On the complexity of cusped non-hyperbolicity

Robert Haraway III Neil R. Hoffman

September 13, 2022

Abstract
We show that the problem of showing that a cusped 3-manifold $M$ is not hyperbolic is in NP, assuming $S^3$ recognition is in coNP. To this end, we show that Irreducible toroidal recognition lies in NP. Along the way we unconditionally recover Satellite knot recognition lying in NP. This was previously known only assuming the Generalized Riemann Hypothesis. Our key contribution is to certify closed essential normal surfaces as essential in polynomial time in compact orientable irreducible $\partial$-irreducible triangulations. Our work is made possible by recent work of Lackenby showing several basic decision problems in 3-manifold topology are in NP or coNP.

Declarations and Acknowledgements
Both authors declare no conflict of interest.
Both authors thank Bus Jaco and Ben Burton for separate summaries of crushing; William Pettersen for conversations at the start of this project; and the MATRIX Institute who hosted these conversations. They also thank the referee for careful reading and extensive constructive criticism. Robert Haraway thanks Nathan Dunfield and Marc Lackenby for questions and helpful comments about surface bundle recognition. Neil Hoffman thanks Gary Miller for questions about $S^3$ recognition that led to this project. Neil Hoffman was also partially supported by Simons Foundation grant #524123.

1 Introduction
1.1 Our main results
One useful property to know about a 3-manifold is whether or not it is hyperbolic—that is, whether or not it is homeomorphic to a finite volume quotient of $\mathbb{H}^3$ by a group of isometries acting properly discontinuously. The decision problem of Hyperbolicity is computable (\cite{20, 22}), but not much is known about its complexity class. We will focus on the class of cusped orientable 3-manifolds. Here a cusped 3-manifold is a compact orientable 3-manifold with nonempty boundary consisting of a finite disjoint union of tori. We stress that all 3-manifolds
we discuss will be orientable here and throughout the paper. More specifically, we seek to understand the complexity of certifying a negative answer to this decision problem. The main result of this paper is as follows:

**Theorem 1.** Suppose $S^3$ recognition lies in coNP. Then among cusped 3-manifolds, hyperbolicity lies in coNP.

We have taken care to minimize our result’s dependence on a coNP solution to $S^3$ recognition, the decision problem to recognize $S^3$ among triangulations of manifolds. Of course, this problem is known to be decidable ([25, 28]) and lie in NP ([16, 27]), but the hypothesis is about certificates for affirming a negative result. If we restrict to the set of irreducible manifolds, we may obtain the unconditional result:

**Theorem 2.** Among irreducible orientable cusped 3-manifolds, hyperbolicity lies in coNP.

Along the way, we recover unconditionally the following theorem of Baldwin and Sivek [2, Thm. 1.3], removing its dependence upon the Generalized Riemann Hypothesis. We follow the convention that satellite knot recognition is the decision problem which takes as its input a knot (here a set of $n$ edges in embedded in $S^3$) and determines if it has a toroidal complement.

**Theorem 3.** Satellite knot recognition lies in NP.

This follows as a special case of the following theorem. We say the irreducible toroidal recognition problem is the decision problem to decide if an irreducible manifold is toroidal.

**Theorem 4.** Irreducible toroidal recognition lies in NP.

In other words, if $T$ triangulates an orientable closed or cusped 3-manifold that is also irreducible and toroidal, then there is a certificate that $T$ is irreducible and toroidal that is verifiable in time polynomial in $|T|$.

We structure our nonhyperbolicity certificate according to a celebrated theorem of Thurston. Assuming $M$ is both irreducible and neither a solid torus nor $T^2 \times I$, Thurston [29] showed that $M$ is either Seifert fibered, toroidal, or hyperbolic. Typically, the theorem below is presented adhering to that trichotomy, but the following reformulation is more useful for disproving hyperbolicity.

**Theorem 5 ([29, Thm. 2.3]).** Let $M$ be a cusped 3-manifold. $M$ is non-hyperbolic if and only if it admits an essential connected compact surface of nonnegative Euler characteristic.

There are but seven connected compact surfaces of nonnegative Euler characteristic: the projective plane $P^2$, the sphere $S^2$, the disk $D^2$, the Klein bottle $K^2$, the torus $T^2$, the Möbius strip $M^2$, and finally the annulus $A^2$. Thus, to prove our main theorem, it will suffice to give, for any triangulation $T$ of a non-hyperbolic cusped 3-manifold, a certificate verifiable in time polynomial in $T$. 
(that is, polynomial in its number of tetrahedra) that $\mathcal{T}$ admits such a surface. The certificates we give are either normal such surfaces or appeals to the works of others, which themselves appeal in no small part to normal surfaces. Thus we will begin the body of this paper with a review of normal surfaces, and of useful intermediate results from [1] and [21]. Then, after building up the necessary intermediate certificates, we give the certificates advertised above. Before doing so, however, we now give a brief review of the literature.

1.2 Brief review of some relevant literature

Haken’s foundational result that UNKNOT RECOGNITION is decidable [13] established the importance of algorithms in low dimensional topology using normal surface theory. Hass, Lagarias and Pippenger [15] analyzed the complexity of this problem and showed that UNKNOT RECOGNITION lies in NP. Their paper contains a number of other foundational results—namely, the bounds on the size of fundamental and vertex normal surfaces’ coordinates—which continue to be relied upon or imitated (for example, later in this paper).

We point the reader to [19] for many of the original solutions to important decision problems utilizing normal surface theory, and we also point the reader to Matveev’s book [23] for further background.

In Theorem 3 of [16], Ivanov showed, among many other things, that $S^1 \times D^2$ RECOGNITION lies in NP. We appeal to this result frequently. This is distinct from UNKNOT RECOGNITION, since in the latter problem one is allowed the assumption during verification that the given 3-manifold is known to be irreducible. One could show that $S^1 \times D^2$ RECOGNITION lies in NP more or less directly using Schleimer’s result in [27] that $S^3$ RECOGNITION lies in NP, after appealing to [1] as Lackenby did to take exteriors in polynomial time.

Reducibility is where we assume that $S^3$ RECOGNITION lies in coNP. This assumption follows from the Generalized Riemann Hypothesis by the work of Zentner in [31], using his own work on splicing irreducible representations into $SL(2, \mathbb{C})$, and using Kuperberg’s work in [20] on turning such representations into nonabelian representations into $SL(2, \mathbb{F}_p)$ for sufficiently small $p$; one bounds the size required on such a prime $p$ using the Generalized Riemann Hypothesis.

Lackenby in [21] has shown that among irreducible cusped 3-manifolds, $S^1 \times D^2$ RECOGNITION lies in coNP. In fact, much more is true—he showed that IRREDUCIBLE KNOTTED RECOGNITION lies in NP. That is, if $M$ is irreducible and not $S^1 \times D^2$, then there is a certificate verifying both of these properties simultaneously.

For their satellite knot certificate, in [2] Baldwin and Sivek made an appeal to the work of Berge [3] and Gabai [10, 11] on classifying knots in solid tori. However, Baldwin and Sivek got a certificate using representations into $SL(2, \mathbb{C})$. Thus, their certificate’s size bound depends on Kuperberg’s work, and hence on the Generalized Riemann Hypothesis. Our appeals to normal surface theory removes this dependence in a number of relevant cases. Nevertheless, we still depend on Berge and Gabai.
2 Background

To provide the minimal background needed in complexity theory, the reader should consult Schleimer’s brief summary in [27]. For our purposes, a decision problem lies in NP if there is a polynomial time verifiable certificate, or proof, of an affirmative answer. Likewise, a decision problem lies in coNP if there is a polynomial time verifiable certificate of a negative answer.

When constructing such a certificate, one can assume more about a given input than one can at verification time. A trivial general example is that during construction, one can assume the answer to the decision problem is Yes (if the problem is in NP). But during verification, this is just what the certificate asserts. If we were allowed to assume the answer were Yes during verification, we could dispense with the certificate entirely. In general, during verification, the only assumptions you can make about the input are those derivable in polynomial time from the input itself and from the certificate. We gave an example above: the distinction between unknot recognition and $S^1 \times D^2$ recognition. With unknot recognition, knot exteriors in $S^3$ are all irreducible, so one may assume irreducibility during verification. The same is not true for $S^1 \times D^2$ recognition; the input is any triangulation, and arbitrary triangulations might be reducible. To assume irreducibility during verification, one would have to include a short proof of it in the certificate.

We will work throughout in the PL category, and we will use the standard kind of triangulation, defined as follows:

**Definition.** Given a disjoint union $T$ of closed tetrahedra; and given a partition $\Pi$ of some subset of the faces of these tetrahedra into pairs; and, finally, for each pair $(f, f')$ in $\Pi$, given a cell-isomorphism or gluing $\phi_{(f, f')}$ between $f$ and $f'$, one may construct a cell-complex by identifying the tetrahedra along the gluings, and remembering all this information. A cell-complex so constructed we call a triangulation. All triangulations are constructed this way. The underlying space of a triangulation is the topological space resulting from the identification.

A triangulation $T$ with finitely many tetrahedra is a (material) triangulation of a compact 3-manifold $M$ when $T$ is homeomorphic to $M$. This will be the convention throughout this paper and we will use $|T|$ to denote the number of tetrahedra in the triangulation $T$.

Finally, we use $T^{(0)}, T^{(1)}, T^{(2)}$ to denote the 0-, 1-, and 2-skeletons of $T$.

Because $T$ is a representative of the manifold $M$ and is indeed the input to our algorithms, we will use $T$ to denote the manifold of interest throughout the paper.

**Remark 6.** The above definition is more permissive than the definition of a simplicial complex, since it does not require cell-inclusion maps to be embeddings. For instance, there is a triangulation of the 3-sphere with one tetrahedron. But the only simplicial complex with one tetrahedron is the tetrahedron itself.

**Remark 7.** Another notion of triangulation is ideal triangulations, which typically use fewer tetrahedra. As useful as ideal triangulations are in other contexts,
we eschew them here. We mention “material” triangulations only to emphasize this. It is worth pointing out that, given an ideal triangulation $T$ of a 3-manifold $M$, one may associate a material triangulation $T'$ to $M$ in time polynomial in $T$ by taking a second barycentric subdivision and removing the tetrahedra around the ideal vertices of $T$. A construction due to Weeks (see [30, pp. 469–470]) allows the converse operation, going from a material triangulation to an ideal triangulation.

Remark 8. Lackenby prefers to use handle structures instead of triangulations (for good reason; see [21, §1.3]), but we relied mainly on triangulations in this work. These two kinds of structure are polynomially equivalent. That is, given a handle structure $H$ on a 3-manifold with a given total number of cells $h$, one may calculate in time polynomial in $h$ a triangulation $T$ of the same 3-manifold, and vice versa. Lackenby gives one such equivalence in [21]. Triangulations admitting splitting surfaces as in [4, Chapter 4] provide another such equivalence.

Our work depends on the theory of normal surfaces.

Definition. Suppose $T$ is an orientable triangulation. All the following definitions depend upon this choice of $T$.

A normal isotopy of a triangulation is an isotopy $\phi : T \times I \to T$ leaving the triangulation invariant—i.e. such that, for every $t \in I$, the homeomorphism $x \mapsto \phi(x, t)$ is a cell-isomorphism from $T$ to itself.

A normal disk in a tetrahedron $\tau$ of $T$ is a properly embedded disk in $\tau$ normally isotopic to the intersection of $\tau$ with an affine plane transverse to $\tau$. If it separates one vertex from the others, or links the vertex, then the disk is a triangle. Otherwise the plane separates two pairs of vertices, and the disk is a quadrilateral, or quad.

A normal surface in $T$ is a properly embedded surface $\Sigma \hookrightarrow T$ transverse to $T^{(2)}$ such that $\Sigma$ is the union of finitely many normal disks.

A link of a vertex $v$ of $T$ is a normal surface in $T$ consisting of one of each normal triangle disk linking $v$. These are “trivial” normal surfaces.

The normal disk set of $T$ is the set $\Delta$ of normal isotopy classes of normal disks in $T$. It has cardinality $\tau \cdot |T|$.

The (normal) coordinates of a normal surface $\Sigma$ are constituted by the function $x_{\Sigma} : \Delta \to \mathbb{N}$ defined by letting $x_{\Sigma}(d)$ be the number of normal disks of $\Sigma$ in the normal isotopy class $d$.

The (total) weight of a PL surface $\Sigma$ in $T$ transverse to $T^{(2)}$ is $|\Sigma \cap T^{(1)}|$.

A normal surface is determined up to normal isotopy by its coordinates. Therefore, one may combinatorially represent a normal surface via its coordinates. That is to say, letting $N(T)$ be the set of normal isotopy classes of normal surfaces in $T$, the function $x : N(T) \to \mathbb{N}^{\Delta(T)}$ taking such a class to the coordinates of one of its members is not only well-defined, but also is injective. However, it is not surjective. For instance, no normal surface $\Sigma$ has $x_{\Sigma}(q) > 0$ and $x_{\Sigma}(q') > 0$ for two distinct normal isotopy types $q, q'$ in a single tetrahedron of $T$. 

5
Not every surface in $\mathcal{T}$ is isotopic to a normal surface. However, many surfaces important for 3-manifold topology can be so isotoped. We will also regard those properties $\mathcal{T}$ (or $M$) that can be computed from $\mathcal{T}$ in polynomial time as inherent to $\mathcal{T}$. For example, if $\mathcal{T}$ can be distinguished from $\mathbb{T}^2 \times I$ by a polynomial-time computable invariant such as number of cusps or homology, we say it can be distinguished via the empty certificate. Our convention here would be to avoid unnecessary storage of certificates in such cases.

We refer the reader to [15] for a simple “shrinking” normalization procedure that produces normal such surfaces from non-normal ones.

The set of normal surfaces is infinite, even when considered only up to normal isotopy. However, normal surfaces can sometimes be added together. Normal surfaces that cannot be expressed as such a sum end up forming a finite set. That is the class of surfaces we will focus on. While summation can be defined strictly with respect to vectors, we use geometric sum in Lemma 31. Geometric sum uses the following definition.

**Definition.** Two quads $q, q'$ in the same tetrahedron with different normal isotopy type are said to clash. A pair of normal surfaces $X, Y$ is admissible when no two normal quads from $X$ and $Y$ clash.

If $S, S'$ are an admissible pair of normal surfaces, then $x_S + x_{S'}$ is the vector of a normal surface. Briefly, this is because both $x_S, x_{S'}$ are solutions to a homogeneous linear system of equations, Haken’s matching equations; by homogeneity, $x_S + x_{S'}$ is therefore also a solution; and by admissibility of the pair, the formal solution is the vector of an actual normal surface.

Haken gave a geometric construction of this surface, which construction is called the geometric or Haken sum $S + S'$. Briefly, we may normally isotope $S$ so that $S, S'$ are transverse. Suppose $\kappa$ is a component of $S \cap S'$. Let $N$ be a small regular neighborhood of $\kappa$ in $\mathcal{T}$. We can establish a product structure on $N$ such that $N = \kappa \times D^2$ and such that for all $p \in \kappa$, $(S \cup S') \cap \{p\} \times D^2$ is $\times$ in the disc, i.e. two properly embedded arcs intersecting once in their interiors. We can replace $(S \cup S') \cap N$ with one of two surfaces, whose intersection with every such $\{p\} \times D^2$ is instead a pair of disjoint arcs with the same four boundary points as the $\times$. This resolves the intersection. Haken showed that when $X, Y$ are admissible, exactly one of the two resolutions produces an immersed normal surface, i.e. a (possibly non-disjoint) union of normal discs. On performing all such resolutions, one gets an immersed normal surface with no self-intersections, i.e. just a normal surface. Any two such normal surfaces gotten by completely resolving the intersections are normally isotopic. So $X + Y$, the geometric sum of $X$ and $Y$, is well-defined up to normal isotopy.

For Lemma 31 we note here that if $[X]$ and $[Y]$ are the classes of $X$ and $Y$ in $H_2(\mathcal{T}, \partial \mathcal{T}; \mathbb{Z}/2\mathbb{Z})$, then $[X + Y] = [X] + [Y]$, because resolutions don’t change $\mathbb{Z}/2\mathbb{Z}$ homology. Resolutions also respect weight, so that we have $\text{wt}(X + Y) = \text{wt}(X) + \text{wt}(Y)$. Finally, $X + Y$ has as many $d$-cells as $X$ and $Y$ combined, for all $d = 0, 1, 2$. So in particular, $\chi(X + Y) = \chi(X) + \chi(Y)$.

Now we define the finite class of normal surfaces we use.
A normal surface $\Sigma$ is fundamental when, for any two normal surfaces $X, Y$, we have $X + Y = \Sigma$ if and only if $\{X, Y\} = \{\Sigma, \emptyset\}$.

A common refrain in normal surface theory is that if there is an “interesting” surface, then there is a fundamental one. We first give some examples of “interesting” surfaces. We follow that by a proposition that fits the trope. It is of fundamental importance to this paper, and is how we structure our certificate of non-hyperbolicity and its verification. Its proof mostly just points the reader to [23].

Suppose $\mathcal{T}$ triangulates a compact 3-manifold. Suppose $\Sigma$ is a tame, connected, properly embedded surface in $\mathcal{T}$. $\Sigma$ is an essential sphere when it is a sphere that does not bound a ball. $\mathcal{T}$ is irreducible when it admits no essential sphere. $\Sigma$ is a compressing disk when it is a disk whose boundary is essential in $\partial\mathcal{T}$. $\mathcal{T}$ is $\partial$-irreducible when it admits no compressing disk. $\mathcal{T}$ is 0-efficient when it admits no nontrivial normal surfaces of positive Euler characteristic.

$\Sigma$ is compressible when there is an essential curve $\gamma$ in $\Sigma$ and a tame embedded disk $D$ in $\mathcal{T}$ such that $D \cap \Sigma = \gamma = \partial D$.

$\Sigma$ is $\partial$-compressible when there is an essential arc $\alpha$ in $\Sigma$ and a tame embedded disk $D$ in $\mathcal{T}$ and an arc $\beta$ of $D$ such that $\alpha = D \cap \Sigma$, $\beta = D \cap \partial \mathcal{T}$, $\alpha \cap \beta = \partial \alpha = \partial \beta$, and $\alpha \cup \beta = \partial D$.

$\Sigma$ is $\partial$-parallel when it is isotopic relative to its boundary to a subsurface of $\partial \mathcal{T}$.

$\Sigma$ is essential (assuming it is not a sphere) when it is incompressible, $\partial$-incompressible, and not $\partial$-parallel.

$\mathcal{T}$ is toroidal when it is irreducible and $\partial$-irreducible and admits an essential torus.

Proposition 9. Suppose $\mathcal{T}$ is an orientable material triangulation of a 3-manifold. Let $\mathcal{F}$ be the set of fundamental normal surfaces in $\mathcal{T}$ up to normal isotopy. Then

- if there is an embedded $P^2$, then there is one in $\mathcal{F}$;
- otherwise, if there is an essential $S^2$, then there is one in $\mathcal{F}$;
- otherwise, if there is a compressing $D^2$, then there is one in $\mathcal{F}$;
- otherwise, if there is an essential $K^2$, then there is one in $\mathcal{F}$;
- otherwise, if there is an essential $T^2$, then there is one in $\mathcal{F}$;
- otherwise, if there is an essential $M^2$, then there is one in $\mathcal{F}$;
- otherwise, if there is an essential $A^2$, then there is one in $\mathcal{F}$.

Proof. Suppose $\mathcal{T}$ is an orientable material triangulation. Let $\mathcal{F}$ be the set of fundamental normal surfaces (up to normal isotopy).
$P^2$: If $\mathcal{T}$ admits an embedded $P^2$, then by [23, Theorem 4.1.12], $\mathcal{T}$ admits a fundamental such surface.

$S^2$: Otherwise, if $\mathcal{T}$ admits an essential sphere, then again by [23, Theorem 4.1.12], $\mathcal{T}$ admits a fundamental such sphere, since $\mathcal{T}$ admits no embedded $P^2$.

$D^2$: Otherwise, if $\mathcal{T}$ admits a compressing disk, then by the proof of [23, Theorem 4.1.13], $\mathcal{T}$ admits a fundamental such disk, since $\mathcal{T}$ is irreducible.

$K^2$: Otherwise, if $\mathcal{T}$ admits an essential $K^2$, then by irreducibility there is a normal surface $\Sigma$ isotopic to this Klein bottle, e.g. by applying the shrinking procedure of [18]. Suppose $\Sigma = S + S'$. We follow an argument similar to the proof of [23, Lemma 6.4.7]. Since $\mathcal{T}$ is irreducible and orientable, and since $\Sigma$ is incompressible, by [23, Lemma 3.3.30] and [23, Theorem 4.1.36], both $S$ and $S'$ are connected, incompressible, and not $S^2$ or $P^2$. Hence they both have Euler characteristic 0. Also, they are closed. Since $\Sigma$ is not orientable, at least one of $S, S'$ is not orientable. Without loss of generality, $S$ is not orientable; since it is closed and $\chi(S) = 0$, $S$ is a Klein bottle. If $S'$ is not empty, then the weight $w(S) = |S \cap \mathcal{T}(1)|$ is less than $w(\Sigma) = |\Sigma \cap \mathcal{T}(1)|$. Hence by descent on weight, one arrives at an embedded Klein bottle $\Sigma$ such that if $\Sigma = S + S'$, then one of $S$ or $S'$ is empty—that is, we arrive at a fundamental normal essential Klein bottle.

$T^2$: Otherwise, suppose $\mathcal{T}$ admits an essential $T^2$. By [23, Lemma 6.4.7], $\mathcal{T}$ admits either a fundamental normal such surface, or a fundamental normal Klein bottle $K$ with $K + K$ being an essential $T^2$. But this latter case would mean $K$ was an essential Klein bottle, contrary to assumption. Thus $\mathcal{T}$ admits a fundamental normal essential $T^2$.

$M^2$: Otherwise, if $\mathcal{T}$ admits an essential Möbius strip $M^2$, then it admits a normal essential band $\Sigma$, again by [18]. Just as before, if $\Sigma = F + F'$, then by the same lemmata, $F$ and $F'$ are connected, incompressible, $\partial$-incompressible, and not $S^2$, $P^2$, or $D^2$. Hence their Euler characteristics are 0. One of them, say $F$, has exactly one boundary component, and the other $F'$ is closed. If $F'$ were nonorientable, then it would be an embedded Klein bottle, contrary to assumption. Hence $F$ is nonorientable, and is thus an embedded Möbius band; and by the same lemmata as above is essential, being incompressible and $\partial$-incompressible. By descent as above, $\mathcal{T}$ admits a fundamental normal embedded Möbius band.

$A^2$: Otherwise, if $\mathcal{T}$ admits an essential annulus, then it admits a normal such annulus $\Sigma$. By [23, Lemma 6.4.8], there is a fundamental such annulus, since $\mathcal{T}$ admits no Möbius band.

\[ \square \]

The following bound of Hass, Lagarias, and Pippenger improves on the mere computability of $\mathcal{F}$. 

8
Lemma 10 (Hass, Lagarias, Pippenger [15 Lemma 6.1(2)]). If $T$ is a triangulation of a compact 3-manifold with $t$ tetrahedra, and $F$ is the set of coordinates of fundamental normal surfaces of $T$, then for every $f \in F$,

$$\max_{d \in \Delta(T)} f(d) \leq t \cdot 2^{2t+2}.$$ 

The point about this bound is that the surfaces from the previous proposition admit representations of (bit-)size polynomial in $t$, since to represent a surface one may represent its coordinates. One may represent these coordinates in place-value notation, which only requires space proportional to the logarithm of these coordinates.

The fact that one may represent such a normal surface with a polynomial amount of data suggests, together with Kneser-Haken finiteness, that the topological classification of a normal surface $F$ of total weight $W$ ought to be at least representable with an amount of data polynomial in $T$ and $\log W$. In fact, much more is true. We have the following remarkable corollary of Agol, Hass, and Thurston in [1, Corollary 17], another result to which we appeal frequently:

Proposition 11 (Agol, Hass, Thurston). Suppose $T$ is a triangulation with $t$ tetrahedra, and suppose $F$ is a normal surface in $T$ of total weight $W = |F \cap T(1)|$.

There is an algorithm that, in time polynomial in $T$ and $\log W$, determines the coordinate vectors of the normal isotopy types of components of $F$, determines the homeomorphism class of each such type, and determines how many of each such type there are.

We also recall here a crucial intermediate result, a simple consequence of [21 Theorem 9.3], which Baldwin and Sivek also relied upon in [2]. The result relies on the notion of parallelity bundle. In general this is a notion to do with handle structures. For us the particular kind of handle structure that motivates the definition is this. Suppose $\Sigma$ is a normal surface in a triangulation $T$. Let $C$ be the natural cellulation on the exterior of $\Sigma$ in $T$. Let $H$ be the inverted corresponding handle structure on the underlying space of $C$. That is, let the 3-handles $H_3$ of $H$ be a small regular neighborhood of the vertices of $C$; and for $0 \leq i < 3$ let the $(2-i)$-handles $H^{2-i}$ of $H$ be a small regular neighborhood of $C^{(i+1)} \setminus \text{int } H^{1-i}$ in $C$. So 2-handles come from edges of $C$, 1-handles from faces, and 0-handles from 3-cells. See Figures 1, 2, and 3.

Let $F^0$ be $H^1 \cap \partial H^0$ and $F^1$ be $H^2 \cap \partial H^0$. These are “islands” and “bridges” in Matveev’s terminology [23 §3.4]. The choice of the letter $F$ has nothing to do with fundamental surfaces, either.

With these conventions we make the following definition.

Definition (Parallelity bundle). Quoting from [21 §9.2], a parallelity handle $H$ of $H$ is a handle admitting “a product structure $D^2 \times I$ such that

1. $D^2 \times \partial I = H \cap \Sigma$; [and]
2. each component of $F^0 \cap H$ and $F^1 \cap H$ is $\beta \times I$ for a subset $\beta$ of $\partial D^2$.”
Figure 1: A parallelity 0-handle coming from a type IV cell

Figure 2: A parallelity 1-handle coming from a trapezoid
Theorem 12 (Lackenby). There is an algorithm that takes, as its input,

(i) a triangulation $\mathcal{T}$, with $t$ tetrahedra, for a compact orientable manifold $M$; and

(ii) a vector $\vec{S}$ for an orientable normal surface $S$ with no two components normally isotopic,

and provides, as its output, the following data, in time that is bounded by a polynomial in $t \cdot \log |S \cap T^{(1)}|$.

If $M'$ is the manifold that results from decomposing along $S$, and $S'$ is the two copies of $S$ in $\partial M'$, and $B$ is the parallelity bundle for the pair $(M', S')$ with its induced handle structure, then the algorithm determines the following information: a handle structure for $\text{cl}(M' - B)$ and, for each component $B$ of $B$,

(i) the genus and number of boundary components of its base surface;

(ii) whether $B$ is a product or twisted 1-bundle; and

(iii) the location of $\partial_v B$ in $\text{cl}(M' - B)$.

With the above theorem we can state the following proposition. We placed the proof of the proposition in an appendix.

Proposition 13. There is an algorithm that takes as its input both a compact orientable connected triangulation $\mathcal{T}$ of $t$ tetrahedra and a connected normal surface $S$ in $\mathcal{T}$ given as a vector, and provides as its output a triangulation of an exterior of $S$, and that moreover provides this output in time polynomial in $t$ and $|\chi(S)|$. 
The example of a large number of parallel normal discs in a tetrahedron shows it is necessary for $S$ to be connected.

We provide a proof of Proposition 13 in an appendix, since it follows fairly easily from Lackenby’s work.

The above operation due to Lackenby can triangulate the exterior of, say, a normal sphere of weight $2^n$ with $O(|\mathcal{T}| + n)$ tetrahedra, where $\mathcal{T}$ is the original triangulation. As good as this is, it may not reduce the number of tetrahedra.

On the other hand, the crushing operation always produces a smaller triangulation. This procedure was introduced by Jaco and Rubinstein in [18] and refined by Burton in [5]. The implementation of crushing below is in some sense a blend of the two. We omit some of Jaco and Rubinstein’s restrictive conditions to set up a crushing procedure. This reduces the process to relatively easy-to-implement operations at the expense of possibly over-simplifying the prime decomposition of the manifold. In that sense, the result of crushing may not account for all components in the prime decomposition of the exterior. However, when crushing along spheres or discs, the differences from the exterior are well-understood and will be discussed below. Furthermore, we will only use this operation to certify homeomorphism between a triangulation and a 0-efficient triangulation.

Before defining crushing, we start with something more straightforward. Suppose $\Sigma$ is a normal surface in the closed triangulation $\mathcal{T}$. Let $\Sigma^*$ be $\Sigma$ with a disjoint union of vertex links, so that $\Sigma^*$ contains one of each such vertex link as a component. Then the exterior $\downarrow \Sigma^*$ of $\Sigma^*$ in $\mathcal{T}$ naturally inherits a cell structure from $\mathcal{T}$ with interstitial cells of five types. The type I cells are truncated tetrahedra. The type II cells are truncated half-tetrahedra, or purses. The type III and IV cells are triangular and quadrilateral prisms, respectively. Finally, the type V cells are tetrahedra incident to vertices of $\mathcal{T}$. The interesting components of $\downarrow \Sigma^*$ are those without type V cells. So we want to ignore cells of type V.

**Definition.** If $\Sigma$ is normal in $\mathcal{T}$, and $\Sigma^*$ is $\Sigma$ with enough vertex links added to have one of every vertex link, then $\downarrow \Sigma^*$ with all type V cells omitted is $\mathcal{T}$ cracked along $\Sigma$, for which we write $\downarrow \Sigma$.

Now, to crush, from $\downarrow \Sigma$ we first throw out the cells of types III and IV in $\downarrow \Sigma$. Next, suppose $c$ is a type II cell of $\downarrow \Sigma$. Then $c$ has two hexagonal faces $h_0, h_1$ incident along an edge $e$. Since $\mathcal{T}$ is closed, some hexagonal face $h_0'$ of a cell of $\downarrow \Sigma$ different from $h_0$ is glued to $h_0$. If $h_0' = h_1$, then we throw out $c$ from $\downarrow \Sigma$. Otherwise, let $\phi_0$ be the cell-isomorphism pairing $h_0$ to $h_0'$ for $\downarrow \Sigma$. Likewise, let $\phi_1$ be the cell-isomorphism similarly pairing $h_1$ to $h_1'$ for $\downarrow \Sigma$. Finally, let $\phi_c$ be the cell-isomorphism from $h_0$ to $h_1$ that “folds along” their common edge $e$. We throw out $c$, and replace $\phi_0, \phi_1$ with the single face-pairing $\phi_1 \circ \phi_c \circ \phi_0$. Throwing out type II cells this way, we eventually get a cellulation with only type I cells. At this point, we just cone off the triangulated boundary to get a triangulation.

**Definition.** This final coned-off triangulation is $\mathcal{T}$ crushed along $\Sigma$, which we write as $\uparrow \Sigma$. 12
Crushing along a sphere or disc at most can do the following to a triangulation see [5, Cor. 5]:

**Theorem 14** (Burton). Suppose $\mathcal{T}$ is a $3$-triangulation containing no two-sided $P^3$. Let $S$ be a normal sphere or disc in $\mathcal{T}$. Let $\mathcal{T}_{\mathcal{JR}}$ be $\mathcal{T}$ crushed along $S$. Then $\mathcal{T}_{\mathcal{JR}}$ is a valid $3$-triangulation obtained from $\mathcal{T}$ by zero or more of the following operations:

- undoing connected sums, i.e. surgering along spheres;
- cutting open along properly embedded discs;
- filling boundary spheres with $3$-balls;
- deleting components homeomorphic to $D^3$, $S^3$, $RP^3$, $L(3, 1)$, $S^2 \times S^1$, or $S^2 \tilde{\times} S^1$.

### 3 Certificates

#### 3.1 Three-sphere certificates

Rubinstein and Thompson both describe algorithms for $3$-sphere recognition [25, 28]. Later, it was shown that such algorithms could also produce an appropriately sized certificate affirming a manifold is indeed $S^3$.

**Theorem 15** (Ivanov [16], Schleimer [27]). $S^3$ recognition lies in NP.

The companion question remains open.

**Conjecture 1.** $S^3$ recognition lies in coNP.

Zentner [31, Theorem 11.2] proved the following, providing strong evidence for the conjecture.

**Theorem 16** (Zentner). $S^3$ recognition lies in coNP, provided that the Generalized Riemann Hypothesis holds.

#### 3.2 Isomorphism signatures

It may happen on occasion that we will want our triangulations to have a particular form—for instance, we may want to have a triangulation that induces a one-vertex triangulation on a boundary component. One may simplify a triangulation to have such properties in polynomial time, and then one may generate certificates for the simplified triangulation. However, these are not certificates for the original triangulation.

To promote these certificates to certificates of the original triangulation, it suffices to give a polynomial-sized certificate that the simplified triangulation triangulates the same underlying manifold as does the old triangulation. It is almost obvious that one may do this for polynomial-length sequences of Pachner
moves, layerings, close-the-book moves, and other “atomic” modifications of triangulations. However, it is not clear how to name such a sequence in a way that is invariant under isomorphism of the triangulation. Moreover, a representation of, say, a normal surface in a triangulation as a vector of numbers requires some choice of ordering on the normal disk-types in that triangulation. One can consistently specify a natural such ordering given an ordering of the tetrahedra of the triangulation, and given, for each tetrahedron, an ordering of its vertices. But then to use that vector as a certificate, one must make sure to make that particular collection of choices of ordering for one’s triangulation.

Therefore, following [27, §3], let us say that a triangulation together with such choices is a labelled triangulation. Let two such structures be equivalent when there is an isomorphism between the triangulations preserving the orderings (or labellings). In [6] Burton has constructed an injective signature function from the set of equivalence classes of labelled triangulations to the set of bit-sequences; and has constructed a function, the isomorphism signature function, from the class of labelled triangulations to the set of bit-sequences, whose level classes are in bijection with combinatorial isomorphism classes of triangulations; and, most importantly for us, these functions may be computed in polynomial time in their inputs. This gives canonical ways of putting coordinates on normal surfaces and other such objects in triangulations.

Therefore, throughout the work below, we assume that every triangulation is labelled, and in fact has the labelling whose signature is its isomorphism signature, which is just the lexicographic minimum of the set of signatures over all its possible labellings—we assume it has its canonical labelling. When implementing the algorithms below, the first thing one should do with a newly constructed triangulation or with an input triangulation is to endow it with its canonical labelling.

3.3 Simplifying triangulations

A standard “close-the-book-and-layer” algorithm (e.g. the algorithm in [8], close_cusps.c) returns, in time polynomial in \( T \), a new triangulation \( T' \) such that \( T' \) has at most three more tetrahedra in each boundary component than \( T \) and such that \( T' \) induces one-vertex triangulations on \( \partial T' \); and also returns a proof \( P \) of size polynomial in \( T \) that \( T \) and \( T' \) are homeomorphic. The proof is, as described above, a sequence of triples \((\sigma, i, b)\), where \( \sigma \) is an isomorphism signature, \( i \) is a number indicating a boundary edge, and \( b \) is a bit indicating whether to fold along that boundary edge or layer along it. This allows one to promote, as above, a polynomial-sized certificate of a property of \( T' \) to a polynomial-sized certificate of a property of \( T \).

As simple as the above algorithm is, it has this disadvantage, that it increases the number of tetrahedra. If the given triangulation is assumed to be irreducible and \( \partial \)-irreducible, then one can do much better via crushing to a 0-efficient triangulation. The following are essentially restatements and summaries of results from [18].
Lemma 17. Suppose \( T \) is a compact material triangulation that is not 0-efficient. Then \( T \) admits a fundamental surface \( \Sigma \) that is either an embedded \( P^2 \), a non-vertex-linking \( S^2 \), or a non-vertex-linking \( D^2 \).

Proof. Suppose \( T \) is a compact material triangulation that is not 0-efficient. Then \( T \) admits a connected non-vertex-linking normal surface \( \Sigma \) with \( \chi(\Sigma) > 0 \).

Suppose \( \Sigma = X + Y \) for nonempty normal surfaces \( X, Y \neq 0 \). Then \( \chi(\Sigma) = \chi(X) + \chi(Y) > 0 \). Hence either \( \chi(X) > 0 \) or \( \chi(Y) > 0 \). Thus some component \( k \) of \( X \) or \( Y \) has \( \chi(k) > 0 \). Now, since \( \Sigma \) is connected and non-vertex-linking, no component of \( X \) or \( Y \) is a vertex link. Hence in particular, \( k \) is not a vertex link. However, since \( X \) and \( Y \) are nonempty, \( |k \cap T^{(1)}| < |\Sigma \cap T^{(1)}| \). Thus by descent on \( |\Sigma \cap T^{(1)}| \) (the weight of \( \Sigma \)), \( T \) admits a connected non-vertex-linking fundamental surface \( \Sigma \) with \( \chi(\Sigma) > 0 \). The lemma follows.  

The existence of the 0-efficient triangulation in the next proposition can be established by [18, Proposition 5.9, Theorem 5.17]; the certificate is essentially due to Schleimer (see [27, Theorem 16.1]).

Proposition 18. Suppose \( T \) is a triangulation of a compact, orientable, \( P^2 \)-irreducible, \( \partial \)-irreducible 3-manifold.

Then there is a 0-efficient triangulation \( T' \) of the same 3-manifold with \( |T'| \leq |T| \), and also there is a certificate that \( T \cong T' \) verifiable in polynomial time.

Note carefully that we do not claim there is a polynomial-size certificate that the 0-efficient triangulation \( T' \) is in fact 0-efficient—we only provide a certificate that \( T \cong T' \).

This is also not the most computationally efficient way to go about the certification. Instead we have tried to give a simple certification.

Proof. Suppose \( T \) is a triangulation of a compact, orientable, \( P^2 \)-irreducible, \( \partial \)-irreducible 3-manifold.

Define a sequence of triangulations \( T_0, \ldots, T_k \) and \( k < |T| \) homeomorphic to \( T \) as follows. Start with \( i = 0 \) and \( T_i = T \). When we find \( T_i \) is 0-efficient, we set \( k = i \) and stop. Otherwise, by Lemma 17 there is a fundamental nontrivial normal surface \( \Sigma_i \) with \( \chi(\Sigma_i) > 0 \). Since \( T_i \) is \( P^2 \)-irreducible, \( \Sigma_i \) is not an embedded projective plane. So \( \Sigma_i \) is either a sphere or a disc. The proof of Theorem 14 shows that in fact the crushing \( \Sigma_i \) is not just gotten from \( T_i \) by the given collection of operations, but from \( T_i \) surgered along \( \Sigma_i \). So let \( T_{i+1} \) be \( T_i \) surgered along \( \Sigma_i \). Since \( T_i \) is \( P^2 \)-irreducible, some component \( T_{i+1} \) of \( T_{i+1} \) is homeomorphic to \( T_j \). Let \( S_{i+1} \) be the other component. Then \( S_{i+1} \) is either \( S^3 \) or \( D^3 \) according as \( \Sigma_i \) is \( S^2 \) or \( D^2 \). Use Proposition 13 to triangulate the exterior of \( \Sigma_i \), then cone off the appropriate sphere boundary component to triangulate \( S_{i+1} \). Let \( C_{i+1} \) be a certificate from Theorem 14 that \( S_{i+1} \) is \( S^3 \) or that the double of \( S_{i+1} \) is \( S^3 \), according as \( \Sigma_i \) is \( S^2 \) or \( D^2 \). Next, let \( R_{i+1} \) be the part of the crushing \( \Sigma_i \) coming from applying the operations of Theorem 14 to \( T_{i+1} \). Then by the irreducibility conditions on \( T_i \) and thus \( T_{i+1} \), and by Theorem 14, either \( R_{i+1} \) is homeomorphic to \( T_{i+1} \) or \( R_{i+1} \) is empty. In the
former case, let $T_{i+1} = R_{i+1}$. In the latter case, $R_{i+1}$ is either $S^3$, $D^3$, or $L(3,1)$; we set $T_{i+1}$, respectively, to the triangulation with isomorphism signature either bkaagb, bGab, or cMcabbjak. (The first two have one tetrahedron; the third has two. All three are 0-efficient.)

By Theorem 15 and Lemma 10, the size of each pair $(T_i, \Sigma_i, C_i)$ is bounded above by $p(|T_i|)$ for some polynomial $p$. We may assume $p$ is increasing. Crushing a triangulation along a nontrivial normal surface yields a triangulation with strictly fewer tetrahedra. Hence $p(|T_i|) \leq p(|T|)$. So the size of the sequence of these pairs is at most $|T| \cdot p(|T|)$, a polynomial in $|T|$.

To verify that the sequence establishes a homeomorphism from $T$ to $T_k$, it suffices to verify that the sequence establishes a homeomorphism from $T_i$ to $T_{i+1}$ for each $0 \leq i < k$. To that end, first we verify that $\Sigma_i$ is a sphere or disc in polynomial time using Proposition 11 then use Proposition 13 as above to surger along $\Sigma_i$ then use $C_i$ to verify in polynomial time that the appropriate component of the surgery is $S^3$ or $D^3$. This establishes that the other component of the surgery (not yet constructed) is homeomorphic to $T_i$. Next determine the part $R_{i+1}$ of the crushing corresponding to this other component in polynomial time. If $R_{i+1}$ is nonempty, verify in polynomial time that $R_{i+1}$ is isomorphic to $T_{i+1}$. Otherwise, let $K(M)$ be the predicate on 3-manifolds $M$ that “$M$ is gotten from \emptyset by finitely many operations of Theorem 14.” By Theorem 14 we have proven $K(R_{i+1})$, and therefore $K(T_i)$. If $T_{i+1}$ has isomorphism signature bkaagb, which we can test in polynomial time, then we verify that $T_i$ is closed and a homology $S^3$. The only such manifold satisfying $K$ is $S^3$ itself. Since $T_{i+1}$ is homeomorphic to $S^3$, $T_i$ is homeomorphic to $T_{i+1}$. Similar arguments hold for bGab and cMcabbjak.

3.4 Closed essential surface certificates

To certify a manifold is toroidal, we need to give a certificate that a torus or Klein bottle is essential. In an earlier version of this paper, we gave examples of such certificates. We also conjectured the following.

**Theorem 19.** HANDLEBODY RECOGNITION is in coNP among irreducible 3-manifolds, and HANDLEBODY RECOGNITION is in coNP modulo GRH.

After we posted this version, Marc Lackenby kindly pointed out the following theorems from the latest revision of [21] can be used to prove Theorem 19.

**Theorem 20 ([21 Thm. 1.5]).** THURSTON NORM OF A HOMOLOGY CLASS is in NP.

**Theorem 21 ([21 Thm. 1.6]).** The decision problem IRREDUCIBILITY OF A COMPACT ORIENTABLE 3-MANIFOLD WITH TOROIDAL BOUNDARY and $b_1 > 0$ is in NP.

**Theorem 22 ([21 Thm. 1.7]).** INCOMPRESSIBLE BOUNDARY is in NP $\cap$ coNP.
**Definition.** Recall that, for any compact oriented 3-manifold \( M \), the function \( \chi_- : H_2(M, \partial M; \mathbb{Z}) \to \mathbb{Z} \) defined as
\[
\chi_-(\{F\}) = \min_{F \in \{F\}} \{\chi_-(F)\}
\]
is called the Thurston norm, where the minimum is taken over all oriented properly embedded surfaces \( F \) in the homology class \([F]\), where \( \chi_-(S) = \max(0, -\chi(S)) \) for connected surfaces \( S \), and where in general \( \chi_-(F) \) is the sum of \( \chi_-(S) \) over all components \( S \) of \( F \).

In general \( \chi_- \) is only a pseudonorm, but we still call it the Thurston norm.

We prove Theorem 19 below. We then found that it is straightforward to use it and Lackenby’s new results to prove Theorems 23 and 24 and Corollary 25. The following theorem is included both for the sake of completeness and to use a framing device to discuss these other two results. (We thank Nathan Dunfield for a conversation in which he brought the problem of I-bundle recognition to our attention.)

**Theorem 23.** For every compact surface \( \Sigma \), \( \Sigma \times I \) recognition and \( \Sigma \tilde{\times} I \) recognition are in NP.

**Theorem 24.** For every compact surface \( \Sigma \), \( \Sigma \times I \) recognition and \( \Sigma \tilde{\times} I \) recognition are in coNP among orientable irreducible 3-manifolds.

**Corollary 25.** Closed essential surface recognition is in NP \( \cap \) coNP for normal surfaces \( \Sigma \) in connected, orientable, irreducible, \( \partial \)-irreducible 3-manifolds.

Note carefully that in Theorems 23 and 24 and Corollary 25, the size of the certificate returned by the algorithm is polynomial in the input triangulation and in \( |\chi(\Sigma)| \), and in the case of Corollary 25 also polynomial in the bit-size of \( \Sigma \), i.e. \( \log \text{wt}(\Sigma) \). It may be possible to make Corollary 25 depend polynomially only on the bit-size, but we do not pursue that here.

The careful reader will note that the NP portion of Theorem 23 follows almost immediately from the normal-almost-normal sweepout certificates in section 6 of Schleimer’s 2001 PhD thesis [26]. Moreover, it is relatively easy to show from Theorem 3 of [10] that one can extend the \( T^2 \times I \) recognition algorithm of [13] to show that \( T^2 \times I \) recognition is in NP. We regard these approaches as more viable for implementation with current software libraries like Regina (see [7]). However, the result also follows directly from Lackenby’s work, so for ease of reference we rely on [21].

We turn to the proofs of these results now.

**Theorem 19.** Let \( T \) be a triangulation with boundary \( F \) a genus \( g \) surface. Suppose \( T \) is not a handlebody of genus \( g \).

If \( H_1(T, \mathbb{Z}) \not\cong \mathbb{Z}^g \), then \( T \) is not a handlebody. Since homology is computable in polynomial time, \( T \) may be verified not to be a handlebody in polynomial time, with no certificate necessary.
Otherwise, we start out assuming \( T \) is irreducible and will address the reducible case afterward.

In the irreducible case, find a maximal set \( \hat{D} \) of non-isotopic normal (sic) compressing disks in \( T \). By the work of Jaco and Tollefson, specifically Theorem 6.2, we may arrange that the disks of \( \hat{D} \) are all fundamental surfaces. (This is because Jaco and Tollefson construct vertex-normal disks. Briefly, a vertex-normal disk \( S \) is a normal disk admitting no sum of the form \( S + \cdots + S = X + Y \) with \( X, Y \) not consisting of disjoint copies of \( S \). Vertex-normal disks are always fundamental.) So by Lemma [10] and Haken finiteness, the union of these disks has polynomial bit-size. By Proposition [12] above, construct on the exterior \( T - \hat{D} \) a triangulation \( \hat{T} \) of size polynomial in \( |T| \).

Suppose every component of \( \hat{T} \) had \( \beta_1 = 0 \). Then each component would have a sphere boundary component. By irreducibility, each component would be a ball, and \( \hat{T} \) would be a handlebody, contrary to assumption. So some component \( K \) of \( \hat{T} \) has \( \beta_1 > 0 \), and is irreducible. If \( \partial K \) were compressible, then it would admit a compressing disk. This would imply that \( T \) would admit yet another normal disk disjoint from \( \hat{D} \) and not normally isotopic to any element of \( \hat{D} \), contrary to the maximality of \( \hat{D} \). Thus \( \partial K \) is incompressible. We may construct a certificate \( c_{\text{inc}} \) of this fact of size polynomial in \( |T| \) by Theorem 22. Together, we contend \( \hat{D} \), \( \hat{T} \), \( K \), and \( c_{\text{inc}} \) constitute a certificate that \( T \) is not a handlebody.

Finally, if \( T \) is reducible, then we run the standard argument of constructing a polynomially sized reduction along a reducing sphere using Proposition 13 above, coning off the sphere’s sides, and applying [31] Theorem 11.2, which depends upon GRH.

To verify an empty certificate, just determine whether or not \( T \) is a homology handlebody. If not, the certificate is verified; otherwise, the verification fails. To verify the certificate constructed when \( T \) is an irreducible homology handlebody, verify that \( T \) surgers along \( \hat{D} \) into \( \hat{T} \); then verify that \( K \) is a component of \( \hat{T} \); then verify that \( c_{\text{inc}} \) is a certificate that \( \partial K \) is incompressible. All these verifications may be performed in time polynomial in the sizes of the certificates. By [11] we may verify as well that \( \hat{D} \) is a disjoint union of discs. Thus we may verify that \( K \) is gotten from \( T \) by surging along discs. But we have also verified that \( K \) has incompressible boundary. Furthermore, we may calculate \( \beta_1(K) \); if it is 0, the verification fails. Otherwise, \( \beta_1(K) > 0 \). There is no handlebody with \( \beta_1 > 0 \) and with incompressible boundary. Hence \( K \) is not a handlebody. However, surging a handlebody along a disc always produces another handlebody (or two). Hence \( T \) cannot be a handlebody. Thus the given certificate demonstrates \( T \) is not a handlebody.

Finally, to verify the reducibility certificate, verify that the given surface is a sphere, that the reduction along that sphere is as given in the certificate, and that the reduction is nontrivial using the verification of [31] Theorem 11.2.

\textbf{Theorem 23.} Suppose \( \Sigma \) is a compact surface.
First, suppose $T$ triangulates a manifold of the form $\Sigma \times I$, with $\Sigma$ orientable. If $\Sigma$ has nonempty boundary, then $T$ is a handlebody with the same Euler characteristic as $\Sigma$. Theorem 3 of [10] provides a certificate $h_T$ that $T$ is a handlebody. To verify that $T$ triangulates $\Sigma \times I$, verify with $h_T$ that $T$ is a handlebody, then check, in polynomial time, that $T$ has the same Euler characteristic as $\Sigma$. On the other hand, if $\Sigma$ is closed, then $(T, \emptyset)$ is a product sutured manifold. Let $H$ be the handle structure dual to $T$, i.e. the handle structure gotten from thickening the dual spine of $T$. One may construct this handle structure in time polynomial in $|T|$. Then $H$ is of uniform type, as required in Theorem 12.1 of [21], since its 0-handles’ intersection patterns with the 1- and 2-handles are subtetrahedral (in fact, tetrahedral, being the duals of the tetrahedra of the triangulation). So Theorem 12.1 of [21] applies, and $(H, \emptyset)$ admits a polynomial-time verifiable certificate $ps_T$ that it is a product sutured manifold. To verify that $T$ triangulates $\Sigma \times I$, verify with $ps_T$ that it is a product sutured manifold, then check, in polynomial time, that its two boundary components are homeomorphic to $\Sigma$.

Second, suppose that $T$ triangulates a twisted $I$-bundle $\Sigma \hat{\times} I$ with $\Sigma$ nonorientable. Again, if $\Sigma$ has nonempty boundary, one may verify the product as before using Ivanov’s handlebody certificate. If instead $\Sigma$ is closed, then $T$ admits a double cover $\tilde{T} \cong \tilde{\Sigma} \times I$ that is a product $I$-bundle over the orientation cover of $\Sigma$. One may certify that $\tilde{T}$ is $\tilde{\Sigma} \times I$, and this constitutes a proof that $T$ is $\Sigma \hat{\times} I$. Thus, $\Sigma \times I$ RECOGNITION and $\Sigma \hat{\times} I$ RECOGNITION are in NP among orientable 3-manifolds.

Before getting to the proof of Theorem 24 we give the following characterizing lemma.

**Lemma 26.** Let $\Sigma$ be a closed orientable surface. Let $M$ be an irreducible orientable 3-manifold with integer homology equivalent to $\Sigma \times I$. $M$ is homeomorphic to $\Sigma \times I$ if and only if $\chi_- = 0$ on all $H_2(M, \partial M; \mathbb{Z})$.

**Proof.** Suppose an oriented irreducible 3-manifold $M$ is an integral homology $\Sigma \times I$. For the only-if-direction, suppose $M$ is homeomorphic to $\Sigma \times I$. Then every element of $H_2(M, \partial M; \mathbb{Z})$ is representable with a disjoint union of annuli, which has Thurston norm 0. So $\chi_- = 0$ on $H_2(M, \partial M; \mathbb{Z})$.

For the if-direction, suppose $\chi_- = 0$ on all $H_2(M, \partial M; \mathbb{Z})$. First recall the long exact sequence in homology for the pair $(M, \partial M)$. We have that $j_* : H_2(M; \mathbb{Z}) \to H_2(M, \partial M; \mathbb{Z})$ is identically 0, since $M$ is an integer homology $\Sigma \times I$. So closed surfaces are nullhomologous in $H_2(M, \partial M; \mathbb{Z})$. Moreover, $\partial_2 : H_2(M, \partial M; \mathbb{Z}) \to H_1(\partial M; \mathbb{Z})$ is injective. Likewise, $j_* : H_1(M; \mathbb{Z}) \to H_1(M, \partial M; \mathbb{Z})$ is also identically 0. Thus $H_2(M, \partial M; \mathbb{Z}) \simeq \ker i_{\partial M}$, where $i_{\partial M} : H_1(\partial M; \mathbb{Z}) \to H_1(M; \mathbb{Z})$. Also, curves in $\partial M$ nullhomologous in $M$ are nullhomologous in $\partial M$.

Now, let $B$ be a basis for $H_2(M, \partial M; \mathbb{Z})$. Suppose $b \in B$. Then $\chi_-(b) = 0$. Let $A_b$ be an oriented properly embedded surface with $[A_b] = b$, $\chi_-(A_b) = 0$. (1)
All the components of $A_b$ are oriented and hence orientable. Any closed components of $A_b$ are nullhomologous in $H_2(M, \partial M; \mathbb{Z})$, and are spheres or tori. Omitting them preserves (1). The boundary of any disc in $A_b$ is nullhomologous in $M$, and therefore nullhomologous in $\partial M$. Thus any disc in $A_b$ is nullhomologous in $H_2(M, \partial M; \mathbb{Z})$. Thus omitting discs also preserves (1). So we may assume $A_b$ is a disjoint union of annuli.

Suppose $A$ is an oriented recurrent annulus properly embedded in $M$, i.e. an annulus with $\partial A$ lying all on one boundary component. Then $i_*(\partial_2([A])) = 0$. Let $\Sigma_{\pm}$ be the boundary components of $M$. On each of the subspaces $H_1(\Sigma_{\pm}; \mathbb{Z})$, the map $i_*$ restricts to an isomorphism. Therefore $\partial_2([A]) = 0$. Thus $\partial A$ bounds an oriented surface in $\partial M$. Attaching that surface to $A$ yields a closed surface homologous to $A$ in $H_2(M, \partial M; \mathbb{Z})$. So $[A] = 0$ in $H_2(M, \partial M; \mathbb{Z})$. Thus we may omit recurrent annuli from $A_b$ preserving (1).

Finally, suppose $\gamma$ is a boundary component of a non-recurrent annulus $A$ properly embedded in $M$ such that $\gamma$ is nullhomologous in $M$. Then $\gamma$ is nullhomologous in $\partial M$. Therefore $\gamma$ bounds an oriented surface $Y$ in $\partial M$ such that $Y \cup A$ is an oriented surface homologous to $A$ in $H_2(M, \partial M; \mathbb{Z})$. Pushing this surface off from that boundary component of $M$ yields a surface bounded by the other boundary curve of $A$. The same argument now applies to that boundary curve, so that $A$ is homologous to a closed surface in $H_2(M, \partial M; \mathbb{Z})$. Thus $A$ is nullhomologous. Therefore we may omit any annulus with a nullhomologous boundary curve from $A_b$ preserving (1).

Let $A$ be the set of all the oriented annulus components of all the $A_b$. Let $[A]$ be the set of all their homology classes. Then the span of $[A]$ is $H_2(M, \partial M; \mathbb{Z})$ since $B$ is a basis. Select a new basis from $[A]$, and let $A'$ be the set of the corresponding annuli. We may isotope these annuli so that they are all transverse. By a standard argument, after isotoping the annuli to lie in minimal position, they only intersect in core curves or essential arcs.

Suppose two distinct annuli $A, A'$ intersect in a core curve. One resolution of this intersection curve yields two recurrent annuli. That means $[\partial A] = \pm [\partial A']$. That is, $\partial_2([A]) = \pm \partial_2([A'])$. Since $\partial_2$ is injective, that means $[A] = \pm [A']$. This contradicts $[A]$ being a basis. So no two distinct annuli intersect in core curves. Hence, after isotoping the annuli to lie in minimal position, they intersect only in essential arcs.

Now, the union of their boundary curves on $\partial M$ is filling. That is, its complement consists of discs. Let $X$ be a regular neighborhood of the union of $\partial M$ with these annuli. The boundary of $X$ consists of $\partial M$ and spheres. By irreducibility the spheres must bound balls, and they must bound them away from $\partial M$. Hence $M$ is $\Sigma \times I$.

\begin{flushright}
$\square$
\end{flushright}

\textit{Theorem 24.} Suppose first that $\Sigma$ is orientable.

Suppose $T$ is a triangulation of a compact orientable irreducible 3-manifold that is not $\Sigma \times I$.

If $T$ is not an integer homology $\Sigma \times I$, we can use the empty certificate.
Otherwise $\mathcal{T}$ is an integer homology $\Sigma \times I$. Let $\Sigma_+$ be one of the boundary components of $M$. Select a basis for $H_1(\Sigma_+; \mathbb{Z}/2\mathbb{Z})$ every element of which is represented by a simple closed normal curve intersecting every edge of $\Sigma_+$ at most once. Let $\Gamma$ be a set consisting of one such curve from each homology class in the basis. Picking some orientation of these curves, we get a basis $B_+$ for $H_1(\Sigma_+; \mathbb{Z})$ of size polynomial in $\mathcal{T}$ and $|\chi(\Sigma)|$.

Let $i_\pm : \Sigma_\pm \to M$ be the inclusions. By assumption, these induce isomorphisms on homology. Define the map $k : H_1(\Sigma_+; \mathbb{Z}) \to H_1(\partial M; \mathbb{Z})$ by $k(c) = c - i_+^{-1}(i_-^*(c))$. Then $B' = \{ k(b_+) \mid b_+ \in B_+ \}$ is a basis for $\ker i_\pm$, where $i_+ : H_1(\partial M; \mathbb{Z}) \to H_1(M; \mathbb{Z})$. However, by the long exact sequence of the pair $(M, \partial M)$, since $M$ is a homology $\Sigma \times I$, $\ker i_+ = \im \partial_2$. So $B'' = \partial_2^{-1}(B')$ is a basis for $H_2(M, \partial M; \mathbb{Z})$. Since $B_+$ had size polynomial in $\mathcal{T}$ and $|\chi(\Sigma)|$, and since the above maps on homology and their inverses are representable with matrices with polynomially many coefficients of polynomial size, likewise $B''$ has size polynomial in $\mathcal{T}$ and $|\chi(\Sigma)|$.

Since $\mathcal{T}$ is an orientable irreducible integer homology $\Sigma \times I$ but isn't $\Sigma \times I$, by the if-direction of Lemma 26, $\chi_-$ is not identically 0 on $H_2(M, \partial M; \mathbb{Z})$. Therefore, $\chi_-$ is not identically 0 on $B''$. So we may pick an element $b \in B''$ with $\chi_-(b) > 0$. A natural isomorphism $L : H_2(M, \partial M; \mathbb{Z}) \to H^1(M; \mathbb{Z})$ representable by a matrix of polynomially many coefficients of polynomial size is given by Lefschetz duality. (Theorem 20 is phrased in terms of $H^1(M; \mathbb{Z})$, not $H_2(M, \partial M; \mathbb{Z})$.) So $L(b)$ is of size polynomial in $\mathcal{T}$ and $b$, i.e. in $\mathcal{T}$ and $|\chi(\Sigma)|$.

By Theorem 20 there is a certificate $C$ verifiable in time polynomial in $\mathcal{T}$ and $L(b)$, i.e. in $\mathcal{T}$ and $\chi(\Sigma)$, that $\chi_-(b) > 0$.

To verify, suppose one is given $\mathcal{T}$, and either an empty certificate, or a simplicial 1-cocycle $\eta$ and a certificate $C$ that $\chi_-(L(\eta)) > 0$. If the certificate is empty, check in time polynomial in $\mathcal{T}$ and $|\chi(\Sigma)|$ that the integral homology of $\mathcal{T}$ differs from $\Sigma \times I$. If that is verified, then $\mathcal{T}$ is not $\Sigma \times I$. Otherwise, use $C$ to check in time polynomial in $\mathcal{T}$ and $|\chi(\Sigma)|$ that $\chi_-(L(\eta)) > 0$. If that is verified, then by the only-if direction of Lemma 26, $\mathcal{T}$ is not $\Sigma \times I$.

Finally, if $\Sigma$ is nonorientable, we may verify that $\mathcal{T}$ is not $\Sigma \times I$ by showing that $\mathcal{T}$ has no double cover, or by showing that its unique connected double cover is not $\Sigma \times I$.

We remind the reader that the verification in the above proof does not assume $\mathcal{T}$ is irreducible. Only the construction of the certificate makes that assumption.

**Corollary 26.** Suppose $\Sigma$ is a closed essential normal surface in $\mathcal{T}$ with $\mathcal{T}$ orientable, irreducible, and $\partial$-irreducible. That is, suppose $\Sigma$ is incompressible and not boundary parallel. ($\Sigma$ is automatically $\partial$-incompressible, being closed, and this is why we restrict to the closed case.) If $\Sigma$ is nonorientable, its normal double is its orientation cover, and is essential if and only if $\Sigma$ is. Thus we may assume $\Sigma$ is orientable. To certify $\Sigma$ is incompressible, take a polynomial-time verifiable triangulation $\mathcal{T}'$ of its exterior with Proposition 13 and use Theorem...
to verify that $\mathcal{T}'$ has incompressible boundary. To show $\Sigma$ is not boundary-parallel, either show that $\mathcal{T}'$ is connected, or for both components of $\mathcal{T}'$ use Theorem 24 to verify that they are not $\Sigma \times I$. The latter certificate will be verifiable in time polynomial in $\mathcal{T}'$ and $\Sigma$, which is polynomial in $\mathcal{T}$ and $\Sigma$.  

3.5 Toroidality

We now consider the other decision problems discussed in the introduction. We begin with Theorem 4 on toroidality. First we require the following proposition.

**Proposition 27.** Toroidal recognition lies in NP among compact, connected, irreducible, $\partial$-irreducible, orientable 3-manifolds admitting no essential Klein bottles.

**Proof.** Suppose $\mathcal{T}$ is a triangulation of a compact, connected, irreducible, $\partial$-irreducible, orientable 3-manifold that has no Klein bottle and is toroidal. By Proposition 9 there is a fundamental essential torus $F$ in $\mathcal{T}$. By Lemma 10, $F$ is representable in size polynomial in $\mathcal{T}$. By Proposition 13, we may construct a triangulation $\mathcal{T}'$ of the exterior of $F$ in time polynomial in the sizes of $\mathcal{T}$ and $F$, hence in time polynomial in $\mathcal{T}$.

If $\mathcal{T}'$ is connected, then $\mathcal{T}'$ is $\partial$-irreducible, since $\mathcal{T}$ is $\partial$-irreducible and $F$ is essential. Lackenby’s Theorem 22 provides a certificate that $\mathcal{T}'$ is $\partial$-irreducible. Given such a certificate, we can verify that $F$ is incompressible in time polynomial in $\mathcal{T}$, and hence that $\mathcal{T}$ is toroidal.

Otherwise, since $F$ is essential and $\mathcal{T}$ is connected, $\mathcal{T}'$ has two components, $L$ and $R$, neither of which is homeomorphic to $\mathbb{T}^2 \times I$, neither of which is homeomorphic to $S^1 \times D^2$, and both of which are irreducible (and hence $\partial$-irreducible, not being $S^1 \times D^2$). The certificate we return is the quintuple $(F, L_T, R_T, L_D, R_D)$, where $L_T, R_T$ are the certificates guaranteed by Theorem 24 that $L$ and $R$ are not $\mathbb{T}^2 \times I$, and where $L_D, R_D$ are the certificates guaranteed by Theorems 21 and 22 that $L, R$ are irreducible and are not solid tori. By Theorem 24 and Lackenby’s Theorems 21 and 22 verifying these certificates takes time polynomial in $\mathcal{T}'$, and hence polynomial in $\mathcal{T}$. This verifies that $\mathcal{T}$ is toroidal.

We may now prove a theorem asserted in the introduction.

**Theorem 4.** Suppose $\mathcal{T}$ is a triangulation of a connected, orientable, irreducible, $\partial$-irreducible, toroidal 3-manifold. Either $\mathcal{T}$ contains an essential Klein bottle or not. If it does, then by Proposition 9 there is a fundamental one. Corollary 25 produces a certificate verifiable in time polynomial in $\mathcal{T}$ that this Klein bottle is essential. Otherwise, since $\mathcal{T}$ is toroidal, by Proposition 24 there is a certificate verifiable in time polynomial in $\mathcal{T}$ that $\mathcal{T}$ contains an essential torus. In the latter case we already have a proof of toroidality. In the former case, the double of the Klein bottle is a torus. Since the Klein bottle is essential, the torus is necessarily essential. Since the Klein bottle is fundamental, the torus has size polynomial in $\mathcal{T}$. Either option is a certificate of toroidality.
Since $\mathcal{T}$ admits an essential torus, $b_1(\mathcal{T}) > 0$. So a certificate of irreducibility follows immediately from Lackenby’s work, stated here as Theorem 21.

Corollary 3 follows immediately; it only requires going from a knot diagram to a triangulation, which is a standard argument of Hass, Lagarias, and Pippenger [15, Lemma 7.1]. This result was achieved by Baldwin and Sivek in [2] under the additional assumption of the Generalized Riemann Hypothesis.

3.6 Essential Möbius strips and annuli

We now discuss the final situations: when the manifold contains an essential Möbius strip or annulus.

**Proposition 28.** Suppose a compact, orientable, $P^2$-irreducible, $\partial$-irreducible triangulation $\mathcal{T}$ has no essential tori or Klein bottles. If $\mathcal{T}$ admits a properly embedded Möbius strip, then there is a certificate of this fact verifiable in time polynomial in $\mathcal{T}$.

**Proof.** Suppose $\mathcal{T}$ admits an embedded Möbius strip $M$.

If $M$ is compressible, then $\mathcal{T}$ admits an embedded $P^2$, contrary to $P^2$-irreducibility. If $M$ is incompressible but is $\partial$-compressible, let $D$ be a $\partial$-compressing disk for $M$. Then surgering $M$ along $D$ yields another disk $Z$. Since $M$ is incompressible, $Z$ is a compressing disk for $\partial \mathcal{T}$, contrary to $\partial$-irreducibility. Thus $M$ must be incompressible and $\partial$-irreducible. Therefore $M$ is not $\partial$-parallel, and hence $M$ is essential. By Proposition 9 there is a fundamental normal embedded Möbius strip $\mu$ in $\mathcal{T}$. By Lemma 10 and Proposition 11, $\mu$ constitutes a certificate verifiable in time polynomial in $\mathcal{T}$ that $\mathcal{T}$ admits an embedded Möbius strip.

The following is the main result of this subsection.

**Proposition 29.** Suppose $\mathcal{T}$ is compact and orientable.

Suppose further that $\mathcal{T}$ has no essential surfaces of nonnegative Euler characteristic apart from annuli.

If $\mathcal{T}$ admits an essential embedded annulus, there is a certificate verifiable in time polynomial in $\mathcal{T}$ of this fact.

We prove this at the conclusion of this subsection, using the following three results.

**Lemma 30.** Suppose a $\theta$-efficient triangulation $\mathcal{T}$ admits a non-separating annulus $A$. Then $A$ is essential.

This holds simply because inessential annuli are separating in irreducible, $\partial$-irreducible 3-manifolds.

We now show that if a non-separating annulus exists in the manifold, there is one of manageable size for our purposes.
Lemma 31. Suppose $T$ is compact, orientable, and 0-efficient. Suppose further that $T$ has no essential surfaces of nonnegative Euler characteristic apart from annuli. Finally, suppose $T$ admits a non-separating annulus.

Then $T$ admits a fundamental non-separating annulus.

Proof. Suppose $A$ is a non-separating annulus in $T$. Being essential by Lemma 30, $A$ must admit an isotopic normal representative, the isotopy coming from the normalization procedure of [15] and the fact that $T$ is irreducible and $\partial$-irreducible by assumption. Suppose that $A = X + Y$ for nontrivial normal surfaces $X, Y$, such that $X \cap Y$ has a minimal number of components. By a standard trick (see for example [23, Lem. 3.3.30]), we may assume $X$ and $Y$ are both connected. Let $[\cdot]$ denote the homology class in $H_2(T, \partial T; \mathbb{Z}/2\mathbb{Z})$. Then $[A] = [X + Y] = [X] + [Y]$, since Haken sum respects $\mathbb{Z}/2\mathbb{Z}$ homology. Since $A$ is nonseparating, $[A] \neq 0$. Therefore, without loss of generality, $[X] \neq 0$.

Since $[X] \neq 0$ and $T$ is orientable, $X$ is nonseparating. Since $T$ is 0-efficient, $\chi(X) = \chi(Y) = 0$. Suppose $X$ were not an essential annulus. Then a minimal genus representative of $[X]$ would be a nonseparating surface of nonnegative Euler characteristic different from an annulus, contrary to assumption. So $X$ is an essential annulus. Finally, since $\text{wt}(A) = \text{wt}(X) + \text{wt}(Y)$ and $\text{wt}(Y) > 0$ by nontriviality, $\text{wt}(X) < \text{wt}(A)$. The result follows by descent on weight.

The following proposition handles one of the final cases we need to deal with, an essential separating annulus.

Proposition 32. Suppose an orientable, irreducible, $\partial$-irreducible 3-manifold $T$ is obtained by identifying two solid tori along two disjoint annuli in their boundaries, and has one boundary component, a torus. Let $A$ be the annulus in $T$ gotten by identifying these annuli.

Then $T$ is Seifert fibered over the disk with two exceptional fibers, and $A$ is an essential annulus fibered by regular fibers.

Proof. Call the annuli of the solid tori $\alpha$ and $\beta$.

Suppose first that $\alpha$ and $\beta$ are $\pi_1$-injective in their respective components. Then the $S^1 \times D^2$ components admit Seifert fiberings such that $\alpha$ and $\beta$ are fibered by regular fibers. If either $\alpha$ or $\beta$ is longitudinal in its component, then $T$ would be $S^1 \times D^2$, and hence be $\partial$-reducible, contrary to assumption. Therefore, neither $\alpha$ nor $\beta$ is longitudinal. Thus, both the Seifert fiberings have exceptional fibers. Therefore, $T$ is Seifert fibered over a disk with two exceptional fibers, and $A$ is an essential annulus fibered by regular fibers.

Thus to conclude the proof it will suffice to assume not both $\alpha$ and $\beta$ are $\pi_1$-injective in their components, and derive a contradiction. As before, if but one of them were $\pi_1$-injective, then $T$ would have a compressible boundary component, contrary to $\partial$-irreducibility. Thus, suppose both $\alpha$ and $\beta$ are not $\pi_1$-injective in their respective components. If either were meridional, then $T$ would admit a non-separating sphere, contrary to irreducibility. Thus we may assume both $\alpha$ and $\beta$ are trivial. But in this case, $T$ would have two boundary components.
We may now conclude this subsection with a proof of its main result.

Prop. 29. Suppose $T$ has no essential surfaces of nonnegative Euler characteristic, except for essential annuli. By Theorems 21 and 22 there is a certificate $c_I$ that $T$ is a compact irreducible $\partial$-irreducible 3-manifold verifiable in time polynomial in $T$. If $T$ admits a nonseparating annulus, then by Lemma 31, $T$ admits a fundamental such annulus $A$. By Proposition 13, one may construct a triangulation $T'$ of $T - A$ from $A$ and $T$ in time polynomial in $T$ and $\log |A \cap T(1)|$. By Proposition 13 and Lemma 30, since $T'$ is connected, $c_I$ constitutes a certificate that $A$ is essential. Thus, $(A, c_I)$ together constitute a certificate that $T$ admits an essential annulus. Since $A$ and $c_I$ have size polynomial in $T$, this certificate has size polynomial in $T$.

Otherwise, $T$ admits an essential separating annulus $A$. Since $A$ is separating, $\partial A \subset T$ for some boundary torus $T$ of $T$. A regular neighborhood of $A \cup T$ in $T$ has two torus boundary components $T', T''$. Since $T$ has no essential tori, $T', T''$ are compressible. They must compress away from $T$ to spheres $S, S'$. Since $T$ is irreducible, these spheres must bound balls away from $T$. Thus in fact $T', T''$ bound solid tori away from $T$. Hence $A$ separates $T$ into two solid tori. Since $A$ is essential in $T$, the core of $A$ is incompressible in each solid torus. Hence this core induces Seifert fiberings in these solid tori. Therefore $T$ is Seifert-fibered over a disk with two exceptional fibers, with $A$ being a vertical annulus. If $T$ admits a horizontal essential annulus, then $T$ is either $T^2 \times I$ or $K^2 \times I$; since $T$ has but one boundary component, $T$ must be $K^2 \times I$. But we assumed $T$ admitted no Klein bottle, a contradiction. Thus essential annuli in $T$ are vertical. By Proposition 9 $T$ admits a fundamental essential annulus $A$, and by the above argument, $A$ is vertical. Thus $T - A$ is two solid tori, and $T$ fits the conditions of Proposition 32. Now, by Proposition 13 we may triangulate $T - A$ by $T'$ given $A$ and $T$ in time polynomial in $T$ and $\log |A \cap T(1)|$, and by Theorem 3, we may construct a certificate $c_I$ that $T'$ is two solid tori, verifiable in time polynomial in $T'$, and hence polynomial in $T$. Thus, $c_I$ and $c_I$ together constitute a proof that $A$ is essential, by Proposition 32. So $(A, c_I, c_I)$ constitutes a certificate that $T$ admits an essential annulus. Since $A$ and $c_I$ have size polynomial in $T$, and since $c_I$ has size polynomial in $T'$, and hence polynomial in $T$, this certificate has size polynomial in $T$.

3.7 Non-hyperbolicity

We end this section on certificates with the main theorem stated in the introduction, following the outline of Proposition 9.

Thm. 1. Suppose $T$ is a compact orientable triangulation and $\partial T$ is a nonempty union of tori, and suppose $T$ is not hyperbolic. Then by Theorem 5 $T$ admits an essential surface of nonnegative Euler characteristic. If $T$ admits an embedded projective plane, then by Proposition 9 it admits a fundamental normal such surface $\Sigma$. $\Sigma$ itself constitutes a proof against hy-
perbolicity, verifiable as an embedded projective plane in time polynomial in $T$ by the bounds of Lemma 10 and the algorithm of Proposition 11.

Otherwise, if $T$ admits an essential sphere, then by Proposition 9 since it has no embedded projective plane, it admits a fundamental normal essential sphere $\Sigma$. If $\Sigma$ is non-separating, then $\Sigma$ on its own constitutes a proof against hyperbolicity, verifiable in time polynomial in $T$ by the bounds of Lemma 10, the algorithm of Proposition 11, and the exterior algorithm of Proposition 13, since one may determine whether or not a triangulation (in this case, the exterior of $\Sigma$) is connected in time polynomial in the triangulation. Otherwise, the exterior $T' = T - \Sigma$ has two components $L'$ and $R'$; cap them off with balls to get the connect-summands $L$ and $R$ of $T$. By assumption $S^3$ recognition is in coNP, so there are certificates $c_L$ and $c_R$ verifiable in time polynomial in $L$ and $R$, and hence in $T$, that $L$ and $R$ are not $S^3$. Thus $(\Sigma, c_L, c_R)$ constitutes a certificate verifiable in time polynomial in $T$ that $T$ is reducible, and hence is not hyperbolic.

Otherwise, if $T$ admits a compressing disk, then by irreducibility, $T$ must be a solid torus. There is a certificate $c_d$ that $T$ is a solid torus verifiable in time polynomial in $T$ by Theorem 3 of [16].

Otherwise, if $T$ admits an essential Klein bottle or torus, then by Corollary 25 there is a certificate $c_{ess}$ of this fact verifiable in time polynomial in $T$.

Otherwise, if $T$ admits an essential Möbius strip, then by Proposition 28 there is a certificate $c_m$ of this fact verifiable in time polynomial in $T$.

Otherwise, and finally, if $T$ admits an essential annulus, then by Proposition 29 either there is a certificate $c_a$ of this fact verifiable in time polynomial in $T$, or there is a certificate $c_a$ verifiable in time polynomial in $T$ that $T$ splits along an annulus into two solid tori.

In all of the above cases, the given certificates show that $T$ is not hyperbolic.

If $T$ has none of these surfaces, then since $T$ is Haken, having nonempty torus boundary, by a well-known result of Thurston (Theorem 5 $T$ is hyperbolic contrary to assumption.

\[ \square \square \]

### 4 Discussion

One initial remark is that in practice, one would want to use vertex-normal surfaces instead of fundamental normal surfaces. Reproving the above results for vertex-normal surfaces would be a useful next task to do.

In the course of showing that $S^3$ recognition lies in coNP modulo the Generalized Riemann Hypothesis [31, Theorem 11.2], a good bit of the proof is allocated to constructing irreducible $SL(2, \mathbb{C})$ representations of toroidal manifold groups. Theorem 4 removes the need for splicing, and hence reduces one to the case of closed, irreducible, atoroidal 3-manifolds—that is, by Perelman’s resolution to Thurston’s Geometrization Conjecture, it reduces one to geometric 3-manifolds. We can further assume that the manifold is small, i.e. it does not
contain an incompressible surface of positive genus. Otherwise, we can use an incompressible surface which is given by a fundamental normal surface, together with Theorem 22 as a certificate of incompressibility, that the manifold is not $S^3$. Thus, if the following conjecture is true, then $S^3$ recognition is in fact in coNP, and the results of this paper are unconditionally true.

**Conjecture 2.** If $T$ triangulates a small geometric integral homology sphere, and $T$ is not $S^3$, then there is a proof that $T$ is not $S^3$ of length polynomial in $T$. That is, among small geometric integral homology spheres, $S^3$ recognition is coNP.

As mentioned above, Zentner’s work specifically [31, Theorem 11.2] combines with Kuperberg’s work to give a proof of this conjecture, assuming the Generalized Riemann Hypothesis. To remove this assumption, it seems a promising line of inquiry to approach this first by considering small Seifert spaces, for the hyperbolic integral homology spheres will likely prove much more difficult to verify.

We will conclude with a discussion of the affirmative problem. As mentioned in the introduction, a 3-manifold $M$ is said to be hyperbolic if $M \cong \mathbb{H}^3/\Gamma$, such that $\text{vol}(\mathbb{H}^3/\Gamma) < \infty$ and $\Gamma$ is a subgroup of the isometry group acting properly discontinuously. Now, an ideal triangulation $T$ of $M$ admits a *strict angle structure* if it determines a map from $\mathbb{R}^3n \to \mathbb{R}^n$ that corresponds each pair of opposite edges in a tetrahedron are assigned a positive number, the dihedral angle, such that all (six) dihedral angles in a tetrahedron sum to $2\pi$ and all dihedral angles in an edge class of $T$ sum to $2\pi$. Thus, an angle structure is a solution to a system of linear equations that lies in the positive cone of the solution space. Work of Casson and Rivin [24] (see also [9]) shows that the existence of such a structure rules out each of the obstructions to non-hyperbolicity, so that a strict angle structure on $T$ implies the hyperbolicity of $M$. We point out that if a triangulation supports an angle structure, an argument analogous to Lemma 10 shows there is a fundamental solution to the angle structure equations that can be verified in polynomial time. The relevant question is then “Which triangulations support angle structures?” To determine how far an input triangulation $T$ is from a triangulation that supports an angle structure, we ask the following question:

**Question 33.** Is there a polynomial $P$ such that for any ideal triangulation $T$ of a cusped hyperbolic 3-manifold, there is an ideal triangulation $T'$ supporting a strict angle structure that is connected to $T$ by at most $P(|T|)$ 2-3 and 3-2 moves?

An affirmative answer to that question together with an affirmative answer to Conjecture 2 would provide an affirmative answer to the following:

**Question 34.** Is the Hyperbolicity problem for cusped manifolds in $NP \cap coNP$?
Appendix

**Prop. 13.** Let $B$ be the parallelity bundle for the handle structure on $M' = \text{cl}(T \setminus S)$ inherited from $T$ as defined above. Let $X$ be $\text{cl}(M' - B)$. Let $V$ be $B \cap X$. Then $V$ is the common frontier of $B$ and $X$ in $M'$. Now, $X$ is the union of the non-parallelity 0-handles of the (inverted) handle structure. The non-parallelity 0-handles have two isomorphism types: a truncated octahedron, and a hexagonal prism. $V$ is the union of the vertical 4-sided 2-cells of these non-parallelity 0-handles (i.e. those 4-sided 2-cells not lying on $S$). There are at least $4 \cdot t$ and at most $6 \cdot t$ such 2-cells in $X$, the maximum occurring when $S$ has a normal quad in every tetrahedron. Therefore, $V$ can be triangulated in time linear in $t$. Moreover $X$ can be triangulated in time linear in $t$ agreeing with the triangulation on $V$.

It remains to triangulate $B$ in time linear in $t$ and $|\chi(S)|$ in a way agreeing with $V$. Note that $V$ has a number of components linear in $t$. Since $V$ is the frontier of $B$ in $M'$, $B$ has at most as many components as $V$. Suppose $B$ is any component of $B$. The algorithm of Theorem 12 yields for $B$ the given data from items (i)–(iii). The data from (iii) indicates how to identify the frontier of $B$ in $M'$ with a component of $V$. So it will suffice to show $B$ can be triangulated in polynomial time.

The data from (i) and (ii) identify the homeomorphism type of $B$ in polynomial time. Now, $B$ is an I-bundle over a base surface $\Sigma_B$. The data from (i) and (ii) identifies the homeomorphism type of $\Sigma_B$ since $T$ is orientable. Now $\Sigma_B$ is doubly-covered by a unique subsurface $Q$ of $S$, such that $B$ is the mapping cylinder of the double-cover. Then $\chi(Q) = 2 \cdot \chi(\Sigma_B)$. Let $\Theta$ be formed from $Q$ by filling in all boundary components bounding discs in $S$ disjoint from $Q$. We have $\chi(\Theta) \geq \chi(S)$ and $\chi(\Theta) = \chi(Q) + d$ where $d$ is the number of discs filled in. The number of boundary components of $Q$ is at most twice $|\pi_0(V)|$, which is linear in $t$. So $d$ has an upper bound linear in $t$. Thus $\chi(Q) = \chi(\Theta) - d \geq \chi(S) - d$ has a lower bound linear in $t$ and $\chi(S)$. Hence $\chi(\Sigma_B)$ has such a lower bound. Consequently, $|\chi(\Sigma_B)|$ has an upper bound linear in $t$ and $|\chi(S)|$. Since $\Sigma_B$ is connected, this means $\Sigma_B$ can be triangulated with a number of triangles linear in $t$ and $|\chi(S)|$. Therefore $B$ can be triangulated with a number of tetrahedra linear in $t$ and $|\chi(S)|$, a polynomial as desired.
