The dc Josephson effect is investigated in a single-walled metallic carbon nanotube connected to two superconducting leads. In particular, by using the Luttinger liquid theory, we analyze the effects of the electron-electron interaction on the supercurrent. We find that in the long junction limit the strong electronic correlations of the nanotube, together with its peculiar band structure, induce oscillations in the critical current as a function of the junction length and/or the nanotube electron filling. These oscillations represent a signature of the Luttinger liquid physics of the nanotube, for they are absent if the interaction is vanishing. We show that this effect can be exploited to reverse the sign of the supercurrent, realizing a tunable π-junction.

I. INTRODUCTION

Since the discovery by Iijima in 1991, carbon nanotubes have attracted much interest in the community of Mesoscopic Physics. Due to their peculiar electronic and mechanical properties, they are regarded as optimal candidates for nanotechnological implementations, and have been successfully applied to the realization of quantum transistors, electron waveguides, interferometric devices as well as nanoelectromechanical systems. Recent experiments have spurred the interest in superconducting properties of these materials: it has been observed indeed that proximity-induced superconductivity can arise in nanotube bundles contacted to superconductors (S); in ropes, intrinsic superconductivity has also been measured and explained in terms of combination of electron coupling to the breathing phonon modes and intertube Cooper-pair tunneling. Individual multiwall nanotubes have recently been utilized in the fabrication of superconductor-nanotube-superconductor hybrid structures, allowing to reveal the dynamics of multiple Andreev reflections and to realize a controllable supercurrent transistor. By contrast, the investigation of superconducting properties of single-walled nanotubes in hybrid structures has been only partly explored so far.

Metallc Single-walled carbon nanotubes (SWNT) are known to behave as one-dimensional (1D) conductors with four conduction channels exhibiting ballistic transport up to several μm. Differently from other 1D metals, SWNT preserve their conduction properties even at very low temperature, since the cylindrical lattice geometry prevents the arising of Peierls distortion. They thus offer promising features for interconnecting components of nanodevices. Due to their 1D character, electronic correlations have dramatic effects on the behavior of SWNT: experimental evidences of a power-law behavior for the conductance as a function of temperature indicate that SWNT exhibit a Luttinger liquid (LL) behavior, and that their elementary excitations are not fermionic quasi-particles like in normal 3D metals. It is thus expected that, when a SWNT is contacted to S leads at equilibrium, electronic correlations might significantly modify the behavior of the supercurrent with respect to junctions realized with a normal metal. This issue has been addressed in the literature and it has been shown that the effect of interaction is particularly enhanced when the coupling between the LL and the S leads is realized through tunnel junctions. However, most of these investigations focused on the case of a two-channel (i.e. one spinful mode) LL, and cannot be straightforwardly applied to the case of a four-channel SWNT. In this paper we discuss this problem investigating the dc Josephson effect in a S-I-SWNT-I-S junction, and show that new features arise due to the peculiar band structure of SWNT. The paper is organized as follows: in Sec. II we briefly review the model used to describe SWNT, accounting for electron-electron interaction within the Luttinger Liquid theory. In Sec. III we present our results about the Josephson current. We find that the interaction yields a twofold effect on the critical current $j_c$: on the one hand it modifies the scaling law of $j_c$ as a function of the junction length $d$; on the other hand, it introduces oscillations of $j_c$ as a function of either the electron filling or the junction length $d$. The latter oscillations are absent for a non-interacting system, and therefore represent a signature of Luttinger liquid behavior on the supercurrent. Finally, in Sec. IV we discuss the results and propose possible implementations to observe this effect.
where $d$ denotes the band crossing points, whereas $q_F$ accounts for the deviation from $k_F$, i.e. the electron filling of the SWNT.

II. MODELING THE SYSTEM

The set-up of the system is depicted in Fig.1, a metallic SWNT is coupled through tunnel contacts to two superconducting leads to realize a S-I-SWNT-I-S junction. For simplicity, we limit here our treatment to the case of armchair nanotubes; we also assume that the S leads have the same gap $|\Delta|$: the two superconducting order parameters thus read $\Delta_{1,2} = |\Delta|e^{i\chi_{1,2}}$, where $\chi_i$ is the superconducting phase of the $i$-th lead. We are interested in the dependence of the critical current on the junction length $d$; we thus analyze the regime

$$\lambda_c, \xi \ll d \ll L$$

where $\lambda_c$ represents the width of the contacts, $\xi$ the coherence length of the S electrodes, $d$ the electrode distance, and $L$ the length of the nanotube. The regime (1) is quite realistic in view of customary fabrication of $\mu$m long ballistic nanotubes\textsuperscript{12}, and the recent realization of superconducting tips for Scanning Tunneling Microscope (STM)\textsuperscript{22,23,24} or of 10-20 nm short superconducting finger leads. In order to simplify the mathematical treatment without altering the essential physical features of the regime (1), we shall henceforth assume that the tunnel contacts are point-like, the coherence length $\xi$ is vanishing, and the length of the nanotube is infinite, $L \to \infty$.

In a metallic nanotube the lowest band consists of four electron branches located around two Fermi points $\alpha k_F$, with $\alpha = \pm 1$; the energy separation to the second band is of the order of eV, so that the latter can be in practice neglected up to a broad range of thermal excitations. Within this energy scale, the energy dispersion of the lower band is linear under quite good approximation, as shown in Fig.2 SWNT can thus be regarded as four-channel 1D metals. As discussed in the introduction, their 1D character implies that a careful treatment of the electron-electron interaction is needed. It is indeed well known that transport properties of SWNT cannot be explained in terms of the customary Fermi liquid theory, since their elementary excitations are bosonic plasmon modes, rather than fermionic quasi-particles. A model for SWNT based on the Luttinger liquid theory has been formulated a decade ago\textsuperscript{25,26}, and applied in a number of problems\textsuperscript{27-30,31,32-33}. Here we briefly remind the main aspects that are relevant to our discussion: A SWNT can be ideally obtained by wrapping into a cylinder shape a graphene sheet, whose honeycomb carbon lattice consists of two sublattices $p = \pm$. A nearest-neighbor tight-binding calculation of the $\pi$-electrons in the graphite, together with appropriate wrapping boundary conditions, leads to express the electron field in the nanotube as

$$\Psi(\mathbf{x}) = \sum_{\alpha = \pm, r = R/L} \sum_{\nu = \pm} U_{\nu r} e^{i(\alpha k_F + q_F)\mathbf{x}} \psi_{\alpha \nu}(\mathbf{x})$$

where $\sigma = \uparrow, \downarrow$ denotes the spin component and $x$ the longitudinal coordinate in the nanotube. In Eq. (2), $U_{\nu r}$ are the entries of the matrix

$$U = -\frac{e^{-i\pi/4}}{\sqrt{2}} \begin{pmatrix} 1 & 1 \\ i & -i \end{pmatrix}$$

describing the unitary transformation from the sublattice electron fields into the right(left) moving fields description. The exponential terms in Eq. (2) represent the fast oscillating contribution to the electron wave function, where the wave vector $q_F$ is related to the electron filling exceeding the Fermi points $\pm k_F$, as illustrated in Fig.2 Finally the field $\psi_{\alpha \nu}(\mathbf{x})$ varies slowly over the scale of Fermi wavelength.

In order to account for the electron-electron interaction, it is useful to represent the electron fields $\psi_{\alpha \nu}$ through the bosonization identity

$$\psi_{\alpha \nu}(\mathbf{x}) = \frac{\eta_{\alpha \nu}}{\sqrt{2\pi a}} \exp\{i\varphi_{\alpha \nu}(\mathbf{x})\}$$

where $\varphi_{\alpha \nu}(\mathbf{x})$ is the plasmonic field describing the long wavelength fluctuations. The operators $\eta_{\alpha \nu}$ are Klein factors obeying a Clifford algebra and ensuring the correct anticommutation between different fermionic species. Finally $a$ is a cut-off length regularizing the theory, and is of the order of the lattice spacing. The effective hamiltonian for the SWNT reads

$$H_{\text{SWNT}} = \sum_{j\delta} v_F \int_{-\infty}^{+\infty} dx \left[ \frac{1}{2} \left( \partial_x \phi_{j\delta} \right)^2 + \frac{\left( \partial_x \theta_{j\delta} \right)^2}{K_{j\delta}^2} \right]$$

with $v_F \approx 8 \cdot 10^6$ ms\textsuperscript{-1}. Here $\theta_{j\delta}(x)$ are four independent bosonic fields, with $j$ labeling charge($c$) and spin($s$) degrees of freedom, and $\delta = \pm$ denoting two independent linear combinations of the $\alpha = \pm$ branches. The

![Figure 2: The electron band dispersion relation of a SWNT originates from the two-sublattices honeycomb carbon structure, and is characterized by four Fermi points. The latter can be identified through two Fermi momenta: $k_F$ denotes the band crossing points, whereas $q_F$ accounts for the deviation from $k_F$, i.e. the electron filling of the SWNT.](#)
fields \( \phi_{j\delta}(x) \) are related to \( \theta_{j\delta}(x) \) by the duality relation 
\[
[\theta_{j\delta}(x), \phi_{j\delta}(y)] = i\delta(x - y),
\]
and \( K_{j\delta} \) are interaction parameters, with \( K_{j\delta} < 1 \) for repulsive
(\( K_{j\delta} > 1 \)) for attractive interaction and \( K_{j\delta} = 1 \) for
vanishing interaction. It can be shown\footnote{Footnote text.} that the mode \((j = e, \delta = +)\) is
strongly interacting \((K \doteq 0.3)\), while the three other modes are neutral \( K_{j\delta} = 1 \). The fields \( \varphi_{\alpha\sigma} \)
appearing in the bosonization identity \ref{bosonization_identity} are linear combinations of
the decoupled modes
\[
\varphi_{\alpha\sigma} = \frac{\sqrt{\pi}}{2} \left\{ \phi_{c+} + r\theta_{c+} + \alpha\phi_{c-} + r\alpha\theta_{c-} + \sigma\phi_{s+} + r\sigma\theta_{s+} + \alpha\sigma\phi_{s-} + r\alpha\sigma\theta_{s-} \right\}
\]  
(6)

The Hamiltonian modeling the S-I-SWNT-I-S junction thus reads
\[
\mathcal{H} = \mathcal{H}_{\text{SWNT}} + \mathcal{H}_{\text{SC}_1} + \mathcal{H}_{\text{SC}_2} + \mathcal{H}_T
\]  
(7)
where \( \mathcal{H}_{\text{SWNT}} \) is given by \ref{swnt_hamiltonian}, \( \mathcal{H}_{\text{SC}_1}, \mathcal{H}_{\text{SC}_2} \) are the usual BCS
hamiltonians for the electrodes, and \( \mathcal{H}_T \) describes the nanotube-electrodes electron
tunneling. Denoting by \( x_i \) the nanotube coordinate of the injection point to the \( i \)-th
electrode, one can write
\[
\mathcal{H}_T = \sum_{i=1,2} \sum_{\sigma = \uparrow, \downarrow} T_i \left( \bar{\Xi}^\dagger_i(x_i)\psi^\dagger_{\sigma}(x_i) + \psi^\dagger_{\sigma}(x_i)\bar{\Xi}^\dagger_i(x_i) \right)
\]  
(8)
where \( \bar{\Xi}^\dagger_i \) is the electron field operator in the \( i \)-th lead, and \( T_{1,2} \) are
tunneling amplitudes. The Josephson current is computed perturbatively in the tunneling
amplitudes.

### III. DC JOSEPHSON CURRENT

Denoting by \( F \) the free energy of the S-I-SWNT-I-S junction, and by \( \chi = \chi_2 - \chi_1 \) the phase difference between
the two superconductors, the dc Josephson current is obtained as
\[
I_J = \frac{2e}{\hbar} \frac{\partial F}{\partial \chi}.
\]  
(9)
Evaluating \( I_J \) to the fourth order in the tunneling amplitudes \( T_i \), one obtains (up to \( \chi \)-independent terms)
\[
F = -2 \left( \frac{T_1 T_2}{\beta} \right)^2 \Re \prod_{i=1}^4 \int_0^\beta d\tau_i
\times \mathcal{F}_i(\tau_1 - \tau_2) \mathcal{G}(\tau_1, \tau_2, \tau_3, \tau_4; d) \mathcal{F}_2(\tau_3 - \tau_4) \bigg] .
\]  
(10)
In Eq. (10) \( \beta \) denotes the inverse temperature and
\[
\mathcal{F}_i(\tau - \tau') = \left\langle T \left\{ \Sigma_{\uparrow i}^\dagger(x, \tau) \Sigma_{\uparrow i}^\dagger(x, \tau') \right\} \right\rangle = \frac{\pi N(0)}{\beta} e^{-i\chi} \sum_{n \in \mathbb{Z}} e^{-i\omega_n(\tau - \tau')} \frac{|\Delta|}{\sqrt{\omega_n^2 + |\Delta|^2}}
\]  
(11)
the anomalous BCS T-ordered correlator in the \( i \)-th S
lead, with a density of states of the normal state \( N(0) \)
at the Fermi energy, and Matsubara frequencies \( \omega_n = (2n + 1)\pi/\beta \). Finally
\[
\mathcal{G}(\tau_1, \tau_2, \tau_3, \tau_4; d) = \langle \langle \left\{ \Psi^\dagger_{\uparrow i}(0, \tau_1) \Psi^\dagger_{\downarrow i}(0, \tau_2) \Psi^\dagger_{\downarrow i}(d, \tau_3) \Psi^\dagger_{\uparrow i}(d, \tau_4) \right\} \rangle \rangle
\]  
(12)
is the two-electron T-ordered correlator in the SWNT. Under the condition \ref{condition}, one has \( \Delta \gg \hbar v_F / d \), implying
that the lead-nanotube tunneling time is much shorter than the traversal time \( \hbar v_F / d \) along the junction. Eq. (11)
is then well approximated by a \( \delta(\tau - \tau') \), and tunneling effectively involves electron pairs. In this regime the
Josephson current can be written as
\[
I_J = I_0(\chi) j_c(d; T)
\]  
(13)
Here the first term \( I_0 = (2e/\hbar)(\hbar v_F / d) T \sin \chi \) accounts for the dependence on the superconducting phase difference \( \chi \), and corresponds to the Josephson current of a
long ballistic junction with bare transmission coefficient \( T = (4/\pi)|T_1 T_2|^2 \pi^2 N(0) / \hbar v_F^2 \) at zero temperature. The second term represents the (dimensionless)
critical current and encodes the details of the junction: it depends on the length, on the temperature, and on the
interaction effects, as we shall see below. Explicitly, it reads
\[
j_c(d; T) = \frac{1}{2\pi} \left( \frac{d}{a} \right)^2 \int_{-1/\theta}^{1/\theta} d\xi (1 - \Theta(\xi)) \times
\sum_{r = \pm, \alpha \neq \alpha'} e^{i(\alpha - \alpha') k_F d} \frac{C_{r, \alpha \alpha'}(k_F d, \xi) + e^{2i\pi F d} C_{r, \alpha \alpha'}^P(k_F d, \xi)}{2}
\]  
(14)
with \( \Theta = k_B T d / \hbar v_F \). Two types of processes, denoted by \( P \) and \( A \), contribute to \( j_c \): the former (latter) describes
tunneling of Cooper pairs formed by electrons with parallel (antiparallel) momenta. The related pair operators
\[
O^{P/A}_{r, \alpha \alpha'}(x, \tau) = \bar{\psi}_{\alpha r}(x, \tau) \psi_{\alpha' r}(x, \tau)
\]  
(15)
yield the two correlators
\[
C^{P/A}_{r, \alpha \alpha'}(k_F d, \xi_3 - \xi_1) = \langle \langle T \left\{ O^{P/A}_{r, \alpha \alpha'}(0, d, \xi_1) O^{P/A}_{r, \alpha \alpha'}(d, \hbar v_F \xi_3) \right\} \rangle \rangle
\]  
(16)
appearing in Eq. (14). Importantly, these two terms correspond to different dependences on the momenta defining
the four Fermi points of the SWNT: while \( A \) processes only involve \( k_F \), \( P \) processes are also characterized
by the electron filling momentum \( q_F \), as can be seen from the phase factors multiplying \( C^{P/A}_{r, \alpha \alpha'} \). Since typically
\( q_F \ll k_F \), two periods are expected to arise in the dependence of the Josephson current on the junction length \( d \). However, this is not necessarily the case. In the first instance, indeed, the dependence on \( k_F \) amounts to a prefactor \( 1 + \cos(2kFd) \), and is extremely difficult to be observed in a realistic system where the approximation of point-like contacts is not valid, for the period of these oscillations is usually smaller than the typical contact width \( \lambda_c \). Even in the regime (IV), the observed current is in fact an average \((\ldots)_{\lambda_c}\), over lengths \( d + x \), where \( x \) ranges over \( \lambda_c \). This averaging effectively yields

\[
\langle 1 + \cos(2kFd) \rangle_{\lambda_c} = 1
\]

(17)

so that the dependence on \( k_F \) disappears. The results for the current presented henceforth are thus meant upon performing this averaging procedure.

Secondly, the electron-electron interaction strongly affects the behavior of the correlators \( C_{\rho\alpha\alpha'}^{P/A} \). Although the full expression for the latter is quite lengthy (see the appendix for details), important insights can be gained from the analysis of the scaling dimensions of the two operators; one obtains that for \( k_F d \gg 1 \)

\[
|C_{\rho\alpha\alpha'}^{P/A}(k_F d, \xi)| \sim \left| \frac{a}{d} \right|^{2\delta_{P/A}}
\]

(18)

with \( \delta_P = (K + 1/K + 2)/4 \) and \( \delta_A = (1/K + 3)/4 \). While for vanishing interaction \((K = 1)\) the scaling dimensions of the two processes coincide, the electron interaction modifies the power laws of these two processes in a different way: the contribution of \( A \) processes decays faster than the one of \( P \) processes \((\delta_P < \delta_A)\). Remarkably, this does not imply that for a sufficiently long junction the Josephson current is mainly due to \( P \) processes. Indeed, an electron pair traveling along the junction also acquires a phase, which results into oscillating factors in the correlators. Since the Josephson current depends on the integral over the imaginary time variable \( \xi \), not only the decay rate but also the phase of \( C_{\rho\alpha\alpha'}^{P/A} \) matters. Since the dynamics of the electrons is coupled by the interaction, these phase factor are also affected by the value of \( K \).

In the case that electron interaction is neglected \((K = 1)\), the effect of alternating phases is so strong that the total contribution of \( P \) processes vanishes. Indeed, when integrating over all possible pair momenta, the phase acquired by the electron pair traveling along the junction oscillates, yielding a cancellation of the different contributions, except for those processes in which the total pair momentum is vanishing. While this condition can be fulfilled by \( A \) processes, simple phase-space considerations show that the total contribution of \( P \) processes is suppressed. As a consequence, the Josephson current through a SWNT is predicted to be independent of the filling momentum \( q_F \), and one obtains

\[
\bar{j}_c = \frac{2\pi\Theta}{\sinh(2\pi\Theta)}
\]

(19)

At zero temperature, \( j_c = 1 \), and the Josephson current scales as \( 1/d \) due to the \( J_0 \) term (see Eq. (18)), whereas at finite temperature it is exponentially suppressed.

In contrast, when electron-electron interaction is taken into account \((K \approx 0.3)\), the dynamics of the two electrons forming any pair is coupled, and the mechanism leading to the cancellation occurring in the non-interacting case is not valid. Electronic correlations both affect the contribution of \( A \) processes and make an oscillating contribution in \( 2qFd \) arise from \( P \) processes. These oscillations are characterized by a much longer period than the one discussed above, and may become observable if \( q_F \lambda_c \ll 1 \), a condition which is definitely realistic: The value of the filling factor \( q_F/k_F \) can indeed be adjusted by an external gate bias, and the recent developments in contact technology allow to realize extremely thin contacts, such as finger-shaped electrodes of about 10nm, or superconducting STM tips. Here we show that in this case the Josephson current exhibits interesting novel features.

Fig. 3 displays the dimensionless Josephson critical current \( j_c \), Eq. (14), as a function of the junction length \( d \) for a SWNT with interaction strength \( K = 0.3 \) at zero temperature. We recall that the approximation of
non-interacting electrons would predict a constant value for $j_c$. In contrast, in a SWNT the strong electron interaction leads $j_c$ to decay with an oscillatory behavior as a function of $d$. While the power law decay has been predicted also for usual two-channel LL, the oscillatory behavior is purely due to the four channel band structure of nanotube. Importantly, this implies that the sign of the Josephson current depends on the length of the junction, and that SWNT can be used to realize a $\pi$-state. We emphasize that this effect originates from $P$ processes; the contribution to $j_c$ due to the $A$ processes, described by the dashed curve in Fig. 3 is indeed monotonous and always positive.

Fig. 4 shows $j_c$ for a S-I-SWNT-I-S junction with length $d = 6 \cdot 10^3 k_F^{-1} \sim 360$ nm: the Josephson current oscillates with a period $\pi/k_Fd$ as a function of the filling factor $q_F/k_F$, around a value (dashed line) which represents the contribution of $A$ processes, independent of $q_F$. By tuning $q_F$ with a gate voltage, the switching from a 0 to a $\pi$-junction behavior can be induced.

Finally, Fig. 5 shows the behavior of $j_c$ as a function of the dimensionless temperature $\Theta = k_BT d/\hbar v_F$. As expected from Eq. (14), thermal fluctuations suppress the Josephson effect at a temperature of the order of $k_BT \sim \hbar v_F/d$ (for a 100 nm long junction this corresponds to $T = 60^\circ$K); the figure elucidates the crucial role played by the interaction in determining the relative magnitude of $P$ processes with respect to $A$ processes: while for a non-interacting wire ($K = 1$) the $P$ processes contribution vanishes, for a SWNT ($K \approx 0.3$) the latter dominate for a sufficiently long junction.

IV. CONCLUSIONS

In this paper we have investigated the dc Josephson effect in a S-I-SWNT-I-S junction. The effects of the electron-electron interaction on the critical current $j_c$ have been particularly analyzed by using the Luttinger Liquid theory. We have found that $j_c$ oscillates with a factor $2q_F d$, where $d$ is the junction length and $q_F$ the Fermi momentum characterizing the electron filling with respect to the band crossing point $k_F$. These oscillations are a signature of the peculiar band structure and of the strong electronic correlations present in SWNT. We emphasize that they would indeed not appear in non-interacting systems. Remarkably, this effect implies that ballistic SWNT can be used to realize tunable $\pi$-junctions, for the sign of the critical current can be controlled by varying either the filling factor or the junction length (see Figs. 3 and 4). The former can be tuned through an external gate voltage. The latter can be changed for instance by moving the superconducting tip of an STM along the nanotube. The typical value of $k_F$ is of the order of 20 nm$^{-1}$, so that the predicted oscillations should be observable in junctions with length $d \geq 100$nm operating at temperature of the order of some $\sim$K or below; the SWNT should have an electron filling momentum $q_F$ ranging from 0 up to a small fraction of $\lambda^{-1}_c$.

Fruitful discussions with F. Giazotto as well as financial support from HYSWITCH EU Project are greatly acknowledged.

Appendix A: $O_v^f$ Correlation Functions

In this appendix we provide the expressions for the $T$-ordered correlation functions appearing in the computation of the Josephson current Eq. (14). The correlation functions can be written as the product of their ground state value and a thermal fluctuations contribution, which equals 1 at zero temperature. Explicitly:

$$C^A_r(k_Fd, \xi) = |g^A_r(GS)(k_Fd, \xi) g^{A(TF)}_r(k_Fd, \xi)|^2$$

$$C^P_r(k_Fd, \xi) = |g^P_r(GS)(k_Fd, \xi) g^{P(TF)}_r(k_Fd, \xi)|^2$$

where:
Figure 5: (solid): The dimensionless critical current $j_c$ as a function of the reduced temperature $\Theta$ for a junction with length $d = 6 \cdot 10^3 k_F^{-1}$, realized with a SWNT with filling factor $q_F/k_F = 10^{-3} \pi/12$ and interaction parameter $K = 0.3$. (dashed): The contribution of $A$-processes to the critical current. Differently from the case of a non-interacting wire, in a SWNT the contribution due to tunnel of pairs with antiparallel momenta ($A$ processes) is dominated by the one originating from pairs with parallel momenta ($P$ processes).

\begin{align}
\mathcal{g}_r^{(GS)}(k_F d, \xi) &= \frac{\tilde{a}}{\tilde{a} + z_K^*} \left[ \frac{\tilde{a} + z_K^*}{\tilde{a} + z_1^*} \right]^3, \quad (A2)
\end{align}

with $z_K^* = k_F d (i \text{sign}(\xi) + |\xi|/K)$ and $\tilde{a} = k_F a$. The contribution due to thermal fluctuations reads

\begin{align}
\mathcal{g}_r^{(TF)}(k_F d, \xi) &= \left| \frac{K \pi \Theta z_K^*}{\sin(K \pi \Theta z_K^*)} \right|^{\delta_P} \left( \frac{K \pi \Theta z_K^*}{\sin(K \pi \Theta z_K^*)} \right)^{-\frac{1}{4}} \cdot \left( \frac{\pi \Theta z_1^*}{\sin(\pi \Theta z_1^*)} \right)^{\frac{1}{4}}, \quad (A4)
\end{align}

The cut-off $\tilde{a}$ renormalizes the bare tunneling amplitude $\mathcal{T}$ in different ways for $P$ and $A$ processes. In particular, one has $\mathcal{T} \to \mathcal{T}_i = \mathcal{T}(k_F a)^{2(A-1)}$, with $i = A, P$. Typically $\tilde{a} \lesssim 1$ (here we have chosen $\tilde{a} = 0.5$).
