In the cerebral cortex, local circuits consist of tens of thousands of neurons, each of which makes thousands of synaptic connections. Perhaps the biggest impediment to understanding these networks is that we have no wiring diagrams of their interconnections. Even if we had a partial or complete wiring diagram, however, understanding the network would also require information about each neuron’s function. Here we show that the relationship between structure and function can be studied in the cortex with a combination of in vivo physiology and network anatomy. We used two-photon calcium imaging to characterize a functional property—the preferred stimulus orientation—of a group of neurons in the mouse primary visual cortex. Large-scale electron microscopy of serial thin sections was then used to trace a portion of these neurons’ local network. Consistent with a prediction from recent physiological experiments, inhibitory interneurons received convergent anatomical input from nearby excitatory neurons with a broad range of preferred orientations, although weak biases could not be rejected.

Past studies of the synaptic connections in the cortex have focused on a few cells at a time, so that today we have only partial information about the structure of highly interconnected cortical networks. Until recently, anatomists relied on the sparse labelling of individual neurons to trace the extensive axonal and dendritic arbors of cortical neurons. Synaptic connectivity was originally inferred from the overlap of axonal and dendritic arbors1, an approach that remains fruitful today2,3. Combined physiological and anatomical studies of cortical slices in vitro have extended this analysis to include rules of pair-wise connectivity between different cell types and cortical layers4–6. It has been argued that the cortical network might be random beyond these simple statistical rules7, but recent studies suggest that there could be higher-order patterns of connections in cortical networks, such as mutually interconnected triplets of cells8, and subnetworks of neurons that are highly connected within a group, but not between groups9,10. Although these hypothesized patterns are based on in vitro physiological data, they have never been demonstrated anatomically, nor have they been related to information processing as measured from neural response properties in vivo.

Electron microscopy (EM) is an ideal tool for characterizing the highly interconnected structure of cortical networks. From visualizing quanta release by synaptic vesicles11 to generating a complete wiring diagram of a model organism12, it has provided definitive data for examining the relationship between structure and function in the nervous system. Electrophysiology combined with light microscopy and serial-section EM has allowed the inspection of structure–function relationships of single cells within neural circuits, such as the hippocampus13, retina14,15, thalamus16 and cortex17–20. A crucial difference from light microscopy is that serial-section EM can be used to follow the three-dimensional contours of neuronal membranes, so that any given axon or dendrite can be traced over hundreds of micrometres without selective, sparse staining of individual neurons. This feature of serial-section EM has been used to examine small volumes of cortical tissue, typically numbering in the thousands of cubic micrometres, in which portions of multiple dendrites and axons were reconstructed to examine synaptic relationships amongst them (refs 21, 22, compare ref. 23).

Here we exploited recent improvements in computer speed and storage capacity to perform serial-section EM of a volume that encompasses millions of cubic micrometres, sufficient to contain large portions of the dendritic and axonal arbors of more than 1,000 cells. With this data set, we could attempt a sampling—targeted to a subset of functionally imaged cells—of the dense interconnections found in a cortical network. In particular, we tested a somewhat controversial prediction from recent physiological work (refs 24–27, compare refs 28, 29): that inhibitory interneurons in the mouse primary visual cortex receive dense, convergent input from nearby excitatory (pyramidal) neurons with widely varying preferred stimulus orientations (Fig. 1a).

Functional imaging and large-scale EM

We used in vivo two-photon calcium imaging to determine the preferences for stimulus orientation of a cohort of cells in layer 2/3 of mouse primary visual cortex27,30. After loading cells with the fluorescent calcium indicator Oregon Green BAPTA-1 AM (OGB)31, we recorded neuronal activity as reflected by increases in intracellular calcium from a single plane of cells 186 μm beneath the brain surface. Black and white bars of varying orientations and directions were presented to the anaesthetized animal, and the cellular responses were used to generate a map of orientation preference (Fig. 1b and Supplementary Fig. 1; Methods). We concluded the in vivo experiment by collecting a stack of images from a volume surrounding the calcium-imaged plane (Fig. 1c; red, vessels; green, neurons). We then immediately perfused the animal and prepared the corresponding volume of visual cortex for serial-section transmission EM (TEM; Methods).

After finding the calcium-imaged region of cortex (Methods), we cut a series of 1,215 thin sections (40–45 nm), oriented radially, at right angles to the functionally imaged plane (Fig. 1b, c). Each section was wide enough (450 μm) to encompass the imaged plane, and tall enough (350 μm) to include cortical layers 1, 2/3 and upper 4 (Fig. 2a, b, Supplementary Movie 1). Although cortical axons can...
travel for millimetres, the proximal axonal collaterals of pyramidal cells arborize more locally7, such that a portion of their local connectivity could be sampled within the span of the EM volume. In line with previous work, we found that in order to reliably trace the finest neural processes and to identify chemical synapses (Fig. 2f, Supplementary Movie 2), we needed <50 nm section thickness and <5 nm lateral resolution32.

We built a custom TEM Camera Array (TEMCA) that used four high-speed CCD (charge-coupled device) cameras to efficiently acquire EM images of the required size and resolution (Supplementary Fig. 2; Methods). The TEMCA achieves an order of magnitude increase in throughput over most commercially available TEM imaging systems. This system enabled us to collect the thousands of individual images required to mosaic each of the serial sections in approximately 20 min (Fig. 2a), so that we could image the entire series over the course of several months.

The $3.2 \times 10^6$ camera images in our data set were converted into a seamless three-dimensional image volume by globally registering and aligning the EM volume after automated stitching of adjacent images into sections (Methods). The raw image data were approximately $36 \times 10^{12}$ bytes (36 terabytes, TB), with the final stitched and registered EM data set encompassing approximately ten million megapixels (10 TB), spanning $\sim 450 \times 350 \times 52$ μm and containing approximately 1,500 cell bodies (Fig. 2b).

We next re-located in the EM volume the cells whose function had been characterized by in vivo calcium imaging. The large extent of the EM data set permitted registration of the fluorescently labelled vessels or astrocytes; green, OGB-loaded somata or yellow fluorescent protein (YFP)-labelled apical dendrites) separated to expose the functionally imaged plane. Scale bars, 100 μm.

**RESEARCH ARTICLE**

**EM circuit reconstruction and the resultant network graph**

To analyse the circuit’s anatomical connectivity, we manually traced a wire-frame model of the dendritic and axonal arbors of each functionally characterized neuron, and noted the location of each synapse along the axons. For each synapse, we then reconstructed the postsynaptic dendrite centripetally until we reached either the cell body or the boundary of the EM volume (Methods). In this directed manner, we were able to identify all of the postsynaptic targets that could be found in the EM-imaged volume and to determine when multiple axons converged onto a common postsynaptic target, without unnecessary tracing of the target cells’ dendrites (Fig. 4, Supplementary Fig. 5).

We categorized the postsynaptic targets as either excitatory or inhibitory on the basis of morphology. Pyramidal cell dendrites were densely studded with spines, whereas inhibitory interneuron dendrites were sparsely spinous and receive more asymmetric (excitatory) synapses than inhibitory synapses33. The proportion of inhibitory cells in the target population was less than the proportion of synapses onto inhibitory targets because individual axons often made multiple synapses with inhibitory targets. We rendered the anatomical reconstructions of the functionally characterized cells and their postsynaptic targets as a graph (Fig. 5b) to examine the functional logic of the network.

**Convergent excitatory input to inhibitory interneurons**

In the graph of connectivity (Fig. 5b), we found multiple examples of pyramidal cells with diverse preferred stimulus orientations that provided convergent input to inhibitory neurons. We restricted subsequent analysis to a reduced and verified subnetwork that included convergent connections, as well as connections amongst the functionally imaged neurons (Fig. 5, magenta). The proportion of inhibitory cells in the target population was less than the proportion of synapses onto inhibitory targets because individual axons often made multiple synapses with inhibitory targets. We rendered the anatomical reconstructions of the functionally characterized cells and their postsynaptic targets as a graph (Fig. 5b) to examine the functional logic of the network.

**Convergent excitatory input to inhibitory interneurons**

In the graph of connectivity (Fig. 5b), we found multiple examples of pyramidal cells with diverse preferred stimulus orientations that provided convergent input to inhibitory neurons. We restricted subsequent analysis to a reduced and verified subnetwork that included convergent connections, as well as connections amongst the functionally imaged neurons (Fig. 5, magenta). The proportion of inhibitory cells in the target population was less than the proportion of synapses onto inhibitory targets because individual axons often made multiple synapses with inhibitory targets. We rendered the anatomical reconstructions of the functionally characterized cells and their postsynaptic targets as a graph (Fig. 5b) to examine the functional logic of the network.

The functional properties of a pair of excitatory cells, specifically the difference in their preferred orientations, was not predictive of whether they converged onto an inhibitory target. Pairs that converged had a distribution indistinguishable from the uniform distribution (Fig. 6d, red line; $P > 0.30$) and from a distribution in which all possible presynaptic pairs were considered, weighted by their proximity (Fig. 6d, blue line; $P > 0.68$; Methods). In summary, the axonal geometry of two excitatory neurons was a good predictor of whether

they converged upon a nearby inhibitory interneuron, whereas the visual physiology of the excitatory neurons was not.

**Discussion**

The ability to study populations of neurons with a combination of network anatomy and *in vivo* physiology creates new opportunities for examining how neuronal circuits process information. Here we explored how both the geometry and the function of cortical neurons influence the patterns of connections between them. In the case of excitatory input to local inhibitory interneurons, geometry appeared to dominate over function. This finding may provide an anatomical substrate for a prediction from recent physiological studies of mouse visual cortex, in which inhibitory neurons were found to be less selective than excitatory neurons (refs 24–27, compare refs 28, 29; Fig. 1a). Inhibitory interneurons that pool excitatory input could be used to set the gain of orientation-selective pyramidal cells; they might also be involved in modulation of brain state or in attention-dependent normalization of cortical activity.

Several studies have found that some subtypes of inhibitory neurons demonstrate orientation selectivity in the mouse. We did not classify different subtypes of inhibitory neurons, and thus cannot rule out the possibility that some might receive more selective input. Furthermore, although our sample size was large enough to exclude a strong bias in the preferred orientation tuning of convergent cell pairs, a larger sampling is necessary to exclude weaker biases (Methods).

Until it is possible to fully reconstruct large EM volumes, analysis of network connectivity will be limited to a partial sampling of the underlying anatomy. Here we concentrated on reconstructing the axons of functionally characterized pyramidal cells and their postsynaptic targets. Within our sample, we found that 51% of synapses...
Figure 4 | Convergent synaptic input onto inhibitory interneurons. 

a, Three-dimensional rendering of axonal contacts onto a postsynaptic neuron. Large balls at the top represent cell bodies of neurons within the functionally imaged plane. Axons of a horizontally tuned neuron (cell 4; green) and a vertically tuned neuron (cell 10; red) descend and make synapses (small yellow balls) onto dendrites of an inhibitory interneuron (cyan). The axonal and dendritic segments leading to the convergence were independently traced by a second person, blind to the original segmentation (thick tracing). Cell bodies and axons coloured by orientation preference, as in Fig. 1b. Scale bar, 50 μm.

b, c, Electron micrographs showing the synapses onto the inhibitory neuron from cell 4 (b) and cell 10 (c) with corresponding colours overlaid. Scale bar, 1 μm.

d, e, Orientation tuning curves derived from in vivo calcium imaging of the cell bodies of cell 4 (d) and cell 10 (e). Coloured bars and arrows, stimulus orientation and direction. ΔF/F, change in fluorescence. Error bars, ±s.e.m.

Figure 5 | From anatomy to connectivity graphs. 

a, Three-dimensional rendering of the dendrites, axons and cell bodies of 14 neurons in the functionally imaged plane (coloured according to their orientation preference, key right, as in Fig. 1b), and the dendrites and cell bodies of all their postsynaptic targets traced in the EM volume (magenta, excitatory targets; cyan, inhibitory targets; spines on postsynaptic targets not shown; Supplementary Movie 5). Scale bar, 100 μm.

b, Directed network diagram of the functionally characterized cells and their targets, derived from a. Postsynaptic excitatory (magenta) and inhibitory (cyan) targets with cell bodies contained within the EM volume are drawn as circles. Other postsynaptic targets (dendritic fragments) are drawn as squares. (From top to bottom and left to right: functionally characterized cells 5, 2, 7; 13, 6, 14; 1; 10; 11; 3; 9, 12, 4; and 8.)

c, Three-dimensional rendering of the arbors and cell bodies of functionally characterized neurons, along with postsynaptic targets that either receive convergent input from multiple functionally characterized neurons, or were themselves functionally characterized (Supplementary Movie 5).

d, A subset of the network graph showing only the connections in c, all independently verified (from top to bottom and left to right: functionally characterized cells 5, 2, 7; 13, 6; 10; 11, 3; 9, 8 and 4).
tuned neurons by summing all pair-wise overlaps of Gaussians from the two axons ($r = 12 \mu m$; Methods). c, Pairs of axons whose synaptic boutons were in close proximity were more likely to converge onto a common target. The CSP of axon pairs participating in convergences (red) was significantly greater than for non-converging pairs (blue; $P < 1.3 \times 10^{-5}$), two-sample Kolmogorov-Smirnov test, $n_{\text{convergent pairs}} = 21$, $n_{\text{non-convergent pairs}} = 24$. d, Convergences were not predicted by the difference in orientation preference between presynaptic cell pairs. The distribution of differences in orientation preference was not significantly different from a uniform distribution ($P > 0.30$, two-sample Kolmogorov-Smirnov test, $n_{\text{convergences}} = 29$) or a model distribution (Methods) based on CSP ($P > 0.68$, two-sample Kolmogorov-Smirnov test, $n_{\text{convergences}} = 29$).

Figure 6 | Convergent synaptic input onto inhibitory interneurons is predicted by proximity, not function. a, A portion of the aligned and registered EM image series re-sliced parallel to the functionally imaged plane, through 1,153 EM sections. Overlaid is a network graph of the convergences onto inhibitory interneurons. Visually responsive cell bodies are pseudo-coloured according to their preferred orientation (as in Fig. 1b), and numbered as in Figs 4 and 5. Convergences onto inhibitory neuronal targets are represented by lines, corresponding to one or more synapses, leading either to filled cyan circles (targets traced to cell bodies in the EM volume) or squares (dendritic fragments). Cell 14 was partially contained in the EM volume and is not shown. Scale bars, 10 \mu m. b, Diagram of cumulative synaptic proximity (CSP). Line segments represent axons, with three-dimensional Gaussians centred at each synapse. A CSP was calculated for each pair of orientation-related cortical function to network anatomy. We collected the series of wide-field (350 x 450 \mu m) high-resolution EM images to encompass the axonal arbors of the functionally characterized neurons and the dendrites of their targets. Nonetheless, we were limited by the shortest dimension in our volume (52 \mu m), determined by the number of thin sections, so we could trace only 245 out of the thousands of synapses made by the functionally characterized neurons.

Although the volume we imaged using EM was comparatively large, it proved to be near the minimum required to perform an analysis relating cortical function to network anatomy. We collected the series of wide-field (350 x 450 \mu m) high-resolution EM images to encompass the axonal arbors of the functionally characterized neurons and the dendrites of their targets. Nonetheless, we were limited by the shortest dimension in our volume (52 \mu m), determined by the number of thin sections, so we could trace only 245 out of the thousands of synapses made by the functionally characterized neurons.

We anticipate that the size of serial EM volumes will increase substantially in the near future, owing to increases in imaging throughput and series length made possible by automated techniques\(^\text{45,46}\). The time required to trace connectivity between neurons is likely to remain a limiting factor, although semi-automated techniques have already achieved 10-fold increases in throughput over purely manual approaches\(^\text{27}\). For large-scale reconstruction, data quality is paramount. To trace unlabelled, fine-calibre axons, it is essential to have minimum section thickness, minimum section loss, and optimal tissue quality.

In the current study, we found a large number of convergent inputs onto inhibitory neurons principally because they were densely innervated by the excitatory axons we reconstructed. Probing the network anatomy of more sparsely interconnected (and possibly weakly biased\(^\text{47}\)) excitatory neurons\(^\text{48}\), however, will require larger samples. Here we sought to limit tissue damage from the infrared laser, so...
TrakEM2 and objects were classified using classical criteria\textsuperscript{22}. Neurons or dendritic fragments receiving synapses from multiple functionally characterized cells were included in analysis of convergence. For each synapse participating in a convergence, a second individual (blind to the original reconstruction) traced the pre- and post-synaptic processes, starting from the synapse. Segmentation that diverged between the two tracers was excluded from further analysis. Cumulative synaptic proximity (CSP) of pairs of axes was calculated by centring a three-dimensional Gaussian density function at each synaptic bouton and taking the sum of their dot products over all pairs of synapses.

METHODS
Animal preparation and in vivo calcium imaging. We imaged the visual cortex of an adult mouse (male Thy1-YFP-H<sup>+</sup>), as described previously<sup>27,28</sup>, using a custom-built two-photon microscope with a 20× objective (Olympus, 0.95 NA) at a frame rate of 2 Hz. Randomized drifting gratings (100% contrast, 2 Hz) were presented for 4 s, followed by 4 s of uniform mean luminance on an LCD monitor, positioned 18 cm from the contralateral eye, spanning approximately 80° (azimuth) by 60° (elevation) of visual space. To determine orientation tuning, square-wave gratings (0.05 cycles per degree) were presented at 16 directions of motion. Cellular responses were measured with the calcium indicator Oregon Green BAPTA-1 AM (Invitrogen). We next injected the tail vein with SR101 (100 mM; Invitrogen) to fluorescently label vasculature and acquired Oregon Green BAPTA-1 AM (OGB; Invitrogen). We next injected the tail vein with SR101 (100 mM; Invitrogen) to fluorescently label vasculature and acquired an in vivo fluorescent anatomy volume of the region (600 × 600 × 250 μm) surrounding the vibratome-imaged plane (Fig. 1c).

EM material preparation. Following in vivo two-photon imaging the animal was perfused transcardially (2% paraformaldehyde/2.5% glutaraldehyde) and the brain was processed for serial-section TEM. Seven 300-μm-thick coronal vibratome sections were cut. The vibratome sections were post-fixed and stained with uranyl acetate and lead citrate. Of the 4,150 serial sections, we targeted 1,215 with SR101 (100 mM; Invitrogen) to fluorescently label vasculature and acquired EM material preparation.

Transmission electron microscope camera array (TEMCA). A 120-kV TEM (JEOL 1200 EX) was placed atop scaffolding with a custom-built 1.2 m vacuum chamber extension beneath the microscope’s final projector lens, culminating in a 226 mm diameter scintillator (Grant Scientific) resting above optical-quality leaded vacuum glass (Computer Optics) (Supplementary Fig. 2). Custom software (LabView) controlled x–y–z stage motion and image acquisition from a 2 × 2 array<sup>32</sup> of CCD cameras (Impex IPX-11MS) coupled to lenses (Zeiss Makro-planar T* 50 mm F2.0 ZF). Each acquired camera frame was cross-correlated, translated, and summed by the camera’s dedicated acquisition computer, which wrote data over a local area network to storage servers (InterPro Microsystems). Magnification at the microscope was 2,000×, accelerating potential was 120 kV, and beam current was ~90 μA through a tungsten filament. Images suitable for circuit reconstruction were acquired at a net rate of 5–8 megapixels per second.

EM image registration and correspondence. A detailed description of the computational methods for registration and alignment of the EM volume will appear elsewhere. Briefly, camera images were aligned in two dimensions by registering adjacent camera images and dewarping, followed by histogram equalization and stitching. Then adjacent sections were registered and three-dimensional bending stresses were equalized to align the EM volume. The imaged volume will be publicly accessible at the Whole Brain Catalog (http://wholebraincatalog.org) and the UCSD Cell Centered Database<sup>53</sup> (http://ccdb.ucsd.edu/, accession number 8448).

The aligned volume (sections 2,990–4,150) was imported into a customized version of TrakEM2<sup>24</sup> for visualization and segmentation. Although we targeted imaging to 1,215 serial-sections, the final stitched and registered data set contains 1,153 sections, since some fragmentary material, typically small pieces cut from an edge of the EM block face, was excluded. Volume renderings of the raw, unsegmented EM image data (Fig 2a, e) were made in TrakEM2 using a false-colour lookup table. To find the correspondence between the cells imaged in vivo with those in the EM data set, we used successively finer scales of vasculature and then somata to re-locate the calcium-imaged neurons in the EM-imaged volume (Fig. 3 and Supplementary Fig. 3). Pixel size (4 nm per pixel) was calibrated using a latex bead-coated replica grating (EMS). Section thicknesses of ~45 nm were estimated using the cylindrical diameters method<sup>49</sup>.

Tracing and independent verification. Axonal and dendritic arbors of the functionally characterized neurons were traced by manually placing a series of marker points down the midline of each process and rendering a wire-frame model of the arbors using TrakEM2<sup>24</sup>. Infrequently, ambiguities arose from poor local data quality or missing sections. In this case, tracing of a process was halted. Fine axons generally could not be traced across three or more consecutive missing sections. Synapses were identified using classical criteria<sup>50</sup>. For each synapse on the axon of a functionally characterized cell, we traced the dendrites of the postsynaptic neuron either to the boundaries of the volume or centripetally back to the cell body. Neurons or dendritic fragments receiving synapses from multiple functionally characterized cells were considered convergence targets.

One individual who had not previously reconstructed the pre- or post-synaptic process, and was blind to previous tracing work, independently verified the anatomical connectivity underlying convergences and connections between functionally characterized cells. Verification started at each synapse (yellow spheres, Fig. 4a and Supplementary Fig. 7) and then proceeded post-synaptic processes only different (thick arc line) to the previous tracing (Fig. 4a and Supplementary Fig. 7). When the initial reconstruction and the subsequent verification of the reconstruction diverged, that connection and all segmentation work distal from the point of the divergence was excluded from further analysis. The verification process revealed that our initial segmentation effort was highly reproducible, consistent with earlier tests looking at reproducibility of full axonal arbors (Supplementary Fig. 6). All postsynaptic dendritic processes were verified. Of 64 presynaptic axonal contacts participating in convergences, 55 were independently verified. Three experienced team members did the bulk of the tracing and verification over a period of three months. Apical dendrites and dendritic spines (Fig. 5a, c and Supplementary Figs 3, 7) not participating in either the full (Fig. 5b) or independently verified (Fig. 5d) connectivity graphs were traced by a small team of students and were not included in the analysis.

Categorization of postsynaptic targets as inhibitory or excitatory. Dendrites postsynaptic to axons of physiologically characterized cells were unambiguously identified as belonging to inhibitory or excitatory neurons. Inhibitory dendrites were smooth and densely coated with asymmetric shaft synapses, whereas excitatory dendrites were spiny and had fewer shaft synapses (Supplementary Fig. 4a, b). One-hundred-and-thirty-three (54%) of the synapses were onto dendritic spines, and 112 (46%) were onto dendritic shafts. Only four (1.6%) of the shaft synapses were onto excitatory targets, and 12 (4.9%) of the spine synapses were onto inhibitory targets. Starting at 10 randomly selected synapses made by functionally characterized neurons, the postsynaptic dendrites’ percentage of synapses on spines was calculated by tracing along the dendrite and counting up to 10 synapses (including those on spines and the shaft) in either direction. The distribution of spine synapses and shaft synapses was non-overlapping between cell types<sup>24</sup> (Supplementary Fig. 4b) and was consistent with the prior categorization of the target. In all cases (n = 8) where the postsynaptic dendrite was categorized as inhibitory and could be traced to a cell body (cyan circles in Figs 5, 6), asymmetric synapses were found contacting the soma (Supplementary Fig. 4c). Cell 2, which was visually responsive, but not selective for stimulus orientation (Supplementary Fig. 1), exhibited all of the aforementioned characteristics. Furthermore, its axon made symmetric contacts with both dendrites and somata (Supplementary Fig. 4d).

Data analysis. Calcium-imaging data analyses were performed with Matlab (MathWorks) and ImageJ (NIH) as described previously<sup>27,28</sup>. Only neurons with an estimated photonic noise floor < 3% ΔF/ΔF<sup>0</sup> were included. Neurons were considered visually responsive if the response to the best direction was > 6% ΔF/ΔF<sup>0</sup> (morphologically identified pyramidal neurons) or > 4% ΔF/ΔF<sup>0</sup> (non-pyramidal neurons). Orientation tuning curves for each neuron were generated from the stimulus orientation distribution to the sum of two Gaussians (Supplementary Fig. 1) and the preferred orientation was estimated from this fit. Orientation selectivity was calculated as the magnitude of the vector average divided by the sum of all responses ((∑R(i)sin(2Πh))/ (∑R(i)cos(2Πh)))<sup>1/2</sup> (refs 56, 57).

The cumulative synaptic proximity (CSP) for a pair of axons was calculated by centring a clipped three-dimensional Gaussian density function at each synaptic bouton, calculating the dot product of these Gaussians for each pair of boutons (one bouton from each axon), and summing over all pairs (Fig. 6b). The dot products were normalized so that two superimposed synapses yielded a value of 1.0. The distribution of CSPs between convergent and non-convergent pairs was significantly different (two-sample Komogorov-Smirnov test, z = 12.8, p < 0.05, Fig. 6a) and the preferred orientation was estimated from this fit. Orientation selectivity was calculated as the magnitude of the vector average divided by the sum of all responses ((∑R(i)sin(2Πh))/ (∑R(i)cos(2Πh)))<sup>1/2</sup> (refs 56, 57).

However, in hypothetical populations exhibiting weak biases larger sample sizes are necessary (data not shown).
