We investigate hydromagnetic turbulence of primordial magnetic fields using magnetohydrodynamics (MHD) in an expanding universe. We present the basic, covariant MHD equations, find solutions for MHD waves in the early universe, and investigate the equations numerically for random magnetic fields in two spatial dimensions. We find the formation of magnetic structures at larger and larger scales as time goes on. In three dimensions we use a cascade (shell) model, that has been rather successful in the study of certain aspects of hydrodynamic turbulence. Using such a model we find that after $\mathcal{O}(10^0)$ times the initial time the scale of the magnetic field fluctuation (in the comoving frame) has increased by 4-5 orders of magnitude as a consequence of an inverse cascade effect (i.e. transfer of energy from smaller to larger scales). Thus at large scales primordial magnetic fields are considerably stronger than expected from considerations which do not take into account the effects of MHD turbulence.

I. INTRODUCTION

It has been suggested that primordial magnetic fields might arise during the early cosmic phase transitions [1], and recently it has been shown that magnetic fields are indeed a stable feature of the electroweak phase transition [2]. In a first order phase transition magnetic fields could also be generated when bubbles of the new vacuum collide, whence a ring of magnetic field may arise in the intersecting region [3]. It has also been suggested that at very high temperatures the ground state of a non-abelian particle theory is a “ferromagnetic” vacuum with a permanent non-zero magnetic field [4]. The plasma of the early universe has a high conductivity so that a primordial magnetic field would be imprinted on the comoving plasma and would dissipate very slowly [5]. Such a field could then contribute to the seed field needed to understand the presently observed galactic magnetic fields [6], which have been measured both in the Milky Way and in other spiral galaxies, including their halos. Typically the observed present day magnetic field is of the order of $\mathcal{O}(10^{-6})$ G.

Locally the primordial field could be very large; it is limited only by the magnetic energy density contribution to primordial nucleosynthesis, which constraints the field at the time of nucleosynthesis by $\rho_B = B_{\text{rms}}^2/8\pi \leq 0.3\rho_\nu$, where $\rho_\nu$ is the energy density of 3 species of massless neutrinos [7]. Because flux conservation implies that $B_{\text{rms}} \sim R^{-2}$, where $R$ is the scale factor, the field could have been much stronger at earlier times. On dimensional grounds, a typical value of the magnetic field fluctuation should be $B_{\text{rms}} \sim T^2$, so that at the time of the electroweak phase transition one could locally obtain fields as high as $10^{24}$ G. Depending on how such a strong, random magnetic field scales at large distances, it could be the seed field needed to explain the magnetic fields observed on the scale of galaxies and larger.

However, even assuming that a primordial magnetic field is created at some very early epoch, a number of issues remain to be worked out before one can say anything definite about the role of primordial fields in generating galactic magnetic fields. At earliest times magnetic fields are generated by particle physics processes with length scales typical to particle physics. If the inflation hypothesis proves correct, then after inflation rather long correlation lengths are possible [8]. The question is if it is at all possible for the small scale fluctuations to grow to large scales, and what exactly is the scaling behaviour of $B_{\text{rms}}$ or the correlator $\langle B(r + x)B(x) \rangle$. Even in an inflationary scenario it would be of interest to see if the relatively large scale can grow even further. To study these problems one needs to consider the detailed evolution of the magnetic field to account for such issues as what happens when uncorrelated field regions come into contact with each other during the course of the expansion of the universe. In general, turbulence is an essential feature of such phenomena. These questions can only be answered by considering magnetohydrodynamics (MHD) in an expanding universe. [9] It is the main purpose of this paper to investigate the subsequent development of the primordial field. Expressed in a general way, our con-
clusion turns out to be that MHD turbulence is opera-
tive, and hence the scale of magnetic fields is consider-
ably larger than one would expect if MHD turbulence was
ignored. This means that the previous estimates of the
strength of the primordial magnetic field "today" need
to be reconsidered.

We begin by posing the basic equations and consider
certain simplified models. A full 1+3-dimensional
numerical simulation would be desirable, but is beyond
the scope of the present paper. In Sec. II we derive the
relativistic MHD equations for relativistic plasma, which
is appropriate for the very early universe. In Sec. III we
discuss the appearance of waves in relativistic MHD. To
illustrate the various MHD effects pertaining the early
universe, we also present numerical solutions to the MHD
equations for a two-dimensional slice. In Sec. IV we study
a cascade model, that reflects important properties of
fully three-dimensional turbulence. The cascade model
has been rather successful in ordinary hydrodynamics.
We find that in the early universe magnetic energy is
transferred from small scales to large scales. We also
compute the correlation function \( \langle B(x)B(x) \rangle \) in the
cascade model. In Sec. V we offer an interpretation of
our results.

II. RELATIVISTIC MHD IN THE EXPANDING
UNIVERSE

We begin by presenting a derivation of the fully gen-
eral relativistic MHD equations (see also ref. [1], where
further references can be found), which we rewrite in a
form suitable for our numerical work. We consider the
early universe as consisting of ideal fluid with an equation
of state of the form

\[ \rho = \frac{p}{\gamma - 1}, \]

and isotropic on scales much larger than the intrinsic cor-
relation scale of the field. Even very large magnetic fields,
together with the ensuing very fast bulk motion, might
not contradict isotropy and homogeneity. The equations
of motion for the fluid arise from energy-momentum con-
servation

\[ T^{\mu\nu} = \frac{\partial}{\partial x^\nu} \sqrt{-g} g^{\mu\nu} + \Gamma_\nu^i \Gamma_\nu^\lambda = 0. \]

The Maxwell equations read

\[ F^{\mu\nu} = 4\pi J^\mu, \quad F_{[\mu\nu\lambda]} = 0. \]

We define \( F_{\mu\nu} \) in terms of the electric and magnetic fields

\[ F_{0i} = RE^i, \quad F_{ij} = \epsilon_{ijk} R^2 B^k, \]

where latin letters go from 1 to 3. With this definition
the expression for the total energy has no \( R \)-factors and
takes therefore the familiar form

\[ T^{00} = (p + \rho)\gamma^2 - p + \frac{1}{8\pi}(B^2 + E^2), \]

where \( \gamma = U^0 \).

In order to solve (2) and (3) we rewrite the equations of
motion explicitly in 3+1 dimensions. We start by writing

\[ \frac{1}{\sqrt{g}} \frac{\partial}{\partial x^\mu} \left[ \sqrt{g}(p + \rho)U^\mu U^\nu \right] + \Gamma_i^\mu \Gamma_i^\nu \rho U^\mu U^\nu \]

\[ + g_{\nu\lambda} \frac{\partial p}{\partial x^\nu} = F_{\mu\nu} g_{\nu\lambda} J^\lambda, \]

where \( \sqrt{-g} = R^3 \), and the nonvanishing Christoffel sym-
ols are \( \Gamma_i^0 = R\delta_i^0 \) and \( \Gamma_i^j = (R/R)\delta_i^j = \Gamma_i^j \).

It is useful to define \( U^i = \gamma R^{-1}v^i \), because then the nor-
malization \( U^\mu U_\mu = -1 \) gives the familiar form for the
Lorentz factor \( \gamma = (1 - v^2)^{-1/2} \).

For \( \mu = i \) we obtain

\[ \frac{\partial R^i S}{\partial t} = \frac{1}{R} \left[ \textbf{\nabla} \cdot (\rho \textbf{\nabla})(R^i S) - (\textbf{v} \cdot \textbf{\nabla})(R^i S) \right] - \nabla(R^i p) + (R^i J) \times (R^i \textbf{B}) \],

where \( S = (p + \rho)\gamma^2 \textbf{v} \). It should be noticed that in this
equation all quantities are scaled by the appropriate pow-
sers of \( R \). Thus, e.g. \( R^i S \) is expected to be independent of
\( R \), because \( p + \rho \) scales like \( 1/R^4 \), and \( \textbf{v} \) is expected to be
independent of \( R \). Also, \( \textbf{\nabla} \) occurs always multiplied by
\( 1/R \), or, alternatively, the operator \( \partial/\partial t \) is replaced by
itself multiplied by \( R \), which means that time is replaced
by conformal time \( t = \int dt/R \). To emphasize this, it is
convenient to introduce new scaled “tilde”-variables,

\[ \tilde{S} = R^4 S, \quad \tilde{\rho} = R^4 \rho, \quad \tilde{p} = R^4 p, \quad \tilde{B} = R^2 \textbf{B}, \quad \tilde{J} = R^3 \textbf{J}, \quad \text{and } \tilde{E} = R^2 \textbf{E}. \]

It should be noticed that \( \textbf{v} \) is not scaled. Equation (7)
can then be written

\[ \frac{\partial R^4 \tilde{S}}{\partial t} = \frac{1}{R} \left[ \textbf{\nabla} \cdot \textbf{\rho} \textbf{\nabla}(R^4 \tilde{S}) - \textbf{v} \cdot \textbf{\nabla}(R^4 \tilde{S}) \right] - \nabla(R^4 \tilde{p}) + (R^4 \tilde{J}) \times (R^2 \tilde{B}) \].
\[
\frac{\partial \tilde{S}}{\partial t} = - (\nabla \cdot \mathbf{v}) \tilde{S} - (\mathbf{v} \cdot \nabla) \tilde{S} - \nabla \tilde{\rho} + \tilde{J} \times \tilde{B}.
\] (9)

For \( \mu = 0 \) we obtain, using scaled quantities,
\[
\left(1 - \frac{1}{4\gamma^2}\right) \frac{\partial \ln \rho \tilde{\rho}}{\partial t} + \frac{\partial \ln \gamma^2}{\partial t} + \mathbf{v} \cdot \nabla \ln (\rho \tilde{\rho}^2) + \nabla \cdot \mathbf{v} = \frac{\tilde{J} \cdot \tilde{E}}{(\tilde{\rho} + \rho \tilde{\rho})^2}.
\] (10)

In order to solve this equation numerically with an explicit code we need to eliminate the time derivative \( \partial \ln \gamma^2/\partial t \). To this end we first solve the normalization condition for \( \gamma^2 \),
\[
\gamma^2 = \frac{1}{2} + \left(1 + \frac{\tilde{S}^2}{(\rho + \tilde{\rho})^2}\right)^{1/2},
\] (11)

where we have used \( \rho + \tilde{\rho} = \frac{4}{5} \rho \) for later convenience. We then differentiate
\[
\frac{\partial \ln \gamma^2}{\partial t} = \frac{\tilde{S}^2/\tilde{\rho}}{\gamma^2(2\gamma^2 - 1)(\rho + \tilde{\rho})^2} - \frac{\partial \ln \rho \tilde{\rho}^2}{\partial t} - \frac{\gamma^2 - 1}{\gamma^2 - \frac{4}{5}} \frac{\partial \ln \tilde{\rho}}{\partial t}.
\] (12)

Combining (10) and (12) we obtain a final equation suitable for numerical work
\[
\frac{2\gamma^2 + 1}{4\gamma^2(2\gamma^2 - 1)} \frac{\partial \ln \rho \tilde{\rho}}{\partial t} = - \frac{\tilde{S}^2/\tilde{\rho}}{(\frac{4}{5} \rho \tilde{\rho})^2 (2\gamma^2 - 1)} - \mathbf{v} \cdot \nabla \ln (\rho \tilde{\rho}^2) - \nabla \cdot \mathbf{v} + \frac{\tilde{J} \cdot \tilde{E}}{\frac{4}{5} \rho \tilde{\rho}^2}.
\] (13)

In this equation only scale invariant quantities enter.

The Maxwell equations can be written explicitly as
\[
\frac{\partial \mathbf{B}}{\partial t} = -\nabla \times \tilde{E}, \quad \nabla \cdot \mathbf{B} = 0,
\] (14)

and
\[
\tilde{J} = \frac{1}{4\pi} \nabla \times \tilde{B} - \frac{\partial \tilde{E}}{\partial t}, \quad \nabla \cdot \tilde{E} = 4\pi \tilde{\rho}.
\] (15)

where \( \rho_c \) is the charge density and \( \tilde{\rho}_c = R^4 \rho_c \). Further,
\[
\tilde{E} = -\mathbf{v} \times \tilde{B},
\] (16)

which is valid in the limit of high conductivity [11].

Again, these equations have the natural scaling properties with respect to powers of \( R \). We emphasize that in the relativistic regime the displacement current, \( -\partial \tilde{E}/\partial t \), cannot be neglected. However, in all cases considered we were able to solve for \( -\tilde{E} = \mathbf{v} \times \tilde{B} + \mathbf{v} \times \tilde{\rho} \) iteratively by evaluating \( \mathbf{v} \) and \( \tilde{B} \) from the previous iteration.

The equation of energy conservation is \( T^{0\nu,\nu} = 0 \), or
\[
\frac{1}{R^3} \frac{\partial}{\partial t} \left( R^3 T^{00} \right) + \frac{\partial}{\partial x^j} T^{0j} + \frac{\partial}{\partial x^3} \frac{R}{R^2} T^{33} = 0,
\] (17)

but since \( T^{0\nu} = 0 \), we have \( T^{3j} = T^{j3} = -T^{00}/R^2 = T^{00}/R^2 \) and therefore the energy equation is
\[
\frac{\partial}{\partial t} R^4 T^{00} = -\frac{\partial}{\partial x^j} R^4 T^{0j},
\] (18)

or integrated over the whole space
\[
\frac{dR^4 E_{\text{tot}}}{dt} = 0,
\] (19)

where
\[
E_{\text{tot}} = \int T^{00} d^3 x \equiv \langle T^{00} \rangle.
\] (20)

Hence \( R^4 E_{\text{tot}} \) is conserved.

The conclusion from the above expressions is thus that the MHD equations in an expanding universe with zero curvature are the same as the relativistic MHD equations in a non-expanding universe, provided the dynamical quantities are replaced by the scaled “tilde” variables, and provided conformal time \( \tilde{t} \) is used. The effect of this is, as usual, that the expansion slows down the rate of dynamical evolution.

It should be noted that the velocity \( \mathbf{v} \) is the bulk velocity. Thus, in general we expect that \( \mathbf{v} \) is nonrelativistic. This is physically reasonable since, although the gas particles move with velocity near unity, we expect no strong collective effects which could give rise to a relativistic bulk velocity. The equations for nonrelativistic bulk motions of a relativistic gas are given in Appendix A.

In the early universe conductivity is large, and hence the diffusion length is also large. The conductivity of the isotropic relativistic electron gas, which interacts with heavy (non-relativistic) ions, is related to the Coulomb scattering cross section and reads [12]
\[
\sigma = \frac{\omega_p^2}{4\pi \sigma_{\text{coll}} n_e} \simeq \frac{T}{3\pi \alpha},
\] (21)

where \( \omega_p \) is the plasma frequency, \( \sigma_{\text{coll}} \) is the collision cross section and \( \alpha \) is the fine structure constant. This result is valid for fields smaller than the critical field \( B_c = m_e^2/e = 4.41 \times 10^{14} \text{ G} \), above which the electrons cannot be treated as free, and the conductivity (21) should be multiplied by a factor \( B/B_c \). On dimensional grounds, conductivity of the fully relativistic Standard Model gas will also scale as \( \sigma \sim T \). The expansion rate of the radiation dominated universe is given by
\[
H = \frac{\dot{R}}{R} = \frac{1}{2t} = \sqrt{\frac{8\pi^3 g_* T^4}{90 M_P}} \frac{M_P}{T^2},
\] (22)

where \( g_* \) is the number of the effective degrees of freedom, and \( M_P = 1.2 \times 10^{19} \text{ GeV} \) is the Planck mass. Equation (22) also provides the time-temperature relationship [13], and the inverse the length scale of the universe. A measure of the importance of the diffusion is the magnetic Reynolds number, which may be defined as
$Re = L v \sigma$, where $L$ and $v$ are respectively the typical length scale and velocity in the system under consideration. A Reynolds number less than one means that diffusion dominates. In the early universe, say at the electroweak phase transition $T_{\text{EW}} \simeq O(100)$ GeV where in the Standard Model $g_\ast = 106.75$, the Reynolds number is huge; typically

$$Re_U \sim v \sigma H^{-1} \sim \frac{M_P}{T} \sim 10^{17}, \quad (23)$$

where $v$ has been arbitrarily chosen to be $10^{-2}$. In this sense the very early universe is almost a perfect conductor. Also, the extremely large value of the Reynold’s number indicates a turbulent situation, which we shall find by other methods later.

### III. ASPECTS OF RELATIVISTIC MHD

#### A. Magnetohydrodynamics waves

Let us begin by first presenting some general considerations. In the framework of relativistic MHD in an expanding universe, we can still discuss waves. Although the equations exhibited in the previous section are considerably more complicated than their non-relativistic counterparts, the MHD-waves are linear perturbations of the standard cosmological background. Thus, the bulk velocity $v$ must necessarily be small relative to the velocity of light. It therefore follows that the displacement current can be ignored. The background is homogeneous, and we assume the relativistic relation $p = \rho/3$ for the background as well as for the fluctuations. The continuity equation, i.e. (10), gives to the lowest order the well known result $\rho = \text{const.}/R^4$. To the next order we get

$$\frac{\partial R^4 \delta \rho}{\partial t} + \frac{4}{3} R^4 \rho \left( \frac{1}{R} \nabla \cdot v \right) = 0, \quad (24)$$

where $\delta \rho$ is the fluctuation in $\rho$. Also, from (7) we get to lowest order in the fluctuations

$$\frac{\partial R^4 \delta S}{\partial t} = -\frac{1}{R} \nabla R^4 \left( \frac{1}{3} \delta \rho + \delta B \right) + \frac{1}{R} (R^2 B) \nabla (R^2 \delta B), \quad (25)$$

Here $\delta S = \frac{1}{2} \delta \rho v$, and $\delta B$ is the fluctuation of the background field $B$, which is assumed to behave like $\sim 1/R^2$. Of course, $\delta B$ is expected to have a similar scaling behavior as a function of time, but it also has a spatial dependence. Finally, we have the fluctuation equation

$$\frac{\partial R^2 \delta B}{\partial t} = \frac{1}{R} \nabla \times (v \times R^2 B), \quad (26)$$

which follows from (14), since the displacement current can be ignored for small bulk velocities.

We now seek a wave solution which, because of the structure of (24)-(26), must contain the scale factor $R$ to the power $-2$,

$$\delta B = \frac{b_0}{R^2} \exp i (k \cdot x - \omega t) \quad (27)$$

and

$$v = v_0 \exp i (k \cdot x - \omega t), \quad (28)$$

$$\delta \rho = \frac{\text{const.}}{R^4} \exp i (k \cdot x - \omega t), \quad (29)$$

where $b_0$ and $v_0$ are constants. These expressions satisfy the basic fluctuation equations (24)-(26) with

$$\dot{t} = \int_{t_0}^{t} \frac{dt'}{R(t')}, \quad (30)$$

where $t_0$ is the initial time, in accordance with the results obtained in the previous section.

We therefore see that with the scaling properties mentioned above the equations are similar to the non-relativistic case (provided we use the time $\tilde{t}$ in (31)). Thus we find the group velocity $\partial \omega / \partial k = B / \sqrt{p + \rho}$. Because the scaling properties of $B$ and $\sqrt{p + \rho}$ with respect to the expansion of the universe are the same, it follows that the group velocity is independent of $R$. As far as the phase velocities are concerned, the same is true. Assuming the background field to be in the $x$-direction, then $\delta B$ and $v$ are in the $z$-direction, as in the case of non-relativistic waves. One then finds that the velocities are given by

$$\frac{1}{2} \left( \frac{1}{3} + \frac{3 B^2}{16 \pi \rho} + \frac{B_T}{\sqrt{\pi \rho}} \pm \sqrt{\frac{1}{3} + \frac{3 B^2}{16 \pi \rho} - \frac{B_T}{\sqrt{\pi \rho}}} \right). \quad (31)$$

Of course, these velocities are given in terms of the conformal time $\tilde{t}$. If we express the result in the standard time $t$, then (31) should be multiplied by $1/R$. It should be noted that the assumption of small bulk velocities can only be maintained if $|B| \ll \sqrt{\rho}$. If this condition is not satisfied, we cannot expect the nonlinear effects to be small.

#### B. Two-dimensional slice

Ideally, we would like to solve the MHD equations in three (plus one) dimensions. However, as indicated in Sect. II, this is a major computational task. We restrict ourselves therefore to a two-dimensional slice only. The main conclusion will be that much of the qualitative behavior of nonrelativistic MHD carries over to the case of relativistic MHD.

We solve (4) and (6)-(10) numerically using 6th order centered differences to compute the spatial derivatives.
and a 3rd order Runge-Kutta scheme for the timestep. We adopt random initial conditions for B. In order to guarantee that $\nabla \cdot B = 0$ for all times, we advance the $z$-component of the vector potential by means of the equation $\partial A_z/\partial t = e_z \cdot (\mathbf{v} \times B)$, where $\mathbf{B} = \nabla \times (A_x, A_y, A_z)$. The initial $A_z$ is computed by solving $\nabla^2 A_z = -4\pi J_z$. Initially ($t = t_0$, i.e. $\dot{t} = 0$) we put $\mathbf{v}$ to unity. Periodic boundary conditions are adopted in the $x$- and $y$-directions.

Our new equations (1) + (3)–(6) are scale-invariant, so it is sufficient to solve them on a computational domain with size $L = 1$. The results for a different domain size $L'$ are the same, but taken at a different time $t' = (L'/L)\dot{t}$.

Like in all turbulence calculations there has to be some diffusion to prevent the accumulation of energy at the smallest scale. In order to restrict the effects of dissipation only to the largest possible wave numbers we use hyperdiffusion, i.e. instead of the usual diffusion operator $\nabla^2$, we use an operator of the form $-\nabla^4$ for the evolution of all variables. This technique is well known in turbulence research (see e.g. [15]). Also, since this procedure is merely of computational relevance, we did not use the relativistic expressions.

The minimum diffusion coefficient $\nu$ we can afford is given by the empirical constraint that the “mesh Reynolds number” $Re_{\text{mesh}} = U\delta x/\nu$ must not exceed the value $5 - 10$. Here, $\delta x$ is the mesh size and $U$ is a typical velocity that includes the velocity of waves and bulk motions. As was pointed out before, in the early universe the Reynolds number is very large, which means that the magnetic diffusivity $\eta = 4\pi/\sigma$ should be much smaller than the adopted value of $\nu$. In other words, in order to have realistic values of $\nu$, $\delta x$ has to be extremely small. However, the maximum number of meshpoints, $N = L/\delta x$, is limited by computer memory and time. Our present, rather exploratory calculations were carried out on a workstation, and so we restricted ourselves to $N_{\text{max}} = 128$. Even on larger computers we would never reach realistic values. This demonstrates the difficulty of a realistic simulation. It is obvious that numerical simulations with a low Reynolds number cannot provide a realistic picture of the early universe MHD. However, we believe they are useful in illustrating the qualitative features of the problem.

The evolution of the magnetic field is compared in Fig. 1 for lower and higher resolution. As time goes on, the coalescence of magnetic structures leads to the gradual formation of larger and larger scales. In the higher resolution case there are more small scale structures, but also here the development of large scale fields is evident. In turbulence research this phenomenon is known as an inverse cascade. Such a cascade processes are linked to certain conservation properties that the basic equations obey. For further details see ref. [16]. We mention here only a few important aspects. An inverse cascade exists both in two-dimensional and in three-dimensional MHD turbulence. The only difference is that in the two-dimensional case it is an inverse cascade of the magnetic helicity density $A \cdot B$. In fact, the conserved quantities in the two cases are $\int d^2x A^2$ and $\int d^3x A \cdot B$, respectively. For comparison we also mention that the difference between two and three-dimensional hydrodynamic (non-magnetic) turbulence is more drastic. In two-dimensional hydrodynamics there is an inverse energy cascade associated with the conservation of enstrophy (mean squared vorticity), which has no counterpart in three-dimensional hydrodynamics.

The significance of an inverse cascade is that it leads to a transfer of magnetic energy to larger and larger scales. This process is due to the nonlinear terms giving rise to a mode interactions. Energy spreads over different scales...
until some balance is achieved where the kinetic and magnetic energy spectra have a certain slope. In the ordinary MHD turbulence a relevant energy spectrum could be the Iroshnikov-Kraichnan spectrum \( \tilde{f} \), where the spectral energy goes like \( k^{-3/2} \), or a Kolmogorov type spectrum like \( k^{-5/3} \). These different spectra describe equilibrium situations, but in any case it is clear that the spectrum will be very different from white noise, which has a \( k^{-2} \) power spectrum (see Sec. IV.B below). The possibility of energy transfer from small to large scales via an inverse cascade could be of major importance in cosmology. It could provide a seed field at the parsec or kiloparsec scale, albeit at small amplitude.

### IV. A CASCADE MODEL

#### A. Description

The ultimate goal is to solve the basic MHD equations in three dimensions at high resolution, using random initial conditions. Although we would be unable to cover a realistically large range of length scales, it is important to know whether dynamo action could be possible in a relativistic flow. This is a major task, which would go beyond the scope of this paper. To see the difficulties involved in such a program, the reader should recall the difficulties in making long term weather predictions based on the Navier-Stokes equations. Therefore, in order to demonstrate some of the anticipated behavior of the full 1+3 MHD universe, we now study a cascade model of hydromagnetic turbulence.

In ordinary hydrodynamics and hydromagnetics many properties of turbulence, in particular those related to energy transfer and to the spectral properties, including small intermittency corrections, have been studied successfully using a simple cascade model \([13]\). This is true not only qualitatively, but also quantitatively, which is the reason why the cascade model is now much used in studies of nonlinear physics (see e.g. \([19]\) and references therein).

The basic idea is that the interactions due to the nonlinear terms in the MHD equations are local in wavenumber space. In \( k \)-space the quadratic nonlinear terms, such as \( \nabla \times (v \times B) \), \( v \cdot \nabla v \), and \( \nabla \times B \), become a convolution and have the general form \([2]\)

\[
N_k(v, B) = \int C_{ij}v_{n_i}B_{n_j}(p - k)d^3p.
\]

(There are similar terms also for the other two nonlinearities,) where \( C_{ij} = C_{ij}(k) \) is a tensor which is linear in \( k \). Interactions in \( k \)-space involving triangles with similar side lengths have the largest contribution, as discussed in \([2]\). This has led to the shell model (see e.g. \([19]\) and references therein), which is formulated in the space of the modulus of the wave numbers. This space is approximated by \( N \) shells, where each shell consists of wave numbers with \( 2^n \leq k \leq 2^{n+1} \) (in the appropriate units). The Fourier transform of the velocity over a length scale \( k_n^{-1} \) \( (k_n = 2^n) \) is given by the complex quantity \( v_n \), and \( B_n \) denotes a similar quantity for the \( B \)-field. Furthermore, the convolution is approximated by a sum over the nearest and the next nearest neighbors,

\[
N_n(v, B) = \sum_{i,j=-2}^{2} C_{ij}v_{n+i}B_{n+j}.
\]  

(33)

Here \( v \) and \( B \) have lost their vectorial character, which reflects the fact that this model is not supposed to be an approximation of the original equations, but it should be considered as a toy model that has similar conservation properties as the original equations. Thus e.g. the energy flow should be represented by these equations. It is quite remarkable that such models show several realistic features, including intermittency corrections to the structure function exponents, and are therefore rather popular both in the absence \([13]\) and in the presence \([21]\) of magnetic fields. Therefore we propose to apply such a model also to the early universe.

Velocity and magnetic fields are thus represented by a scalar at the discrete wave numbers \( k_n = 2^n \) \( (n = 1, ..., N) \), i.e. \( k_n \) increases exponentially. Therefore such a model can cover a large range of length scales (typically up to ten orders of magnitude). The important conserved quantity is \( E_{\text{tot}}R^4 \), where \( E_{\text{tot}} = \int T^{00}d^3x \) is the total energy. Using that the bulk velocity is nonrelativistic, we have \( \gamma \to 1 \), so we can expand \( \gamma^2 \approx 1 + v^2 \). Hence

\[
E_{\text{tot}} \approx \int (\rho + \frac{4}{3} \rho v^2 + \frac{1}{2} B^2) d^3x.
\]  

(34)

Since we are here mostly interested in the evolution of the magnetic field we ignore the detailed evolution of \( \rho \) and assume \( \rho \approx \rho_0 R^{-4} \). Thus, we require that

\[
\int (\frac{4}{3} \rho_0 v^2 + \frac{1}{2} B^2 R^4) d^3x = \text{const}.
\]  

(35)

We use \( \mathbf{b} = \mathbf{B} R^2 \) and construct equations for \( v_n \) and \( b_n \) such that

\[
\frac{4}{3} \rho_0 \sum_{n=1}^{N} v_n^* \frac{dv_n}{dt} + \sum_{n=1}^{N} b_n^* \frac{db_n}{dt} = 0.
\]  

(36)

In computing the conservation of the energy, the complex conjugate of this equation should be added. However, it turns out that the “complex energy” (exhibited in the above equation) is conserved by the following construction.

As pointed out, the main idea of the cascade model is to construct a set of equations that share the same basic conservation properties of the nonlinear (quadratic) terms as the original equations. Thus we write equations which mimic equations \([1]\) and \([14]\),

\[
\frac{4}{3} \rho_0 \frac{dv_n}{dt} = N_n(v, b),
\]  

(37)
where

$$\frac{db_n}{dt} = M_n(v, b), \quad (38)$$

with $A$, $B$, and $C$ being free parameters. It is straightforward to verify that $2 \sum v_n^2 n + \sum b_n^2 M_n = 0$, using that $k_n = 2^n$. The $t$ differentiations in Eqs. (37) and (38) are included to mimic closely the nonrelativistic form of eqs. (9) and (14). In the actual computations we have restored magnetic and kinematic diffusion terms, $-\nu k_n^2 u_n$ and $-\eta k_n^2 b_n$, on the right hand sides of (37) and (38), respectively. We chose $\nu = \eta$ and as time goes on, lowered $\nu$ gradually using the formula $\nu \geq (\sum k_n^2 |u_n|^2)^{1/2} / k_{\text{max}}$, where $k_{\text{max}} = 2^N$. This formula estimates the minimum amount of diffusion necessary to prevent the buildup of energy at the smallest resolved scale. We use a 3rd order timestep, which is calculated via the formula $\delta_t = 0.25 \min(\sum k_n^2 |u_n|^2)^{-1/2}$.

### B. Results

The numerical study of the cascade model requires of course that the parameters $A, B, C$ are fixed. This problem turns out to be quite interesting, since it allows one to associate the cascade model with a dimension. In hydrodynamics the parameters are fixed by taking into account a conservation law which is non-trivial in the dimension considered. In two dimensions, for example, one uses the requirement that the enstrophy is conserved, whereas in three dimensions the helicity should be conserved. In three dimensions Jensen et al. [19] used the values $A = 1$, $B = -1/2$, and $C = 0$, which we have adopted also in several models presented here. We compare the results with another set of parameter for which the quantity

$$H_M = \sum (-1)^n k_n^{-1} b_n^* b_n,$$  

(41)

is conserved, in addition to the total energy [21]. This requires that $A = 7/5$, $B = -1/10$, and $C = 1$. The quantity $H_M$ resembles the magnetic helicity $A \cdot B$, which is important, because associated with it is the inverse cascade of magnetic helicity and energy [22]. In Fig. [2] we plot the spectral magnetic energy density $E_M(k_n) = |b_n|^2 / (k R^2)$ computed for these values, with the initial field taken to be random (i.e., $E_M(k) = k^2$). The reason we interpret this expression as the magnetic energy is that we know that $\sum b_n^2 b_n^*$ enters in the conserved energy. However, $\sum \sim \int \, dk \sim \int \, dk / (k \log 2)$, so $E_M(k_n)$ is the energy in $k$-space. We used $N = 30$, which covers a range of length scales of approximately ten orders of magnitude. As one can clearly see, magnetic energy is transferred from small scales to large scales. This is called the inverse cascade effect. Such an effect is found in many nonlinear systems, for example in two dimensional turbulence, relevant e.g. for the atmosphere.

**FIG. 2.** Spectra of the magnetic energy at different times. The straight dotted-dashed line gives the initial condition ($t_0 = 1$), the solid line gives the final time ($t = 3 \times 10^4$), and the dotted curves are for intermediate times (in uniform intervals of $\Delta \log(t - t_0) = 0.6$). $A = 1$, $B = -1/2$, and $C = 0$.

The quantity of paramount interest is the the magnetic field correlation function

$$C_B(r) = \langle B(r + x)B(x) \rangle,$$  

(42)

which is related to the power spectrum via a Fourier transform, $C_B(r) = \int E_M(k) \cos(kr) \, dk$. It is difficult in general to compute this quantity, due to the fluctuations...
in the spectrum $E_M(k)$. Therefore we have computed $C_B(r)$ from the spectra of the cascade model by interpolating $E_M(k)$ on a uniformly spaced mesh. This of course introduces some uncertainty. The result is shown in Fig. 3. Note the clear increase of the widths of the correlation functions.

$$\langle B(r)^2 \rangle = \frac{1}{r^{2D}} \int d^D x \int d^D y \langle B(x)B(y) \rangle,$$

where both integrations are over a volume of size $r^D$. Thus the root mean square magnetic field

$$B_r = \langle B(r)^2 \rangle^{1/2}$$

can be computed directly from the correlation function $C_B(r)$ via

$$B_r = \left( \frac{1}{r^D} \int_0^r r'^2 dr' C_B(r') \right)^{1/2}$$

For a random field, $B_r$ behaves like $r^{-\frac{D}{2}}$, so the interesting question is whether this initial behavior changes as time passes. In Fig. 4 we show the results. There is a clear broadening of $B_r$ towards larger distances as time passes, as we would expect from the inverse cascade behavior.

The determination of the width of the correlation function above is not very accurate because of the fit involved in computing the Fourier transform of the spectrum. We shall therefore now introduce another length scale that is easier to compute, but whose value is similar to the width of the correlation function. The relevant length scale in turbulence theory is the so-called integral scale, which is the characteristic length associated with the large energetic eddies of turbulence. Roughly speaking one could view it as a measure of the coherence of the magnetic field, too. It is defined by

$$l_0 = \sqrt{\frac{\int 2\pi k^{-1} E_M(k) dk}{\int E_M(k) dk}},$$

which, in our cascade model, corresponds to $l_0 = \sum 2\pi k_n^{-1} |b_n|^2 / \sum |b_n|^2$. If the spectrum is random we get $l_0 \approx \frac{2\pi k_{\text{max}}^{-1}}{2}$, where $2\pi k_{\text{max}}$ is the shortest length scale present in the model. This length scale in the initial random spectrum is determined by the mechanism generating the primordial field. In Fig. 5 we show the evolution of $l_0(t)$ in two cases, namely for the hydromagnetic $A, B, C$ (circular points) and for the MHD $A, B, C$ (diamond-shaped points). Although the two sets of values for $A, B, C$ do not yield identical results, we see that the curves are qualitatively similar. In both cases $l_0$ increases rapidly by 4-5 orders of magnitude, and there is a plateau structure. The MHD result (diamond-shaped points) has a plateau stretching to $t/t_0 = 10^8$, but for larger times $l_0$ keeps increasing. The increase of $l_0$ by almost 5 orders of magnitude is important, because it could lead to magnetic fields at the present time at length scales comparable to one parsec. If we take the electroweak phase transition as the initial state, the QCD phase transition occurs approximately for $t/t_0=10^5$. The maximum time $t/t_0=10^8$ reached in our simulation corresponds to a temperature of 3 MeV, which is close to the nucleosynthesis. It should be noticed that from these results one cannot, of course, say anything about what
happens at later times. Therefore it could be that \( l_0(t) \) increases further, either by reaching new plateau(s), or otherwise.

\[
\Delta \log(t - t_0) = 0.6. \text{ The circular points correspond to the hydrodynamic values } A = 1, B = -1/2, \text{ and } C = 0, \text{ the diamonds correspond to the MHD values } A = 7/5, B = -1/10, \text{ and } C = 1, \text{ and the triangles are the widths computed for the correlation function.}
\]

We also measured the integral scale of the magnetic field in the two-dimensional model of Sec. III.B and found a clear increase with time. For the three times plotted in Fig. 1 we found for the 64 \times 64 case the values \( l_0 = 0.09, 0.50, \text{ and } 0.95, \) whereas in the 128 \times 128 case values were \( l_0 = 0.04, 0.28, \text{ and } 0.76. \) The initial difference of a factor two is due to the different resolution. At later times the integral scales for low and high resolution are more similar.

The evolution of \( l_0 \) is not straight, but if we make a linear fit through the values given by the diamonds in Fig. 4 we find (ignoring the steep initial increase)

\[
L_0(t) = r_0(t/t_0)^{1/4}. \tag{48}
\]

For further applications of the rough fit formula (48) it may be more sensible to express time in terms of temperature, \( T \propto t^{-1/2}, \) so

\[
L_0(T) = r_0(T/T_0)^{-1/2}, \tag{49}
\]

where \( r_0 \approx 10^{-6}, \) see Fig. 4. If we were to extrapolate to the present time we have to fix the scale \( r_0 \) by physical arguments. The various models presented in the literature \[1\] give characteristic scales for the primordial field when it is generated. This scale should be identified with the lowest scale in our calculations which, in the case of the shell model, is about 10\(^{-9}\). The scale \( r_0 \) is typically somewhat larger (10\(^{-6}\) in the shell model). The reason for this is presumably that a purely random initial condition is not consistent with the MHD equations.

In order to clarify these point we take an example. If we assume that at the time of the electroweak phase transition \( (T = 100 \text{ GeV}) \) \( r_0 = 10^{-3} \text{ cm} \) (the horizon scale was \( \approx 4 \text{ cm} \)) then, using our extrapolation (49), we arrive at a scale of 2 parsec. If we assume that the initial magnetic field was \( 10^{18} \text{ G} \) then the present day value would be \( 10^{-11} \text{ G}. \) Such values would lead to sufficiently strong seed magnetic fields to explain the field even in high redshift galaxies by dynamo action \[1\]. This extrapolation may be too naive, because the nature of turbulence will change as the universe cools down. Furthermore, at later times, when structure formation begins, gravitational energy may lead to additional stirring and enhancement of turbulence in localized regions.

\[\text{V. DISCUSSION}\]

In the two-dimensional case we found that, starting from a small scale magnetic field, magnetic structures develop at progressively larger scales. This process of self-organization corresponds to an inverse cascade of magnetic energy and helicity. Using then a cascade (or shell) model to study three-dimensional MHD turbulence we were able to follow this inverse cascade over much longer times. Such a cascade model has been rather successful in the study of hydrodynamic turbulence.

The possibility of an inverse cascade means that the scale of fluctuations of the primordial magnetic field increases much beyond its original scale given by particle physics. Taking the parameter \( l_0 \) as a measure of the coherence length of the magnetic field, we see that there is an increase in the coherence of 4 to 5 orders of magnitude. This means that previous estimates of the field strengths in various mechanisms for generating a primordial field should be revised accordingly. For example, let us consider the estimate by Vachaspati in ref. \[1\]. Taking the area average one has the estimate

\[
B_r \sim gT^2/4N, \tag{50}
\]

where \( N \) is the number of steps needed to reach a given scale in terms of the “fundamental” scale at which the field is generated. In this case the fundamental scale is the electroweak scale \[1\]. Proceeding as in ref. \[1\] one has \( N \sim 10^{24} \) today, if the relevant scale is of order 100 kpc. However, due to the MHD corrections \( N \) is, from a conservative point of view, reduced because of the effect of turbulence, and one would instead have \( N \lesssim 10^{19}, \) which reduces the stochastic decrease of \( B_r. \) It should be emphasized that from our calculations one can only say what happens up to a time of order \( 10^9 \text{ t}_{\text{ew}}, \) so presumably \( N \) is considerably below \( 10^{19} \) today.

The turbulent nature of the magnetic field may have interesting effects on the various phase transitions in the early universe. Also, the inherent shift of energy from small to large scales may be of interest in connection with the density fluctuations due to the magnetic energy.

Of course, the cascade model is a \textit{model} of the real 1+3 dimensional MHD turbulence. Its successful application in many, widely different nonlinear physical problems suggests, however, that it might also be applicable...
to the primordial magnetic fields of the early universe. Therefore we believe that its indication of the strong increase in the coherence scale of the primordial field should be taken seriously, and that further, more detailed studies are warranted.

ACKNOWLEDGMENTS

We thank Mogens Høgh Jensen for interesting discussions.

APPENDIX A:

We give here the equations for the case where the bulk velocity is small. (The gas remains still relativistic, which is important for the scaling properties of $\tilde{\rho}$ and $\tilde{p}$.)

\[
\frac{\partial \ln \tilde{\rho}}{\partial t} = -\frac{4}{3}(\mathbf{v} \cdot \nabla \ln \tilde{\rho} + \nabla \cdot \mathbf{v}) - \frac{\mathbf{J} \cdot \mathbf{E}}{\tilde{\rho}},
\]  
\[\tag{A1}\]

\[
\frac{D\mathbf{v}}{Dt} = -\mathbf{v} \left( \frac{D \ln \tilde{\rho}}{Dt} + \nabla \cdot \mathbf{v} \right) - \frac{1}{4} \nabla \ln \tilde{\rho} + \frac{\mathbf{J} \times \mathbf{B}}{3\tilde{\rho}},
\]  
\[\tag{A2}\]

where $D/Dt = \partial/\partial t + \mathbf{v} \cdot \nabla$ is the total derivative, and

\[
\frac{\partial \mathbf{B}}{\partial t} = \nabla \times (\mathbf{v} \times \mathbf{B}), \quad \mathbf{J} = \frac{1}{4\pi} \nabla \times \mathbf{B}.
\]

[10] It is often said that since the magnetic field is “frozen in” at large scales, it must decrease exactly like $1/R(t)^2$ according to MHD. However, the charged plasma can have a bulk velocity (peculiar velocity) due to its interaction with the magnetic field, and this may lead to shifts of the coherence scale of the field, and hence the $1/R^2$ decrease does not necessarily give a full description of the situation.
