Neuropsychological changes in FMR1 premutation carriers and onset of fragile X-associated tremor/ataxia syndrome

Jessica Famula1,2, Emilio Ferrer3, Randi J. Hagerman1,4, Flora Tassone1,5, Andrea Schneider1,4, Susan M. Rivera1,3,6 and David Hessl1,2*

Abstract

Background: Carriers of the FMR1 premutation are at increased risk of developing a late-onset progressive neurodegenerative disease, fragile X-associated tremor/ataxia syndrome (FXTAS), characterized by intention tremor, gait ataxia, and cognitive decline. Cross-sectional studies to date have provided evidence that neuropsychological changes, such as executive function alterations, or subtle motor changes, may precede the onset of formal FXTAS, perhaps characterizing a prodromal state. However, the lack of longitudinal data has prevented the field from forming a clear picture of progression over time within individuals, and we lack consensus regarding early markers of risk and measures that may be used to track response to intervention.

Methods: This was a longitudinal study of 64 male FMR1 premutation carriers (Pm) without FXTAS at study entry and 30 normal controls (Nc), aged 40 to 80 years (Pm M = 60.0 years; Nc M = 57.4 years). Fifty of the Pm and 22 of the Nc were re-assessed after an average of 2.33 years, and 37 Pm and 20 Nc were re-assessed a third time after an average of another 2.15 years. Eighteen of 64 carriers (28%) converted to FXTAS during the study to date. Neuropsychological assessments at each time point, including components of the Cambridge Neuropsychological Test Automated Battery (CANTAB), tapped domains of episodic and working memory, inhibitory control, visual attention, planning, executive control of movement, and manual speed and dexterity. Age-based mixed models were used to examine group differences in change over time on the outcomes in the full sample, and differences were further evaluated in 15 trios (n = 45; 15 Pm "converters," 15 Pm "nonconverters," 15 Nc) that were one-one matched on age, education, and socioeconomic status.

Results: Compared to Nc, Pm showed significantly greater rates of change over time in visual working memory, motor dexterity, inhibitory control, and manual movement speed. After multiple comparison correction, significant effects remained for motor dexterity. Worsening inhibitory control and slower manual movements were related to progression in FXTAS stage, but these effects became statistically non-significant after correcting for multiple comparisons. Higher FMR1 mRNA correlated with worsening manual reaction time but did not survive multiple comparisons and no other molecular measures correlated with neuropsychological changes. Finally, trio comparisons revealed greater rate of decline in planning and manual movement speed in Pm converters compared to Pm nonconverters.

**Background**

Carriers of the fragile X premutation, an allelic variant of the *FMR1* gene with 55–200 cytosine-guanine-guanine (CGG) repeats, are at risk of developing a late-onset, progressive neurodegenerative disease—fragile X-associated tremor/ataxia syndrome (FXTAS). FXTAS is primarily characterized by intention tremor, gait ataxia, and radiological signs of white matter changes in the middle cerebellar peduncles and other regions, as well as brain atrophy. However, the disease frequently presents with comorbid cognitive changes including memory deficits and executive dysfunction and dementia in later stages [1, 2]. A primary underlying molecular mechanism is mRNA toxicity, which leads to protein sequestration, DNA damage and repeat-associated non-AUG (RAN) translation, and ultimately to FXTAS degeneration [3]. By the eighth decade of life, roughly 47% of male premutation carriers develop FXTAS, reaching 75% in those above 80 years [4]; however, clinical presentation is highly heterogeneous in terms of disease severity, age of onset, and course [5–7]. As the gene is X-linked, FXTAS has generally been found to have a lower penetrance and milder clinical presentation in female carriers as compared to males [8, 9].

Though recent studies have pointed toward potential biomarkers that can distinguish which carriers are at greatest risk of developing the FXTAS [10–13], clinical measures to assess individual risk, or even detect the disease in its earliest stages, are limited. Even after disease onset, some patients experience a rapid acceleration in symptom severity, while in others the disease appears to plateau or advance slowly [14, 15]. We still lack reliable methods for predicting which of these scenarios each patient will face.

The neuropsychological profile of premutation carriers of various ages with and without FXTAS has been studied broadly since the disease was first described, with all studies to date taking a cross-sectional approach [16–18]. Among carriers without symptoms of FXTAS, studies indicate that subtle cognitive effects may be present before motor signs develop, and the effects are associated with the extent of white matter changes in the brain [19]. Subsequent well-powered brain volumetric studies show that morphological changes may occur in carrier decades before any formal signs of FXTAS are present [20]. Significantly, functional magnetic resonance imaging (fMRI) studies of premutation carriers have revealed irregular brain activity during working memory [21, 22], associative memory recall [18], and magnitude estimation [22] tasks—further illustrating the neurological underpinnings of these neuropsychological findings. However, the cross-sectional nature of prior work, while extensive, precludes a clear delineation of the prodrome of FXTAS and how the disease first emerges from a neuropsychological perspective. Longitudinal research plays a critical role in identifying which carriers are at the greatest risk of developing the disease, which factors may influence the age of onset and rate of progression of the disease, and which treatment domains may be the most important to target in future trials. Here, we present preliminary results from a longitudinal neuropsychological and neurological study of male fragile X premutation carriers at risk for FXTAS.

**Methods**

**Participants**

The full study sample consisted of 94 males, 64 with the *FMR1* premutation (Pm), and 30 non-carrier controls (Nc). *FMR1* allele size was confirmed in all participants; premutation carriers had >54 and <200 CGG repeats, and controls had <45 CGG repeats (Table 1). All participants were between 40 and 80 years of age at their first visit (time 1), and the groups did not significantly differ by age, IQ, education, income level, or ethnicity/race (Table 1). Of the 94 participants, 72 had follow-up data at time 2 (50 Pm; interval length = 2.33 years).

**Table 1** Group descriptive statistics

|                  | Control m (SD) | Premutation m (SD) | P       |
|------------------|----------------|--------------------|---------|
| Age in years     | 57.4 (9.34)    | 60.0 (8.85)        | .198    |
| Education level* | 6.00 (1.34)    | 6.13 (1.01)        | .612    |
| Income level*    | 4.45 (1.18)    | 4.63 (1.80)        | .679    |
| FSIQ             | 122.6 (13.4)   | 122.8 (14.3)       | .933    |
| CGG repeats      | 29.6 (3.95)    | 86.08 (19.3)       | <0.001  |
| Psychoactive medication use (%) | 20.0 | 34.4 | .159|
| Race: non-Hispanic Caucasian (%) | 80.0 | 91.0 | .087|

*Education level of 6.0 is equal to a BA/BS degree

*Income levels between 4 to 5 are equal to $75,000 to $150,000 per year household income

FSIQ full scale IQ

---

**Conclusions:** Accelerated decline in executive function and subtle motor changes, likely mediated by frontocerebellar circuits, may precede, and then track with the emergence of formal FXTAS symptoms. Further research to develop and harmonize clinical assessment of FMR1 carriers across centers is needed to prepare for future prophylactic and treatment trials for this disorder.

**Keywords:** CANTAB, Fragile X premutation, Tremor, Ataxia, Executive function, FXTAS
± 0.88 years), and 57 participants had Time 3 data (37 Pm; interval length = 2.15 ± 0.66 years). Note that the reduced sample sizes with subsequent visits do not indicate drop-out as the study is currently ongoing, and future visits at 2-year increments (or longer, given COVID pandemic constraints) will be completed and reported elsewhere.

*FMR1* premutation carriers were recruited primarily through announcements shared by the National Fragile X Foundation, and by referrals from colleagues at other institutions studying children with FXS and their families for research or in clinic. Non-carrier controls were recruited from the Institute’s research registry system, social media announcements, and presentations given to local organizations. Carriers traveled to UC Davis in Sacramento, CA, from various locations in North America, while the non-carrier control population was recruited locally throughout Northern California. During screening, no participants reported having symptoms of tremor or ataxia interfering with activities of daily living (ADLs), nor did they have a history of a significant medical condition or a brain injury. Upon neurological exam, 18 of the carriers (28.1%) showed no clinical signs of FXTAS at study entry (FXTAS stage 0 or 1) but developed clear FXTAS symptoms by visit 2 or 3 (FXTAS stage ≥ 2) and were classified as “Converters.”

All participants provided a full list of their current prescription and over-the-counter medications at each visit. Medication lists were reviewed for those known to have antidepressant, anxiolytic, anticonvulsant, antipsychotic, stimulant, or other known neurologic effects. Groups did not differ significantly on psychoactive medication use (Table 1).

### Measures and procedures

**FXTAS assessment**

Diagnosis of FXTAS and the evaluation of disease stage was carried out by a physician using established guidelines [4, 16, 23]. The examination was composed of standardized movement disorder assessments from the Unified Parkinson’s Disease Rating Scale (UPDRS; [24]), International Cooperative Ataxia Rating Scale (ICARS; [25]), Clinical Rating Scale for Tremor (CRST), and the Scale for the Assessment and Rating of Ataxia (SARA; [26]) and review of brain MRI to assess white matter disease associated with FXTAS.

**Neuropsychological assessment**

The neuropsychological assessment battery consisted of an intelligence assessment [27, 28], subtests of the Wechsler Memory Scales, Third [29] or Fourth Edition [30], Behavioral Dyscontrol Scale-2 [BDS-2 [31]], Purdue Pegboard Test (Lafayette Instrument, Lafayette, IN), and the Cambridge Neuropsychological Test Automated Battery (CANTAB; Cambridge Cognition, UK). The subtests of the CANTAB included: Paired Associates Learning (PAL), Simple and Five-Choice Reaction Time (RTI), Rapid Visual Processing (RVP), Spatial Working Memory (SWM), Stop Signal Task (SST), and One Touch Stockings of Cambridge (OTS). Together, these tests yielded study measures of spatial memory, episodic memory, auditory working memory, visual working memory, motor dexterity and control, response inhibition, sustained attention, planning, and problem solving, executive control of movement, manual movement speed, and manual reaction time (Table 2).

**Molecular measures**

Genomic DNA (gDNA) was extracted from 3mL of peripheral blood leukocytes using standard methods (Qiagen). CGG repeat allele sizing and methylation status by Southern Blot and PCR analysis were measured as previously described [32, 33]. *FMR1* mRNA expression levels were measured by real time qRT-PCR using *FMR1* specific primer and probes as previously reported [34].

**Statistical analyses**

We first compared Pm and Nc groups at study entry on measures of age, education level, income, IQ, and use of psychoactive medication to identify any potentially significant differences (Table 1).

### Table 2  Neuropsychological functional domains and variables chosen for each domain

| Functional domain          | Variable                                      |
|----------------------------|-----------------------------------------------|
| **Episodic memory**        |                                               |
| Visual                     | CANTAB PAL* total errors                      |
| Verbal                     | WMS Logical Memory II - Recall               |
| **Working memory**         |                                               |
| Visual                     | CANTAB SWM between errors                     |
| Auditory                   | WMS Letter-Number Sequencing                  |
| **Inhibitory control**     |                                               |
| Visual                     | CANTAB SST median correct RT on Go (ms)      |
| **Visual attention**       |                                               |
| **Planning**               |                                               |
| Visual                     | CANTAB RVP A’ signal detection               |
| Auditory                   | CANTAB OTS problems solved on first choice    |
| **Motor function**         |                                               |
| Executive control of movement | BDS-2                              |
| Manual movement speed      | CANTAB RTI 5-choice movement time (ms)        |
| Manual reaction time       | CANTAB RTI 5-choice reaction time (ms)        |
| Manual dexterity           | Purdue Pegboard (R+L+both hands)             |

*CANTAB subtest abbreviations are as follows: PAL: Paired Associates Learning, SWM: Spatial Working Memory, SST: Stop Signal Task, RVP: Rapid Visual Processing, OTS: One Touch Stockings of Cambridge, RTI: reaction time*
confounding variables for subsequent analyses. Second, we applied age-based mixed models using the MIXED procedure in SAS [35] to compare neuropsychological function of all Pm and Nc and to examine differences between these groups in the rate of change over time for each test. Third, to examine potential effects of changes with FXTAS onset (presence vs absence) and to examine potential effects of molecular variables (FMR1 CGG size and mRNA) and in combination with increasing age, we again used mixed models, this time including only Pm. Finally, to examine differences between Pm “converters,” “non-converters” and controls, we selected 15 trios (n=45), one-one matched on age, education level, and income and carried out the age-based mixed models described, with a specific focus on differences in the rate of change over time:

\[ Y_{it} = \beta_0 + \beta_1 \cdot \text{age} + \beta_2 \cdot \text{age} \cdot \beta_3 + \beta_4 + \epsilon_{it} \]

where \( Y_{it} \) is the outcome variable for any given individual \( i \) at time \( t \), \( \beta_0 \) is the intercept, \( \beta_1 \) is the linear slope based on age, \( \beta_2 \) is the contrast testing for differences in the intercept between Pm converters (+1) and nonconverters (−1), \( \beta_3 \) is the contrast testing for differences in the intercept between Pm converters (+1) and Nc (−1), \( \beta_4 \) is the contrast testing for differences in the age slope between Pm converters (+1) and Pm nonconverters (−1), \( \beta_5 \) is \( \beta_2 \), and \( \epsilon_{it} \) is the residual variance. Correction for multiple comparisons was applied using the Benjamini-Hochberg [36] false discovery rate (FDR) method for all effects pertaining to group differences in change over time. Footnotes at the bottom of tables provide guidance for statistical interpretation.

**Results**

**Demographic descriptive statistics**

Demographic, general intelligence and psychoactive medication use in Pm and Nc at study entry (time 1) are shown in Table 1. The two groups did not differ significantly according to these variables and were generally well above average in intellectual functioning. At study entry, antidepressant medications were reported by 15 Pm and 5 Nc; anxiolytic medications were reported by 9 Pm and 0 Nc; anticonvulsant medications were reported by 5 Pm and 0 Nc; antipsychotic medications were reported by 0 Pm and 0 Nc; stimulant medications were reported by 0 Pm and 1 Nc; and medication with other neurologic effects were reported by 2 Pm and 0 Nc.

**Neuropsychological group differences and comparisons of rates of change with age**

Age-based mixed models revealed no significant differences between groups in the value for any variable at age 40 (the youngest age, used as intercept) but showed significantly different rates of change over time between Pm and Nc. Specifically, compared to Nc, Pm showed significantly greater declines in visual working memory, motor dexterity, inhibitory control, and manual movement speed over time (Table 3). However, only the differential rates of change effect in motor dexterity survived multiple comparison correction, while visual working memory and manual movement speed approached significance after correction. Changes in performance over time in the other domains of measurement did not differ between groups.

**Neuropsychological changes associated with FXTAS stage**

The models examining changes associated with FXTAS stage revealed effects for two measures of interest: inhibitory control and manual movement speed. While higher FXTAS stage (≥2 on the scale) was associated with poorer inhibitory control scores at age 40, inhibitory control improved slightly over time, with a positive slope reaching statistical significance for those with FXTAS symptoms, potentially due to there being more data from those with symptoms. Manual movement speed was significantly slower at age 40 among those with higher FXTAS stage, but significant change over time was not detected for this measure. In these models, Pm without FXTAS showed significant worsening on several measures including visual episodic memory, auditory working memory, motor dexterity, inhibitory control, and manual movement speed (the “age” factor in Table 4).

**Neuropsychological changes associated with FMR1 molecular measures**

Models examining the effect of elevated FMR1 mRNA showed a significant effect on manual reaction time in Pm (higher mRNA, worsening reaction time with age) and a marginally significant negative effect of mRNA on planning. These effects did not survive multiple comparison correction, while visual working memory and manual movement speed approached significance after correction. Changes in performance over time in the other domains of measurement did not differ between groups.

**Neuropsychological changes in premutation converters, non-converters, and controls (matched trios)**

In the domain of visual working memory, Pm converters performed significantly worse than Nc and better than Pm non-converters overall; however, Pm converters had a significantly greater rate of decline than Pm non-converters (Table 5). Pm converters performed worse than Nc on motor dexterity but their rate of change on this

*Age* = change in value per year of age, centered at youngest age in this matched sample which is 47.9 years. * < .05, ** < .10 after Benjamini Hochberg correction for multiple comparisons.

Inhibitory control, we have reported reduced hippocampus activation during recall [18], altered hippocampus-prefrontal function during memory encoding [41], reduced activation in the right ventral inferior frontal cortex and left premotor/dorsal inferior frontal cortex during a verbal working memory task [21], and dysfunctions in the “when” pathway (right temporoparietal junction) during a working memory task requiring temporal order...
judgments [22]. Using structural neuroimaging, we have also reported significant reductions of fractional anisotropy in multiple white matter tracts, including the middle and superior cerebellar peduncle, cerebral peduncle, and the fornix and stria terminalis—areas that transmit information from the hippocampus and integrate limbic information and monitor valence [42].

Findings in the present study of a significantly greater rate of decline in motor planning, and significantly slower manual movement speed in converters than in the non-converters is also in line with past structural neuroimaging findings. In these cross-sectional studies, we have reported weaker structural connectivity in motor fiber tracts: middle and superior cerebellar peduncles, descending motor tracts (containing the corticospinal, corticobulbar, and corticopontine tracts), and the anterior body of the corpus callosum [43]. In addition, we have reported involvement of subcortical gray structures: thalamus, caudate nucleus, putamen, and globus pallidus (which serve the functions of relaying motor signals to the cerebral cortex, planning and execution of movement, and regulation of voluntary movements) in FXTAS [44]. Finally, in a report of early longitudinal neuroimaging findings from the same cohort described here, we found that decreasing width of the middle cerebellar peduncle (MCP) appeared to be sensitive to early structural changes associated with FXTAS development [11]. The MCP is a structure through which passes the predominant afferent fiber of the corticopontocerebellar pathway—a pathway involved in the communication between the cerebellum and the prefrontal cortex for the coordination and planning of motor responses.

Among our matched trios of controls, Pm converters, and Pm nonconverters, there were two domains in which the converters performed better than nonconverters overall, but the rate of change over time showed a sharper decline in performance among converters compared to nonconverters: visual working memory and planning/problem solving. The trio sample sizes were small, and because we examined multiple domains of function, correction for multiple comparisons made differences hard to confirm. If these findings are upheld with greater numbers and/or replication, they would align with those from a previous study of neuroimaging abnormalities in premutation carriers, in which executive dysfunction and cognitive processing scores were decreased in correlation with white matter changes in the frontocerebellar region of the brain [19]. Interestingly, increased cognitive “load” during standardized walking protocols significantly impairs gait in premutation carriers [45, 46], further highlighting the role of changes in frontocerebellar pathways and functional connectivity in the development of cognitive and motor symptom decline in this population.

An important finding in this study is the motor and executive function changes that occur before and during the onset of FXTAS. These results suggest that prophylactic treatments for molecular abnormalities that have been reported such as oxidative stress and mitochondrial dysfunction [47–49] could be initiated in patients thus identified at high risk, before the onset of FXTAS, to try to stall disease progression. Future targeted treatments for FXTAS and other neurological and neuropsychological symptoms associated with the premutation will need to rely on a well-validated and scalable battery of outcome measures to track treatment response across research and clinical centers. The research presented here points to several neuropsychological domains that may be important to capture in such studies, especially those capturing specific executive functions and cognitive tasks mediated by frontocerebellar activity. Future work should focus on comparing psychometric properties and sensitivity of various outcome measures for premutation carriers and FXTAS in order to refine and then establish a harmonized battery to facilitate collaboration across centers and prepare for future clinical trials.

Among male premutation carriers, it is estimated that approximately 75% will develop FXTAS by the ninth decade of life, with variable ages of onset and severity of course. Thus, the penetrance of the mutation is incomplete and a variety of environmental or secondary genetic factors are likely to affect outcomes. To date, we have limited information about how to predict which carriers will develop FXTAS and when. Limited studies suggest that CGG repeat length is associated with age of symptom onset and age of death among FXTAS carriers [50], but this molecular marker is not an especially powerful predictor. The prodrome of FXTAS, or the early signs or symptoms indicating the imminent onset of the disease, is not yet fully defined. This is an important area of investigation to better identify carriers in need of intervention, prophylactic treatment or lifestyle changes, and monitoring.

A potential weakness of the current investigation is the reliance on touch-screen technology to measure cognition in a population affected by tremor and movement disorder. However, several CANTAB tests (OTS, SWM) are unaffected by reaction time or manual movement accuracy and were sensitive to cognitive changes. Also, the CANTAB has been implemented to detect mild cognitive impairment (MCI) in Parkinson’s disease [51], and it is sensitive to differences between patients with MCI versus those with Alzheimer’s disease [52], demonstrating its broad utility in the assessment of cognitive neurodegeneration. This battery also provides a highly standardized and objectively quantified method that may be scalable for future multi-center studies or clinical trials. We did not include
balance or gait measures in this report, whereas ataxia is a primary clinical feature of FXTAS. Detailed gait and balance metrics have been collected and will be reported elsewhere. This study presents the only longitudinal neuropsychological data from premutation carriers in the literature to date. However, because we examined multiple neuropsychological domains in the protocol, requiring multiple comparison adjustments, some group differences in change over time were difficult to confirm. This study focused on male premutation carriers, as fragile X-associated disorders are X chromosome linked, and thus males are more likely to be affected. However, female carriers do develop FXTAS and other neurological symptoms [9, 53], and future longitudinal studies should enroll females to examine phenotypic effects and identify individuals most at risk for neurodegenerative changes, as well as protective factors. Finally, it is important to be aware that individuals identified as “non-converters” might present with signs and symptoms of FXTAS after the period of follow-up in this study, as an average period of 5 years might not be adequate to determine clinical conversion.

Conclusions
In this prospective longitudinal study, we show that compared to controls, men with the FMR1 premutation have accelerated decline in manual dexterity and certain domains of executive functioning, including visual working memory, inhibitory control, and that conversion to FXTAS is associated with deterioration in inhibitory control, planning and problem solving, and slowing of manual movement. The findings, in conjunction with prior brain imaging literature, provide critical support for the hypothesis that the prodrome of FXTAS is characterized by executive dysfunction mediated by white matter changes in frontocerebellar pathways. Additional research is needed to select and validate a set of standardized outcome measures that can be used in future multicenter clinical trials of targeted treatments for FXTAS and prophylactic interventions of fragile X carriers who are at increased risk for neurodegeneration.

Acknowledgements
We thank the participants and their families for their effort and dedication to this research. We also thank Drs. Corrissa Jacomini and Sundas Pasha for neuropsychological and psychiatric examinations of participants.

Authors’ contributions
JJ coordinated all participant screening, enrollment, and assessment activities and wrote the initial draft of the manuscript. EF contributed to the design of the study and completed all statistical analyses. RJH completed neurological and medical examinations of the majority of participants and determined participant FXTAS staging and diagnostic information. FT directed all molecular assays. AS assisted with design of the study and measure selection, completed neuropsychological assessments of participants, and contributed to interpretation of study results. SMR is a co-equal principal investigator (with DH) and obtained funding and wrote sections of the manuscript pertaining to integration of study findings with existing brain MRI literature. DH is a co-equal principal investigator and lead the design of the neuropsychological aspects of the project, obtained funding, directed assessment activities, wrote the discussion, and finalized the manuscript. The authors read and approved the final manuscript.

Funding
This work was supported by National Institute of Health Grants MH078041 and NS110100 to Drs. Hessl and Rivera, HD036071 and AG032115 to Dr. Hagerman, HD02274 to Dr. Tassone; 90DD0596 from Health and Human Services Administration of Developmental Disabilities; and by the MIND Institute Intellectual and Developmental Disabilities Research Center (P50 HD103526).

Availability of data and materials
The datasets used and/or analyzed during the current study are available from the corresponding author on reasonable request.

Declarations
Ethics approval and consent to participate
This study was approved by the Institutional Review Board (IRB) at UC Davis (ID# 473010), and all participants gave informed consent.

Consent for publication
Not applicable.

Competing interests
Dr. Hessl has received funding from the following, all of which is directed to UC Davis, in support of fragile X syndrome treatment programs, and he receives no personal funds and has no relevant financial interest in any of the commercial entities listed: Autism, Ovid, Tetra, Heakl, and Zynhera pharmaceutical companies to consult on outcome measures and clinical trial design. RJH has received funding from Zynhera and the Azielo foundation for treatment studies in Fragile X syndrome and unrelated to this study.
