nb sphere and a flat gold plate including in its interior a superconducting Nb strip. The experimental scheme involves a differential measurement of the Casimir force at a point of the gold plate above the Nb strip and away from it. We show that similar to the previous setup, the superconducting system considered here implies widely different modulations of the Casimir force, depending on whether the thermal force is computed using the Drude or the plasma model, thus paving the way to an unambiguous discrimination between these alternative prescriptions.

Keywords: Casimir, superconducting, thermal

(Some figures may appear in colour only in the online journal)

1. Introduction
The last 20 years witnessed a resurgence of interest in the Casimir effect [1], triggered by a series of new precision experiments. Impressive progress has been made both in theoretical modelling, as well as on the experimental side. On the former front, powerful scattering methods have been developed [2, 3] by which it is in principle possible to compute the Casimir force between two bodies of arbitrary shapes and materials. On the other hand many new experiments have been performed to probe the Casimir effect for non-planar microstructured surfaces [4–9] and for many diverse materials (other than conductors) like for instance semiconductors [10], liquids [11], superconductors [12] and magnetic materials [13].

The overall picture is rather satisfying, as it has become abundantly clear that we have achieved a good theoretical understanding of the main factors that significantly affect the Casimir force between real material surfaces, like their geometrical and optical features, as well as possible imperfections of the surfaces like roughness, absorbed impurities, patch potentials and/or stray charges on the surfaces. For a comprehensive review see [14, 15].

In this landscape of successes, however, there still is a dark spot, since an important problem is still waiting for a satisfactory theoretical explanation, as well as for a clear experimental resolution. The problem is about the influence of the temperature on the magnitude of the Casimir force, in the experimentally important case of metallic surfaces. It is useful to briefly review the matter. For finite temperatures, the modes of the em field propagating in the region of space between two surfaces get populated according to the Bose–Einstein distribution, thus modifying the free-energy of the system. The resulting correction to the Casimir force is quite easy to compute for two perfectly conducting parallel plates. One finds that for separations \(a\) smaller than the thermal length \(\lambda_T = \frac{\hbar c}{2\pi k_B T}\) (\(\lambda_T = 1.2 \, \mu m\) at room temperature) the thermal correction scales like \(a/\lambda_T\) and it is negligibly small, while for \(a \gg \lambda_T\) it is linear in the temperature \(F_T(2\pi k_B T) = k_B T \zeta(3)/(4\pi a^3)\) and it represents the dominant contribution to the Casimir force. Surprisingly, it was realized in 2000 [16] that the above simple findings are in sharp contrast with the results of detailed computations taking into full account the finite conductivity of real metals. It was found that the thermal correction scales linearly in the temperature also for small separations and it was orders of magnitude larger than the one for an ideal metal (even though it still represented a small correction to the total force, of a few percent for separations around 400 nm at room...
temperature). Moreover its limiting value for large separations was only one-half the perfect-conductor limit \( F_T^{(1, \infty)} \). A further perplexing feature of the real metal result was that the thermal force could not be reconciled with the perfect conductor limit by taking the conductivity to infinity. It was also found that the finite conductivity result, while consistent at large separations with the Bohr–van Leeuwen theorem of classical statistical physics [17, 18], appeared to violate Nernst third law of thermodynamics in the idealized limit of two plates with a perfect crystal structure [19, 20]. No thermodynamic inconsistencies arise however if account is taken of the finite residual resistance of real metals at low temperatures [21–23].

A thorough investigation quickly revealed the mathematical reason for the large \( T \)-linear thermal correction. One has to recall that the famous Lifshitz formula [24] provides a representation of the Casimir free energy for two parallel slabs in the form of a sum over so-called (imaginary) Matsubara frequencies \( \xi_l = 2\pi lk_B T / h, l = 0, 1, 2, \ldots \) of a series whose terms involve the product of the Fresnel reflection coefficients of the slabs. It was found that the large thermal correction found in [16] originated from vanishing of the contribution to the Matsubara sum of the zero-frequency transverse-electrical TE mode (TE \( \omega_T = 0 \)). The absence of this mode is due to the fact that the Fresnel reflection coefficient of a metallic plate is zero for TE \( \omega_T = 0 \) modes. This is very plausible since TE \( \omega_T = 0 \) modes are nothing but static magnetic fields and ohmic conductors are transparent to magnetic fields. The physical explanation of the \( T \)-linear (repulsive) correction was elucidated by studying the real-frequency spectrum of the thermal Casimir force. This analysis revealed that the \( T \)-linear thermal force originated from the interaction among the Johnson currents that exist inside conductors at finite temperature [25, 26].

The thermodynamical inconsistencies brought about by the Drude prescription motivated some researchers to abandon this prescription. It was found indeed that a thermal correction in agreement with Nernst theorem, proportional to \( T^3 \) at small distances, could be obtained [19, 20] if the contribution to the Casimir force from the TE \( \omega_T = 0 \) was calculated in accordance with the plasma model of infrared optics \( \epsilon_{\text{plasma}} = 1 - \omega_p^2 / \omega^2 \), with \( \omega_p \) the plasma frequency (this has since been dubbed as plasma prescription). Several small-distance Casimir experiments have been interpreted as being in accordance with the plasma prescription and to rule out the Drude prescription (for a review of several of these experiments see [27]).

The view is widely shared that there is a need for experiments probing the thermal Casimir force. So far, there is only one experiment by the Yale group [28] which claims to have observed the thermal force between a large sphere and a plate both covered with gold, in the wide range of separations form 0.7 to 7.3 \( \mu \)m. The results have been interpreted by the authors as being in accordance with the Drude prescription. This experiment has been criticized [29, 30], because the thermal Casimir force was obtained only after subtracting from the total measured force a much larger force of uncertain nature, that the authors attributed to electrostatic forces originating from large patches on the surfaces. The subtraction was performed by making a fit of the total observed force, based on a two-parameter model of the electrostatic force and not by a direct and independent measurement of the electrostatic force, as it would have been desirable.

As of now there is no reported observation of the thermal Casimir force at separations less than 0.7 \( \mu \)m, which is the range in which the Casimir force has been measured most accurately. The reason is that, as noted before, the thermal Casimir force represents a small correction at sub micron separations and therefore tight experimental demands must be fulfilled to observe it: these include a very accurate electrostatic calibration of the apparatus [31–37], a detailed knowledge of the optical properties of the involved surfaces over a wide frequency range [38–40] and a precise determination of the separation between the two surfaces. These factors represent sources of systematic errors that are difficult to quantify, thus complicating the interpretation of the experiments and often stimulating controversies.

In order to circumvent the drawbacks of current Casimir experiments aiming at the observation of the thermal force, the author proposed recently an alternative experimental scheme [41, 42]. The setup described in [41] consists of two aligned sinusoidally corrugated Ni surfaces, one of which is hidden by a thin opaque layer of gold with a flat exposed surface. The gold over-layer, which acts as a low-pass filter, is the key ingredient of the setup. The scheme of measurement is based on the observation of the phase-dependent modulation of the Casimir force, as one of the two corrugations is laterally displaced, relative to the other. It was shown in [41] that the amplitude of the modulation predicted by the Drude and the plasma prescriptions differ by several orders of magnitude and not just by a few percent as with previous setups! In addition to this big improvement, the setup was shown to have a number of distinct advantages that are a consequence of the differential character of the measurement scheme. The first and perhaps the most important one, is that the electrostatic calibration becomes totally unnecessary. This is a consequence of the well known fact that conductors screen out electrostatic fields. Therefore, electric fields generated by stray electric charges and/or potential patches that may exist either on the corrugated surface of the exposed Ni surface, or on the flat exposed surface of the gold over-layer cannot penetrate inside the gold layer and feel the presence of the hidden Ni corrugation. This implies that the associated electrostatic forces are uncorrelated with the relative phase between the two corrugations and are thus automatically subtracted out from the modulation. The second advantage is that the optical properties of Ni or Au are irrelevant too, because it was shown in [41] that the modulation of the Casimir force depends only on the static magnetic permeability of Ni. In this way one gets rid of two of the main sources of uncertainty that affect present measurements of the Casimir force. It was estimated that with the help of this setup a clean observation of the controversial thermal Casimir force should be possible, with currently available Casimir apparatuses. A Si–Au setup aiming at the observation of the thermal Casimir force, which is based on the same principle as [41], is described in [42].

In this paper we present detailed computations for an interesting superconducting variant of the setup in [41, 42]. It has been shown in the past that superconductors provide
The setup, schematically shown in figure 1, consists of a superconducting Nb sphere of radius $R$ above a thick superconducting Nb strip (shown in black) of half-width $s$. The crucial feature of the setup is that the Nb strip is fully embedded in a gold matrix whose flat exposed surface is parallel to the Nb strip. The interesting quantity to consider is the difference

$$\Delta F = F_{\text{Au}} - F_{\text{Nb}}$$

among the magnitude $F_{\text{Nb}}$ of the Casimir force that obtains when the tip of the sphere is right above the center of the Nb strip and the magnitude $F_{\text{Au}}$ of the Casimir force that obtains when the tip of the sphere is instead above a point of the gold plate which is far from the Nb strip.

A little reasoning shows that by measuring $\Delta F$ it should be easily possible to discriminate which among the Drude and the plasma prescriptions is the correct one. The argument is analogous to that of [41], but for the sake of the reader we find it useful to go through it in some detail. According to the scattering approach [2, 3], the Casimir force between the Nb sphere and the Nb–Au plate in figure 1 can be expressed as a discrete sum over the so-called imaginary Matsubara frequencies $\xi_l$ of a series whose terms involve the product of the respective scattering coefficients for em waves of frequency $i\xi_l$. The Matsubara modes that contribute significantly are those with frequencies less than a few times the characteristic frequency $\omega_c = c/(2a)$, where $a$ is the minimum sphere-plate separation. It is easy to convince oneself that non-vanishing Matsubara modes give a negligible contribution to $\Delta F$, provided that the minimum thickness $w$ of the gold matrix at points above the Nb strip is much larger than the characteristic penetration depth $\delta$ of the non-vanishing Matsubara modes in gold (typically $\delta \approx 10$ nm or so), a condition that we assume to be satisfied from now on. Indeed, for

$$w \gg \delta$$

non-vanishing Matsubara modes cannot propagate deep enough inside the gold matrix to reach the Nb strip. The contribution $F^{(\omega \neq 0)}$ of these modes to the Casimir force is therefore practically the same whether the sphere tip is right above the Nb strip or far from it and it thus follows that $\Delta F^{(\omega \neq 0)}$ is nearly zero:

$$\Delta F^{(\omega \neq 0)} \approx 0.$$  (3)

Let us consider now the $\omega = 0$ modes. They come in two types, i.e. TE and TM $\omega = 0$ modes. Since TM $\omega = 0$ modes represent static electric fields, they are clearly screened out by the gold overlayer and therefore their contribution to $\Delta F$ is zero:

$$\Delta F^{(\text{TM};0)} = 0.$$  (4)

We are left then with the TE $\omega = 0$ modes. They represent static magnetic fields and whether they contribute or not to $\Delta F$ crucially depends on the adopted prescription. Consider first the Drude prescription. When modeled as a Drude metal, gold is transparent to static magnetic fields and therefore when the tip of the sphere is far from the Nb strip, the contribution of the TE $\omega = 0$ modes to $F_{\text{Au}}$ is zero:

$$F^{(\text{TE};0)}_{\text{Au}} = 0.$$  (5)

This is not so when the tip of the sphere is above the superconducting Nb strip, because then the TE $\omega = 0$ modes can reach unimpeded the Nb strip. With respect to the TE $\omega = 0$ modes the presence of the Au matrix is indeed immaterial and everything goes as if the Nb sphere were facing a ‘naked’ Nb strip. Since superconductors expel static magnetic fields (Meissner effect) they are strongly scattered by it (we assume that the thickness and width of the Nb strip are both much larger than the penetration depth of magnetic fields). As a result, within the Drude approach $\Delta F$ receives a significant contribution $F^{(\text{TE};0)}_{\text{Nb}}$ from the TE $\omega = 0$ modes:

$$\Delta F^{(\text{TE};0)} \propto -F^{(\text{TE};0)}_{\text{Nb}}, \quad \text{(Drude prescription).}$$  (6)

In view of equations (3)–(6), we arrive at the important conclusion that within the Drude prescription the change $\Delta F$ in the Casimir force originates almost entirely from the contribution to the Casimir force from the TE $\omega = 0$ modes, when the Nb sphere in on top of the Nb strip:

$$\Delta F \approx -F^{(\text{TE};0)}_{\text{Nb}}, \quad \text{(Drude prescription).}$$  (7)

Things go differently with the plasma prescription. While the considerations that led us to equations (3) and (4) remain
unchanged, an important difference arises with regards to the crucial TE $\omega = 0$ modes. When modeled as a dissipationless plasma, gold effectively behaves as a superconductor and it screens out static magnetic fields within a penetration depth $\delta_0 = c/\omega_0 \simeq 20$ nm. Therefore, for $w \gg \delta_0$ not even the TE $\omega = 0$ modes can propagate deep enough in the gold matrix to probe the Nb strip and similarly to the case of the non-vanishing Matsubara modes, we conclude that within the plasma prescription the TE $\omega = 0$ modes also give a negligible contribution to $\Delta F$:

$$\Delta F^{(\text{TE},0)} = 0 \quad (\text{plasma prescription}).$$

(8)

In view of equations (3) and (4) we conclude

$$\Delta F = 0, \quad (\text{plasma prescription}).$$

(9)

The conclusion of the above arguments is that by measuring $\Delta F$ in this setup, a clear-cut discrimination among the two prescriptions should be possible.

## 3. Computing $\Delta F$

We now turn to the computation of the Casimir force change $\Delta F$ for our superconducting setup. The framework for computing the Casimir force between real materials is provided by Lifshitz theory [24]. In its original version the material boundaries of the system are planar dielectrics ($\mu = 1$) fully described by the respective frequency-dependent (complex) dynamical permittivity $\epsilon(\omega)$. The theory was later generalized to deal with layered magneto-dielectric plates in [47, 48]. In our computations we shall assume, as it usually the case in the slopes of the bounding surfaces [50–52]. The gradient in a gradient expansion of the Casimir force, in powers of $\epsilon(\omega)$, has been shown that the PFA represents the leading term more applications of the Proximity Approximation). Recently, the PFA has been widely used to interpret most Casimir experiments [15] (see [49] for more applications of the Proximity Approximation). Recently, it has been shown that the PFA represents the leading term in a gradient expansion of the Casimir force, in powers of the slopes of the bounding surfaces [50–52]. The gradient expansion shows that the PFA is asymptotically exact in the zero-curvature limit and with its help it is now possible to estimate the error introduced by the PFA. Besides $R \gg a$, two further conditions are required to ensure the validity of the PFA in our strip-plane setup. To be definite, we let $(x, y, z)$ a cartesian coordinate system such that the $(x, y)$ coordinates span the exposed surface of the gold plate, placed at $z = 0$, while $z = a$ is the plane containing the sphere tip. Consider first the Casimir force $F_{\text{Nb}}$ which is observed when the tip of the Nb sphere is placed above the center of the Nb strip. To ensure that we can neglect the effect of the sharp edges of the strip, we shall assume that the half-width $s$ of the Nb strip is much larger than the typical radius $\rho = \sqrt{aR}$ of the circular region of the plate that contributes significantly to the Casimir interaction: $s \gg \rho$. When this condition is fulfilled, the force $F_{\text{Nb}}$ is undistinguishable from the force $\tilde{F}_{\text{Nb}}$ between the Nb sphere and a plane-parallel two-layers slab consisting of a gold layer of thickness $w$ on top of an infinite Nb planar slab (we recall that the thickness of the Nb strip was assumed to be large compared to the penetration depth of em field in Nb). Consider now the force $F_{\text{Au}}$ that is observed when the sphere tip is far from the Nb strip. In practical terms, if the sphere tip is placed above a point of the Au plate whose horizontal distance from the nearest edge of the Nb strip is much larger than $\rho$, $F_{\text{Au}}$ becomes undistinguishable from the Casimir force $\tilde{F}_{\text{Au}}$ between the sphere and an infinite homogeneous gold slab. Under these conditions, we can then write for $\Delta F$:

$$\Delta F \simeq \tilde{F}_{\text{Au}} - \tilde{F}_{\text{Nb}} \simeq F^{(\text{PFA})}_{\text{Au}} - F^{(\text{PFA})}_{\text{NbAu}}$$

(10)

where $F^{(\text{PFA})}_{\text{Au}}$ and $F^{(\text{PFA})}_{\text{NbAu}}$ denote the PFA expressions for the Casimir force between a Nb sphere and a two-layer Au–Nb planar slab and a gold planar slab, respectively, while $\tilde{F}_{\text{NbAu}}$ and $\tilde{F}_{\text{Au}}$ denote the unit-area Casimir free energies for a plane-parallel system consisting of a Nb planar slab at distance $a$ from a two-layer Au–Nb planar slab and a gold planar slab, respectively and in the last passage we used the well-known PFA formula for the Casimir free energy of a sphere-plane system:

$$F^{(\text{PFA})}_{\text{sp–pl}} = 2\pi R F.$$  

(11)

According to [48], the Casimir free-energy $F$ (per unit area) between two magnetodielectric possibly layered plane-parallel slabs $S_j$, $j = 1, 2$ at distance $a$ in vacuum can be represented by the formula:

$$F(T, a) = \frac{k_B T}{2\pi} \sum_{l=0}^{\infty} \left( 1 - \frac{1}{2^l} \right) \int_0^\infty dk_L k_L$$

$$\times \sum_a \sum_{i=\text{TE, TM}} \log\left[ 1 - e^{-2d_w} R_0^{\perp} (i\xi_l, k_L) \right] R_0^{(i\xi_l, k_L)} \right],$$

(12)

where $k_B$ is the Boltzmann constant, $\xi_l = 2\pi l k_B T / h$ are the Matsubara frequencies, $k_L$ is the modulus of the in-plane wave-vector, $q_i = \sqrt{\xi_l^2 + \xi_l^2}$ and $R_0^{\perp} (i\xi_l, k_L)$ is the reflection coefficient of slab $j$ for polarization $\alpha$. The Casimir free energy $F_{\text{NbAu}}$ for a planar Nb–Au–Nb system, can be obtained from equation (13) by substituting $R_0^{(i\xi_l, k_L)}$ by the Fresnel reflection coefficient $r_0^{(i\xi_l, k_L)}$ of a Nb slab (given in equations (14) and (15) below, with $a = 0$, $b = \text{Nb}$) and $R_0^{(i\xi_l, k_L)}$ by the reflection coefficient $R_{0\text{Au}}^{(i\xi_l, k_L)}$ of a two-layer planar slab consisting of a layer of thickness $w$ of gold on a Nb substrate. The latter reflection coefficient has the expression:

$$R_0^{(i\xi_l, k_L)} = \frac{1}{r_{0\text{Au}}^{(i\xi_l, k_L); w} + e^{-2w} r_{0\text{Au}}^{(i\xi_l, k_L); w}} \frac{r_{0\text{Au}}^{(i\xi_l, k_L); w}}{r_{0\text{Au}}^{(i\xi_l, k_L); w} + e^{-2w} r_{0\text{Au}}^{(i\xi_l, k_L); w}}.$$  

(13)

Here $r_{0\text{Au}}^{(i\xi_l, k_L); w}$ are the Fresnel reflection coefficients for a planar dielectric (we set $\mu = 1$ for all materials) interface separating medium a from medium b:

$$r_{\text{TE}}^{(i\xi_l, k_L); w} = \frac{k_{\text{TE}}^{(i\xi_l, k_L); w}}{k_{\text{TE}}^{(i\xi_l, k_L); w} + k_{\text{TM}}^{(i\xi_l, k_L); w}},$$

(14)

$$r_{\text{TM}}^{(i\xi_l, k_L); w} = \frac{\epsilon_b (i\xi_l) k_{\text{TM}}^{(i\xi_l, k_L); w} - \epsilon_a (i\xi_l) k_{\text{TM}}^{(i\xi_l, k_L); w}}{\epsilon_b (i\xi_l) k_{\text{TM}}^{(i\xi_l, k_L); w} + \epsilon_a (i\xi_l) k_{\text{TM}}^{(i\xi_l, k_L); w}},$$

(15)
where \( k_\ell^{(a)} = \sqrt{\epsilon_0 (i\xi)^2 / \epsilon^2 + k_\ell^2} \), \( \epsilon_0 \) denotes the electric permittivity of medium \( a \) and we define \( \epsilon_0 = 1 \).

The values \( \epsilon_{\text{Au}}(i\xi) \) of the permittivity of gold were computed using a six-oscillator model of the form:

\[
\epsilon(i\xi) = 1 + \frac{\omega_{\text{Au}}^2}{\xi(\xi + \gamma_{\text{Au}})} + \sum_{j=1}^{6} \frac{g_j}{\xi^2 + \omega_j^2 + \gamma_j \xi},
\]

The first two terms provide the familiar Drude formula and account for the contribution of conduction electrons, while the oscillator terms describe core electrons. For the oscillator parameters \( g_j, \omega_j \) and \( \gamma_j \), which are expected to be temperature independent, we used their room temperature values [53]. For the plasma frequency, which is also temperature independent, we used the standard value \( \omega_{\text{Au}} = 9 \text{ eV} \text{ h}^{-1} \). The relaxation parameter \( \gamma_{\text{Au}} \) is temperature-dependent, but for cryogenic temperatures it reaches a saturation value \( \gamma_{\text{Au}}^{(s)} \) that depends on the amount of impurities and on the fabrication process. In our computations we thus set \( \gamma_{\text{Au}} = \gamma_{\text{Au}}^{(s)} \). It is customary to express \( \gamma_{\text{Au}}^{(s)} \) in terms of the room temperature relaxation parameter \( \gamma_{\text{Au}}^{\text{room}} \left( \gamma_{\text{Au}}^{\text{room}} = 0.035 \text{ eV} \text{ h}^{-1} \right) \) as: \( \gamma_{\text{Au}}^{(s)} = \gamma_{\text{Au}}^{\text{room}}/\text{RRR}_{\text{Au}} \), where \( \text{RRR}_{\text{Au}} \) is the so-called residual-resistance ratio.

The values of \( \epsilon_{\text{Nb}}(i\xi) \) for superconducting Nb were computed using the local limit [54, 55] of the Mattis–Bardeen [56] analytic formula for the conductivity of a BCS superconductor. The analytic continuation of this formula to the imaginary frequency axis was worked out in [46]. We remark that the local approximation is expected to be reliable for separations \( a \) that are sufficiently large compared to the superconducting coherence length \( \xi \) (typically for separations \( a \gtrsim 50 \text{ nm} \) [43, 44, 57]), in which range the effect of spatial dispersion can be safely neglected. While we address the reader to [46] for a detailed discussion of the Mattis–Bardeen dielectric function, we briefly recall here its main features. The permittivity \( \epsilon_{\text{Nb}}(i\xi) \) depends parametrically on the temperature, on the plasma and relaxation frequencies of Nb, \( \omega_{\text{Nb}} \) and \( \gamma_{\text{Nb}} \) and on the temperature-dependent BCS gap \( \Delta(T) \) (in our computations we used the approximate expression of the BCS gap function \( \Delta(T) \) given in [58, 59]). As the temperature \( T \) is increased towards the critical temperature \( T_c \) (\( T_c = 9.25 \text{ K} \)), the BCS gap \( \Delta(T) \) approaches zero and the Mattis–Bardeen formula approaches the Drude formula for the permittivity of normal metals. For the plasma frequency \( \omega_{\text{Nb}} \) we took \( \omega_{\text{Nb}} = 9.3 \text{ eV} \text{ h}^{-1} \). For the relaxation parameter \( \gamma_{\text{Nb}} \), we took again its saturation value \( \gamma_{\text{Nb}} = \gamma_{\text{Nb}}^{\text{room}}/\text{RRR}_{\text{Nb}} \). For simplicity in our computations we used the realistic common value \( \text{RRR}_{\text{Au}} = \text{RRR}_{\text{Nb}} = \text{RRR} = 5 \) both for Au and Nb.

The most important feature of the Mattis–Bardeen formula for our purposes is its double pole at zero frequency:

\[
\epsilon_{\text{Nb}}(i\xi) \sim \frac{\omega_{\text{Nb}}^2(T)}{\xi^2} + O\left( \frac{\log(\Delta/\xi)}{\xi} \right), \quad \text{for } \xi \to 0, \quad (17)
\]

where \( \omega_{\text{Nb}}^2(T) = \kappa \omega_{\text{Nb}}^2 \). The coefficient \( \kappa \), which is positive and always less than one, is a function of the importance parameter \( \eta = \gamma_{\text{Nb}}/(2\Delta) \) and of the reduced temperature \( t = k_b T/(2\Delta) \).

In the limit \( \Delta \to 0 \) (i.e. for \( T \to T_c \)) \( \kappa \) vanishes, as it should because for vanishing gap the Mattis–Bardeen formula approaches the Drude formula. The coefficient \( \kappa \) vanishes also in the impurity limit \( \eta \to \infty \), while in the opposite pure limit \( \eta \to 0 \) \( \kappa \) approaches one. In figure 2 we plot the parameter \( \kappa \) versus \( T/T_c \) for Nb, for three values of RRR.

We can now present the results of our numerical computations for \( \Delta F \). It is useful to separate the contribution \( \Delta F^{(\text{TE})} \) of the TE \( \omega = 0 \) mode from the combined contributions \( \Delta F^{(\text{TM})} + \Delta F^{(\ell 
eq 0)} \) of the TM \( \omega = 0 \) plus all the non-vanishing Matsubara modes: \( \Delta F = \Delta F^{(\text{TE})} + \Delta F^{(\text{TM})} \).

In figure 3 we plot \( \Delta F \) (in units of \( 10^{-15} \text{ N} \)) versus sphere-plate separation (in nm) for \( w = 80 \text{ nm} \) and RRR = 5. The solid black, red and green lines represent the Drude prediction for \( T/T_c = 0.9 \) (black curve), \( T/T_c = 0.5 \) (red curve) and for \( T/T_c = 0.99 \) (green line). The dashed lines represent the respective contributions of the TE \( \omega = 0 \) mode alone. The thick green line represents the plasma-model prediction.

We can now present the results of our numerical computations for \( \Delta F \). It is useful to separate the contribution \( \Delta F^{(\text{TE})} \) of the TE \( \omega = 0 \) mode from the combined contributions \( \Delta F^{(\text{TM})} + \Delta F^{(\ell 
eq 0)} \) of the TM \( \omega = 0 \) plus all the non-vanishing Matsubara modes: \( \Delta F = \Delta F^{(\text{TE})} + \Delta F^{(\text{TM})} \).

In figure 3 we plot \( \Delta F \) (in units of \( 10^{-15} \text{ N} \)) versus sphere-plate separation (in nm) for \( R = 150 \mu \text{m} \) and a minimum thickness \( w = 80 \text{ nm} \) of the gold overlay, for three different temperatures \( T = 0.9 T_c \) (black curve), \( T = 0.5 T_c \) (red curve) and for \( T = 0.99 T_c \) (green curve). The three dashed lines represent the respective contributions \( \Delta F^{(\text{TE})} \) of the TE \( \omega = 0 \) mode alone. All these lines were computed using the Drude prescription. The thick grey line represents the modulation that obtains if the plasma prescription is used. In figure 4 we plot \( \Delta F \) (in units of \( 10^{-15} \text{ N} \)) versus \( T/T_c \) for \( a = 300 \text{ nm} \) (all other parameters as before). The blue and thick grey lines represent the Drude...
The most important conclusion that can be drawn from figures 3 and 4 is that the Drude and the plasma prescriptions lead to widely different predictions for the change of the Casimir force.

4. Conclusions

We have studied a superconducting Casimir setup consisting of a Nb sphere and a Nb strip. The key feature of the device is that the Nb strip is fully immersed into a flat gold matrix, in such a way that the Nb strip is optically hidden by a gold over-layer. The proposed experimental scheme is based on a differential measurement of the Casimir force, at a point of the gold plate above the Nb strip and away from it. We have shown that the Drude and the plasma prescriptions lead to widely different predictions for the change of the Casimir force. We thus expect that by this setup it should be possible to easily discriminate between them, provided that the sensitivity of the apparatus is of the order of 10^{-15} N. The superconducting setup discussed here shares the advantages of two analogous setups that were recently proposed by the author [41, 42]. In particular it requires neither an electrostatic calibration of the apparatus, nor any detailed knowledge of the optical properties of the involved materials.
