Abstract

Objective
To examine the cross-sectional associations between regional tau, β-amyloid (Aβ), and cortical thickness and neuropsychological function across the preclinical and clinical spectrum of Alzheimer disease (AD).

Methods
We included 106 participants from the Swedish Biomarkers for Identifying Neurodegenerative Disorders Early and Reliably (BioFINDER) study, of whom 33 had preclinical AD (Aβ-positive cognitively normal individuals), 25 had prodromal AD (Aβ-positive mild cognitive impairment), and 48 had probable AD dementia. All underwent [18F]flortaucipir (tau) and structural MRI (cortical thickness), and 88 of 106 underwent [18F]flutemetamol (Aβ) PET. Linear regression models adjusted for age, sex, and education were performed to examine associations between 7 regions of interest and 7 neuropsychological tests for all 3 imaging modalities.

Results
In preclinical AD, [18F]flortaucipir, but not [18F]flutemetamol or cortical thickness, was associated with decreased global cognition, memory, and processing speed (range standardized β = 0.35–0.52, p < 0.05 uncorrected for multiple comparisons). In the combined prodromal AD and AD dementia group, both increased [18F]flortaucipir uptake and reduced cortical thickness were associated with worse performance on a variety of neuropsychological tests (most regions of interest survived correction for multiple comparisons at p < 0.05), while increased [18F] flutemetamol uptake was specifically associated with lower scores on a delayed recall memory task (p < 0.05 uncorrected for multiple comparisons). The strongest effects for both [18F] flortaucipir and cortical thickness on cognition were found in the lateral and medial parietal cortex and lateral temporal cortex. The effect of [18F] flutemetamol on cognition was generally weaker and less region specific.

Conclusion
Our findings suggest that tau PET is more sensitive than Aβ PET and measures of cortical thickness for detecting early cognitive changes in preclinical AD. Furthermore, both [18F] flortaucipir PET and cortical thickness show strong cognitive correlates at the clinical stages of AD.
Alzheimer disease (AD) has a long-lasting preclinical stage in which pathogenic proteins (β-amyloid [Aβ] and tau) aggregate and subtle structural and functional brain changes emerge without the co-occurrence of significant cognitive impairment.1-3 The accumulation of Aβ is widespread relatively early in the disease course, while there is an ongoing accumulation of tau pathology and synaptic and neuronal loss, which corresponds to the clinical progression of the disease.4 Advances in the field of neuroimaging now allow in vivo whole-brain mapping of these pathophysiologic (Aβ and tau deposition) and neurodegenerative (atrophy) processes, enabling detailed examination of their relationships with cognitive function. In line with the neuropathology literature,5 PET and MRI studies have shown intimate links between cognitive performance and both tau tracer retention and brain atrophy in AD-specific regions.6-5 Although some variability exists across studies, especially cross-sectionally, the cognitive correlates for Aβ pathology are generally weaker and less region specific.10-12

Identifying the contribution of the neurobiological hallmarks of AD to cognitive changes may inform design, participant selection, and monitoring of clinical trials. In the present study, we performed [18F]flortaucipir PET (tau), [18F]flutemetamol PET (Aβ), structural MRI (cortical thickness), and a neuropsychological test battery in 106 Aβ-positive patients with normal cognition, mild cognitive impairment (MCI), or AD dementia. We aimed to assess to what degree these imaging modalities were related to cognition and whether these relationships differed by disease stage (i.e., preclinical or clinical), specific neuropsychological function, or region of interest (ROI).

Methods

Participants

For this cross-sectional study, participants were recruited from the Swedish Biomarkers for Identifying Neurodegenerative Disorders Early and Reliably study (BioFINDER; biominder.se).13 BioFINDER is a prospective study that focuses on identifying key mechanisms and improvement of diagnostics in AD and other neurodegenerative disorders. All participants underwent [18F]flortaucipir PET, [18F]flutemetamol PET (Aβ), and structural MRI between June 2014 and November 2017. During this period, the majority of patients visiting the Memory Clinic and Clinical Memory Research Unit in Malmö, Sweden, were invited to participate in the study. All underwent a medical history and complete neuropsychologic examination, brain MRI, and neuropsychological testing. We included 33 Aβ-positive cognitively normal individuals (called preclinical AD1), 25 Aβ-positive patients with MCI (called prodromal AD14,15), and 48 Aβ-positive patients with probable AD dementia.16 The preclinical AD groups consisted of both cognitively normal research volunteers (n = 17) and patients with subjective cognitive decline17 referred to the Memory Clinic of Skåne University Hospital in Sweden (n = 8). In line with the “syndromal staging of the cognitive continuum” in the recently proposed research framework by the National Institute on Aging and the Alzheimer’s Association,18 cognitively normal participants had a Clinical Dementia Rating score of 0, a Mini-Mental State Examination (MMSE) score between 27 and 30, and no history of cognitive change over time. All participants underwent [18F]flortaucipir PET and structural MRI, while [18F]flutemetamol PET was available in 86 of 106 (83%) participants. A comparison between the baseline characteristics of the full BioFINDER study sample and the subsample with [18F] flortaucipir PET and a flow diagram showing participant selection data are available from Dryad (table 1 and figure 1, doi.org/10.5061/dryad.ht92839).

Standard protocol approvals, registrations, and patient consents

The regional ethics committee at Lund University, the radiation protection committee at Skåne University Hospital, and the Swedish Medical Products Agency approved the study, and informed consent was obtained from all participants or their assigned surrogate decision makers.

CSF biomarkers

Aβ status was determined with lumbar CSF sampling, performed following the Alzheimer’s Association flowchart.19 Samples were stored in 1-mL polypropylene tubes at ~80°C until analysis. The samples were analyzed with commercially available ELISAs (INNOTEST, Fujirebio/Innogenetics, Ghent, Belgium) to determine the levels of total tau, Aβ42, and phosphorylated tau. Aβ positivity was defined as CSF Aβ42 <650 ng/L.13 Board-certified laboratory technicians who were blinded to clinical data and diagnoses performed all analyses.

Neuropsychological test battery

Participants underwent a neuropsychological test battery covering major cognitive functions, including global cognition (MMSE), episodic memory (immediate and delayed word list recall tests from the Alzheimer’s Disease Assessment Scale...
[ADAS] Cognitive Subscale), semantic memory (category [animal] fluency), language (naming condition of ADAS), and processing speed and attention (Trail Making Test A [TMT-A], A Quick Test for Cognitive Speed [AQT], form and color naming). Scores on ADAS tests were inverted so that higher values indicate better cognitive performance. For TMT-A and AQT, scores represent time needed to complete the task; thus, higher values indicate worse performance. TMT-A and AQT were log transformed to account for their nonnormal distribution. All participants had an MMSE score, but scores were missing for ADAS immediate recall (n = 6), ADAS delayed recall (n = 8), ADAS naming (n = 10), TMT-A (n = 9), animal fluency (n = 12), and AQT (n = 14). Missing data were imputed with the fully conditional specification single-imputation method. This is an iterative Markov chain Monte Carlo method implemented in SPSS software (version 21) that can be used for arbitrary patterns of missing data. For each iteration (we allowed 25 iterations in total) and for each variable (we included the demographic, clinical, CSF, and imaging variables listed in tables 1 and 2), the fully conditional specification method fits a univariate model using all other available variables in the model as predictors and then imputes missing values for the variable being fit.

Characteristics of participants with missing data are provided in table 2 available from Dryad (doi.org/10.5061/dryad.ht92839). To evaluate patterns of missingness, we performed binary logistic regression models with the demographic, clinical, and imaging variables listed in this table as predictors and missing cognitive data on each test (yes/no) as the dependent variable. There were no associations between missing data on neuropsychological tests with any of the variables. In addition, the imputed dataset provided results highly similar to those of the original dataset (data not shown).

**MRI study**

T1-weighted MRI was performed on two 3.0T magnetic resonance scanners (Siemens Tim Trio [n = 91, 30 with preclinical AD and 61 with clinical AD] and Siemens Skyra [n = 15, 3 with preclinical AD and 12 with clinical AD],

Abbreviations: Aβ = β-amyloid; AD = Alzheimer disease; ADAS = Alzheimer's Disease Assessment Scale; AQT = A Quick Test of Cognitive Speed; MMSE = Mini-Mental State Examination; p-tau = phosphorylated tau; TMT-A = Trail Making Test A; t-tau = total tau. Differences in baseline characteristics between groups were assessed with analysis of variance with post hoc Bonferroni tests for continuous variables and χ² and Kruskal-Wallis with post hoc Mann-Whitney U tests for categorical or ordinal data. Number indicates the number of participants within each diagnostic group with the variable available. Note that missing neuropsychological data and education (for 1 patient with AD dementia) were imputed for further analysis.

* AD dementia < preclinical AD, p < 0.05.  
* AD dementia > preclinical AD, p < 0.001, and prodromal AD > preclinical AD, p < 0.05.  
* AD dementia/prodromal AD < preclinical AD, p < 0.001, and AD dementia < prodromal AD, p < 0.01.  
* Scores are inverted so that higher numbers indicate better performance.  
* AD dementia/prodromal AD < preclinical AD, p < 0.01.  
* AD dementia < prodromal AD/preclinical AD, p < 0.05.
Siemens Medical Solutions, Erlangen, Germany), resulting in high-resolution anatomic magnetization-prepared rapid gradient-echo images (Tim Trio: repetition time 1,950 milliseconds, echo time 3.4 milliseconds, 1-mm isotropic voxels, and 176 slices; Skyra: repetition time 1,900 milliseconds, echo time 2.5 milliseconds, 1-mm isotropic voxels, and 176 slices). Cortical reconstruction and volumetric segmentation were performed with the FreeSurfer (version 5.3) image analysis pipelines (surfer.nmr.mgh.harvard.edu/). Briefly, the magnetization-prepared rapid gradient-echo images underwent correction for intensity homogeneity, removal of nonbrain tissue, and segmentation into gray matter and white matter with intensity gradient and connectivity among voxels. Cortical thickness was measured as the distance from the gray matter/white matter boundary to the corresponding pial surface. Reconstructed datasets were visually inspected for accuracy, and segmentation errors were corrected. Cortical thickness was determined for 7 predefined ROIs, including the medial and lateral parietal cortex, medial and lateral temporal cortex, frontal cortex, occipital cortex, and a whole-brain composite (including all cortical gray matter). Detailed composition of each ROI by FreeSurfer label is shown in table 3 available from Dryad (doi.org/10.5061/dryad.ht92839).

Abbreviations: AD = Alzheimer dementia; SUVR = standardized uptake value ratio. Data presented are mean ± SD for the imaging modalities and unadjusted correlation coefficients between modalities. $^{a}p<0.05$, $^{b}p<0.01$, $^{c}p<0.001$, $^{d}p<0.05$ after correction for multiple comparisons using the false discovery rate.

**Tau and Aβ PET**

$[^{18}F]$flortaucipir and $[^{18}F]$flutemetamol were synthesized at Skåne University Hospital, Lund, and PET scans were performed on a GE Discovery 690 PET scanner (General Electric Medical Systems, Chicago, IL) and a Philips Gemini TF 16 scanner (Philips Healthcare, Amsterdam, the Netherlands), respectively. $[^{18}F]$flortaucipir (previously known as $[^{18}F]$AV1451 or $[^{18}F]$T807) is a PET tracer with high affinity to paired helical filaments of tau. The mean injected dose of $[^{18}F]$flortaucipir was ≈370 MBq, and participants underwent a PET scan during the 80- to 100-minute interval after injection. Images were motion corrected with the AFNI 3dvolreg, time averaged, and rigidly coregistered to the skullstripped MRI scan. Standardized uptake value ratio (SUVR) images for the interval between 80 and 100 seconds after injection were created with inferior cerebellar gray matter used as the reference region.
FreeSurfer (version 5.3) parcellation of the T1-weighted MRI scan was applied to the PET data transformed to participants’ native T1 space to extract mean regional SUVR values for each participant in the same 7 ROIs used for analyses of cortical thickness. $[^{18}F]$flutemetamol PET data were missing for 3 participants with preclinical AD, 7 with prodromal AD, and 8 with AD dementia. For 3 participants (1 with preclinical AD, 2 with prodromal AD) with missing CSF data, Aβ positivity was determined with $[^{18}F]$flutemetamol SUVR >0.69 in a composite neocortical ROI. 27

**Statistical analysis**

Differences in baseline characteristics between groups were assessed with analysis of variance with post hoc Bonferroni tests for continuous variables and $\chi^2$ and Kruskal-Wallis with post hoc Mann-Whitney $U$ tests for categorical or ordinal variables. Associations between $[^{18}F]$flortaucipir, $[^{18}F]$flutemetamol, and cortical thickness were examined with the (unadjusted) Pearson correlation analysis. Next, we performed linear regression models with an imaging ROI as the independent variable while adjusting for age, sex, and education. These covariates were included on the basis of their established strong associations with cognitive performance. We did not control for MRI scanner type because the 2 Siemens scanners had highly similar properties and only 15 participants were scanned on the Siemens Skyra. The analyses were performed for each combination of ROI (n = 7), imaging modality (n = 3), and neuropsychological test (n = 7), and we stratified participants on the basis of preclinical (only cognitively normal individuals) or clinical (those with MCI and AD dementia combined) stage of AD. We repeated these analyses using nonparametric linear regression models (adjusted for age, sex, and education) for all 3 imaging markers and using PVE-corrected data for $[^{18}F]$flortaucipir. We repeated the analyses for cortical thickness by adding MRI scanner type as an additional covariate. To provide more fine-grained regional information, we performed the analyses using all 68 (unilateral) FreeSurfer parcellations derived from the Desikan-Kiliany atlas. To assess whether the degree of asymmetry was related to specific neuropsychological functions, we repeated the aforementioned analyses using a left and right hemisphere composite of temporoparietal regions. Statistical significance was set at $p < 0.05$. Because results were mostly in the same and expected direction, which reduces the likelihood of false-positive findings, we indicated the level of significance both without and with correction for multiple comparisons using the Benjamini-Hochberg procedure with a false discovery rate (FDR) Q value of 5%.

**Data availability**

Anonymized data will be shared by request from any qualified investigator for the sole purpose of replicating procedures and results presented in the article and as long as data transfer is in agreement with European Union legislation on the general data protection regulation.

**Results**

**Participants**

There were no significant differences in age, education, and sex between the preclinical, prodromal, and dementia groups. As expected, patients with AD dementia generally had the most severe biomarker or imaging abnormalities and worse cognitive performance, followed by those with prodromal AD and then those with preclinical AD (tables 1 and 2).

**Associations between $[^{18}F]$flortaucipir, $[^{18}F]$flutemetamol, and cortical thickness**

In preclinical AD, regional correlations between $[^{18}F]$flortaucipir and $[^{18}F]$flutemetamol were observed in the medial and temporal cortical cortex and in the whole-brain composite ROI (range Pearson $r = 0.37$–0.53, all $p < 0.05$, table 2). In the prodromal AD and AD dementia group, $[^{18}F]$flortaucipir and $[^{18}F]$flutemetamol SUVRs were correlated in the occipital cortex (Pearson $r = 0.32$, $p < 0.05$, table 2). There was an association between $[^{18}F]$flortaucipir and cortical thickness in all ROIs (range Pearson $r = 0.25$–0.54, all $p < 0.05$), except for the medial temporal lobe. There were no regional associations between $[^{18}F]$flutemetamol and cortical thickness for any of the diagnostic groups (table 2).

**Preclinical AD**

Linear regression models adjusted for age, sex, and education in the preclinical AD group showed associations between increased $[^{18}F]$flortaucipir uptake and worse performance on the ADAS immediate recall (lateral and medial parietal cortex, lateral temporal cortex, and whole brain), ADAS delayed recall (lateral parietal cortex), MMSE (medial temporal cortex), and TMT-A (medial parietal cortex, lateral temporal cortex, frontal cortex, and whole-brain) (table 3 and figure 1). None of these associations survived FDR correction for multiple comparisons. There were no significant associations between regional cortical thickness or $[^{18}F]$flutemetamol uptake and any of the neuropsychological tests (table 3 and figure 1). Analyses for all 3 imaging markers using nonparametric regression models and PVE-corrected $[^{18}F]$flortaucipir data yielded largely similar results (tables 4 and 5 available from Dryad, doi.org/10.5061/dryad.ht92839). Cortical thickness in the medial parietal and occipital cortex was significantly associated with TMA-A when additionally adjusted for MRI scanner type, while all other associations remained nonsignificant (table 6 available from Dryad). The associations between all 68 (unilateral) FreeSurfer parcellations and cognition are shown in table 7 available from Dryad.
Table 3 presents the standardized β coefficients resulting from linear regression models in the combined prodromal AD and AD dementia group. Regional [18F]flortaucipir SUVR and cortical thickness showed strong associations with cognition across all neuropsychological tests (table 4 and figure 2). For both [18F]flortaucipir and cortical thickness, standardized β coefficients were generally higher in temporoparietal regions compared to frontal, occipital, or whole-brain ROIs. Furthermore, for most neuropsychological tests (especially episodic memory tasks), the associations with cognition were slightly stronger for [18F]flortaucipir than for cortical thickness (with the exception of the AQT, table 4). For [18F]flutemetamol, increased uptake was associated with lower scores on the ADAS delayed recall for all ROIs except the occipital cortex (table 4), while occipital [18F]flutemetamol retention was associated with worse performance on tasks involving processing speed and attention (i.e., TMT-A and AQT). For [18F]flortaucipir and cortical thickness, several associations with cognition survived FDR correction for multiple comparisons but not for [18F]flutemetamol (table 4).

Results are also provided for the separate diagnostic groups in table 8 (prodromal AD) and table 9 (AD dementia) available from Dryad (doi.org/10.5061/dryad.ht92839). Results for prodromal AD and AD dementia groups were mostly comparable to...
those of the combined group in terms of direction (figure 2) and strength of the effect sizes but were less (often) significant because of reduced statistical power related to smaller sample sizes. Repeating the analysis for \([18F]\) flortaucipir using PVE corrected data resulted in weaker associations with MMSE and ADAS memory and language tests and yielded comparable associations with TMT, AQT, and animal fluency (table 5 available from Dryad). Analyses for all 3 imaging markers using nonparametric regression models (table 10 available from Dryad) yielded largely similar results compared to its parametric counterpart reported in table 4. When MRI scanner type was added as an additional covariate to the model, the associations between cortical thickness and cognition remained virtually the same (table 6 available from Dryad). The associations between all 68 (unilateral) FreeSurfer parcellations and cognition are given in table 7 available from Dryad.

**Lateralization**

In preclinical AD, associations between \([18F]\) flortaucipir uptake and cognition were more pronounced in the left temporoparietal cortex than in the right temporoparietal cortex for ADAS immediate recall (standardized $\beta$ coefficient $-0.57$...
vs −0.37) and for ADAS delayed recall (−0.40 vs −0.25).
There were no clear asymmetric relationships for temporoparietal \(^{18}F\)flortaucipir uptake with any of the other neuropsychological tests or for temporoparietal \(^{18}F\)flutemetamol or cortical thickness (table 11 available from Dryad, doi.org/10.5061/dryad.h792389). For prodromal AD and AD dementia, \(^{18}F\)flortaucipir uptake and cortical thickness were strongly related to ADAS naming in the left temporoparietal cortex but not the right temporoparietal cortex (figure 3). There were no clear asymmetric findings for the other neuropsychological tests, and \(^{18}F\)flutemetamol showed comparable results for left vs right temporoparietal cortex (table 12 available from Dryad).

### Discussion

In this study, we examined the cross-sectional associations between tau, Aβ, and cortical thickness and neuropsychological function across Aβ-positive individuals at the preclinical and clinical stages of AD. In the preclinical AD group, we found associations with cognition only for tau PET but not for Aβ PET or cortical thickness. In prodromal AD and AD dementia, we found strong relationships between increased tau pathology and reduced cortical thickness with worse performance on a wide variety of neuropsychological tests. These relationships were most pronounced in bilateral temporoparietal regions. Aβ pathology was specifically related to decreased delayed recall on
These findings suggest that \(^{18}\text{F}\)flortaucipir PET is the most sensitive of these markers for detecting early changes in cognitive function, while both \(^{18}\text{F}\)flortaucipir PET and cortical thickness show strong cognitive correlates at the clinical stages of AD.

A main finding in the present study was that regional tau PET was related to cognitive function already in cognitively normal A\(\beta\)-positive individuals in the absence of similar effects for cortical thickness and A\(\beta\) pathology. This is in line with earlier clinicopathologic\(^ 5,28\) and imaging studies\(^ 29,30\) in preclinical stages of AD showing intimate links between tau pathology and cognition. The lack of an effect for A\(\beta\) pathology could be explained by the estimated time interval of \(\approx 15\) to 20 years between its pathologic beginnings and symptom onset\(^ 1,31\).

Relationships between reductions in cortical thickness are less affected by this separation in space and time as observed for A\(\beta\) pathology\(^ 32,33\). Cortical thickness, however, is
characterized by substantial preexisting variation among individuals, which might reduce the sensitivity for separating the earliest AD-related changes from age-related brain changes. Furthermore, tau pathology might be present before neurodegeneration starts and might exert its effects on cognition through both structural (i.e., cortical thickness reductions) and functional (i.e., synaptic alterations) pathways. This finding has potential ramifications for clinical trials in that tau PET might be superior to the other measures for identifying individuals at risk for future cognitive decline and for tracking cognitive trajectories during treatment with disease-modifying drugs.

At the clinical stages of AD (i.e., prodromal AD and AD dementia), regional patterns of both tau pathology and cortical thickness showed strong associations with cognitive function. This finding in a cohort of patients with mostly late-onset AD with memory-predominant presentations is in line with previous tau PET studies characterized by an on average young age at onset and often atypical presentation. Compared to the preclinical stages of AD, the effects of tau PET were considerably stronger and were present across all neuropsychological tests and ROIs, although there was a temporoparietal predominance (table 3). The latter is in agreement with the composition of our neuropsychological test battery (which did not include a specific frontal test) in combination with the localization of tau pathology, which typically strongly occupies temporoparietal regions in AD. The effects of cortical thickness vs tau PET results were overall comparable, although slightly weaker for cortical thickness on memory domains and slightly stronger on a task involving processing speed. Although our models were set up to test cognition-imaging correlates at a group level and not to make individual predictions, the results open the possibility that both tau PET and cortical thickness have potential utility for clinical use (i.e., diagnosis or prognosis) at clinical stages of the disease and for patient selection and monitoring of clinical trials.

In line with the assumptions of a hypothetical biomarker model, the relationships between Aβ pathology and cognition at the clinical stages of AD were modest at best. The rate of accumulation of Aβ pathology is thought to attenuate or even plateau at the time when clinical symptoms have emerged, and at that point, Aβ pathology has spread out into nearly the entire neocortex. It has therefore been argued that Aβ pathology might be triggering tau pathology to spread from entorhinal cortex to neocortical areas and that this event is the actual driver of cognitive loss. Consequently, Aβ pathology is often not or only modestly related to cognitive performance, although there are some exceptions in very young patients with AD or atypical variants of AD. In the present study, the effects of Aβ pathology were much weaker compared to those of tau pathology and cortical thickness, but we found significant associations between Aβ PET and episodic memory (delayed recall) in almost all neocortical areas. This could be explained by the complexity of this task; previous research has shown that cognitively demanding tests may be required to capture the subtle effects of Aβ pathology on cognition. Furthermore, if effects of Aβ

Figure 3 Asymmetric relationships between imaging modalities and object naming

Stronger relationships with Alzheimer’s Disease Assessment Scale (ADAS) object naming for left temporoparietal cortex (A) [18F]flortaucipir uptake and (B) cortical thickness compared to the right temporoparietal cortex. βs are standardized and presented adjusted for age, sex, and education.
pathology on cognition are shown, they typically involve memory function. The reason could be that this is usually the most impaired cognitive domain in patients with AD or with Aβ pathology initially spreading through posterior parts of the default mode network, which could be affecting memory function through its strong connections with medial temporal lobe structures. Occipital Aβ load was associated with reduced processing speed and attention. Because the occipital cortex is among the brain regions affected by Aβ deposition in late stages, this could reflect a more advanced disease stage. Alternatively, the occipital signal may reflect the presence of cerebral amyloid angiopathy, which has a predilection for the occipital cortex and is associated with mental slowness and attentional deficits.

A strength of this study is that we combined 3 imaging modalities in combination with a neuropsychological test battery in individuals across the AD spectrum. There are also some limitations. First, although our neuropsychological battery included tests commonly used in clinical studies and trials, we did not capture all cognitive domains. In particular, tests for visuospatial and some executive functions were missing. Second, Aβ PET was missing in 18 (17%) participants. Third, the sample size differed between analyses in preclinical (n = 33) and clinical (n = 73) stages. Interpretation was therefore focused on effect size (not affected by sample size) and level of significance (affected by sample size). Fourth, [18F]flortaucipir is still a relatively new tracer; thus, only a few antemortem vs postmortem comparisons have been reported, and its binding properties are not yet fully understood. Factors that could affect the accuracy of the signal include off-target binding (e.g., to monoamine oxidase B, neuromelanin, or vascular lesions) and the continued increase in specific tracer binding after the duration of the PET scan. Fifth, it is possible that some patients had comorbid pathologies such as α-synuclein, TAR DNA-binding protein 43, or vascular pathology, which were not examined. The presence of such comorbid conditions may potentially attenuate the associations between cognitive scores and biomarkers of tau, Aβ, and cortical thickness.

We found that tau PET is a more sensitive marker for detecting the earliest cognitive changes in AD than Aβ PET and cortical thickness measures. In clinical stages, both regional tau PET and cortical thickness measures showed strong cognitive correlates, while Aβ PET showed weaker and less region-specific associations with cognition. Future studies should include longitudinal assessments of both neuropsychological scores and neuroimaging to determine which modality is most suited for predicting and monitoring cognitive changes over time. Furthermore, the overlapping and complementary effects of tau and brain atrophy on cognition should be further investigated, and ROIs have to be refined. Identifying the contribution of these neurobiological hallmarks of AD to cognitive changes could eventually improve the diagnostic and prognostic process in AD and may inform design, participant selection, and monitoring of clinical trials.

Author contributions

R.O. contributed to study design, analysis, and interpretation of data, writing and revising the manuscript, and performed statistical analysis. T.O. and O.S. contributed to the acquisition and analysis of data. R.S., N.M., P.S.I., and S.P. critically revised the manuscript for intellectual content. O.H. contributed to study concept and design, acquisition of patient data from the Swedish BioFINDER study, interpretation of data, critical revision of the manuscript for intellectual content, and supervised the study.
