Journal of Global Health Reports
Vol. 3, 2019

Background

Human immunodeficiency virus (HIV) is a serious public health problem and cause of death in many parts of Africa, including Ghana. Ghana has one of the highest rates of HIV in West Africa, yet factors associated with the prevalence of HIV infection are not well characterized.

Objectives

This study aimed to assess HIV prevalence and associated knowledge, attitudes, and behavioral factors among men and women in Ghana.

Methods

This a population-based cross-sectional study of 4,687 women between the ages of 15-49 years and 4,161 men between the ages of 15-59 years who participated in the Ghana Demographic and Health Surveys 2014 (GDHS-2014). The outcome variable was HIV status assessed through a blood test. Multivariable logistic regression was used to identify potential factors that were associated with HIV.

Results

The overall prevalence of HIV in this study was 2%. Among women, the prevalence was 2.5%, and among men the prevalence was 1.1%. Increasing age was positively associated with the likelihood of HIV infection. Women between the ages of 35-49 years (adjusted odds ratio, aOR=3.51, 95% confidence interval, CI=1.65-7.47) and men between the ages of 35-49 years (aOR=7.07, 95% CI=1.48-33.80) were at a higher risk for HIV compared with women and men between the ages 15-24 years. Widowed, divorced, or separated women and men were more likely to test positive for HIV infection (aOR=1.78, 95% CI=1.00-3.15) and (aOR=2.95, 95% CI=1.26-6.91) when compared with never married women and men, respectively.

Conclusions

In Ghana, the prevalence of HIV among women was approximately twice that of men. Factors such as increasing age, marital status, ever been tested for HIV, having one sex partner, and religion were significantly and independently associated with higher odds of HIV infection in Ghana.

According to the Joint United Nations Programme on HIV/AIDS (UNAIDS), Human immunodeficiency virus (HIV) is a pandemic with a worldwide prevalence of 37 million people as of 2016. 1 Sub-Saharan Africa (SSA) is the most affected region accounting for approximately 70% of the people living with HIV worldwide. In Ghana, the estimated number of adults aged 15 and over living with HIV was 310,000 and was higher in women (200,000) than in men (100,000) in 2018. 2 The first HIV cases in Ghana were diagnosed in 1986 3; however, efforts to track prevalence did not begin until 1990. Since then, multiple research programs have been put in place to estimate and reduce the prevalence of HIV. Ghana has made significant progress in the fight against HIV by putting in place the Ghana Acquired immunodeficiency syndrome (AIDS) Commission (GAC), a multi-sectoral organization under the office of the presi-
dent that is responsible for the management and coordination of the national response to the HIV epidemic in Ghana.

Over half of Ghanaians living with HIV are between the ages of 24-59. Heterosexual intercourse is the primary mode of HIV infection in Ghana and accounts for 75 to 80% of all HIV cases. Additional modes of transmission include vertical transmission from mother-to-child and blood transfusions, which account for 20% of HIV infections in Ghana. The most predominant HIV infectious agent in Ghana is HIV-1, accounting for 94% of all HIV cases. The incidence of HIV per 1000 population among adults between the ages of 15-49 was 1.10 in 2018. The estimation of the current HIV prevalence and delineating factors that are associated with HIV infection is vital for the planning and implementation of HIV prevention, education, treatment, and support programs.

The objective of this study was to assess HIV prevalence and HIV related knowledge, attitudes, and behaviors factors associated with HIV infection among women and men aged 15-49 years and 15-59 years, respectively, using Ghana demographics and health survey 2014 (GDHS-2014). To our knowledge, this is the first study to explore factors associated with HIV infection in Ghana using the most recent GDHS with a large sample size.

MATERIALS AND METHODS
DATA SOURCE AND STUDY DESIGN

This is a cross-sectional population-based study using the GDHS-2014 data. The GDHS-2014 is a nationally representative survey that uses a multistage and stratified design to collect information on population health, HIV, malaria, and nutrition. The individual women's and men's data from the GDHS-2014 dataset were used in this analysis. Survey questions analyzed in this study included demographics, socioeconomic status, sexual behaviors, knowledge of HIV, prior HIV testing, and HIV status. The questionnaire was based on Demographic and Health Surveys (DHS) guidelines and adapted to reflect the current health issues that affect the Ghanaian population.

HIV TESTING AND PROCEDURE

Since 2001, the DHS has conducted population-based HIV testing across developing countries to estimate the prevalence of HIV. Furthermore, DHS offers nationally representative estimates of HIV prevalence rates across countries. The protocol of DHS HIV testing includes anonymous testing that is voluntary by accepting informed consent or refusing to take the test. Before testing, each respondent receives free educational materials about HIV, free counseling, and information on where to take an HIV test. After consent, the investigators take a blood sample to be tested using a barcode. To ensure confidentiality, the HIV test results data were linked to individual surveys with no personal identifiers, which helps to perform in-depth statistical analysis of the socio-demographic, knowledge of HIV, and behavioral factors associated with HIV infection.

STUDY POPULATION

Analyses were restricted to 4,161 male respondents aged 15-59 years and 4,687 female respondents aged 15-49 years who had complete HIV test results data in the 2014 GDHS. There were a total of 119 HIV cases among women and 45 HIV cases among men.

RESULTS

DESCRIPTIVE ANALYSIS OF THE SOCIO-DEMOGRAPHIC CHARACTERISTICS OF THE SAMPLE POPULATION

In Table 1, we report the findings of the socio-demographic characteristics of the survey respondents. Among 4,161 male respondents, 45 had a positive HIV test, and among 4,687 female respondents, 119 had a positive HIV test. The overall prevalence of HIV in our study sample was 2% and was higher in women (2.5%) than in men (1.1%). There was...
a statistically significant difference in the HIV status among different age groups for both women and men (P<0.001). Among women, the proportion of HIV was higher between the ages of 35-49 (52%), and men (53%) compared to those between the ages of 15-24. Women living in urban areas were more likely to be infected with HIV (58%) compared to those living in rural areas (42%) (P=0.041). Furthermore, the proportion of HIV was higher among women who were not sexually active in the last four weeks (52%) compared to those who never had sex (2%) and those sexually active in the last four weeks (46%) (P=0.001). However, the proportion of HIV was higher among men who reported being sexually active in the last four weeks (58%) compared to those who never had sex (2%) and those not active in last four weeks (40%) (P=0.009).

HIV-RELATED KNOWLEDGE AND BEHAVIORS

The distributions of HIV knowledge and related behaviors among the survey respondents are summarized in Table 2. Among men who tested positive for HIV, 89% had the knowledge that consistent use of condoms could reduce the risk of contracting HIV (P=0.057). Furthermore, men who did not have a sexually transmitted infection (STI) in the last 12 months had the highest proportion of HIV (89%) (P=0.036). Respondent women and men who knew how to get condoms were more likely to be HIV positive, with 70% (P=0.010) and 100% (P=0.045), respectively. Among women, 74% of respondents with knowledge of where to get a female condom were HIV positive (P=0.015).

UNADJUSTED LOGISTIC REGRESSION ANALYSIS OF HIV ASSOCIATIONS

From the bivariate analysis (Table 3), factors that were associated with the odds of having HIV included: age, marital status, wealth status, living in the rural areas and currently employed (only among men), religion (only among women), recent sexual activity, and that the respondent knows a place to get an HIV test.

INDEPENDENT FACTORS ASSOCIATED WITH HIV INFECTION

The results of the multivariable logistic regression model are summarized in Table 4. Increasing age was positively and independently associated with the prevalence of HIV infection in both women and men. The adjusted odds ratio (aOR) of HIV infection was twice as high among women between the ages of 25-34 years (aOR=2.39, 95% CI=1.18-4.88), and over three times as high among women aged 35-49 years (aOR=3.51, 95% CI=1.65-7.47) compared to women between the ages of 15-24 years. Similarly, men aged 35-49 years were seven times as likely to be infected with HIV infection (aOR=7.07, 95% CI=1.48-33.80) compared to men between the ages of 15-24 years. Widowed, divorced, or separated women and men were more likely to be infected with HIV (aOR=1.78, 95% CI=1.00-3.15) and (aOR=2.95, 95% CI=1.26-6.91) respectively. Men who have ever been tested for HIV were more likely to have an HIV infection (aOR=2.07, 95% CI=1.08-3.99) as compared to those who had never been tested for HIV. Women who reported currently having one sexual partner were three times as likely to be HIV positive (aOR=3.44, 95% CI=1.07-11.10) compared to those that did not report having only one sexual partner. Being a Muslim woman was a protective factor from HIV infection compared with being a Catholic woman (aOR=0.34, 95% CI=0.12-0.97), However, being a female Protestant did not have a significant association with HIV compared to Muslim and Catholic women.

DISCUSSION

This study examined the prevalence and associated factors of HIV infection in Ghana using individual-level data collected in a recent nationally representative GDHS-2014 survey that included HIV testing of women and men. The study found a prevalence of HIV among women approximately twice that of men. The multivariable analysis found a significant positive association between HIV serostatus and age, marital status, ever been tested for HIV, having one sex partner, and religion. There were regional differences in HIV infections. Greater Accra, Western, Central, Volta, and Eastern regions have the highest probability of HIV infections. The findings from this study corroborate with a previous study that looked at the association between exposures such as sociodemographic factors and the risk of getting HIV in SSA. According to the WHO, approximately three million adults aged ≥ 50 years are living with HIV in SSA and account for 14.3% of all HIV positive adults. This study sheds light on the dynamics of HIV infection rates across age groups and gender and could provide evidence for gender and age-specific HIV infection and co-morbidity intervention and treatment programs instead of "one size fits all" prevention strategies. This study found that testing positive for HIV was associated with having been tested for HIV in the previous year.
Table 1. Socio-demographic characteristics of the survey respondents

| Variables                  | HIV negative (N=4568) | HIV positive (N=119) | HIV Negative (N=4116) | HIV Positive (N=45) | P-value |

Journal of Global Health Reports
While testing would not necessarily lead to HIV infection, an understanding of this association would have essential effects on possible HIV intervention efforts to target high-risk populations. Perhaps current testing efforts are reaching populations that need it. Marital status plays a significant role in the prevention of HIV infection, especially in countries where polygamous marriage is allowed. Widowed, divorced, or separated women and men were found to have a higher likelihood of HIV infection. The positive association between marital status and HIV infection found in this study was not surprising. This finding is consistent with previous studies and may illustrate important family dynamics related to HIV infection, including becoming a widow(er) due to a spouse dying of AIDS or possible divorce or separation as a result of HIV infection. HIV infection may spread through new sexual relationships after a spouse dies. In SSA, high-risk practices such as wife inheritance and ritual cleansing, in which a widow is expected to either marry or have sex with relatives of the deceased husband, can increase women’s exposure to the HIV virus. Furthermore, previous studies also found that married individuals are less likely to use condoms compared to single individuals. Lastly, previous studies have also found a higher rate of male infidelity in marriage in Southern Africa, which can cause greater levels of sero-discordancy. The association between HIV and higher socioeconomic status from the bivariate analysis was not surprising and could be, in part, explained by the higher sexual bargaining power of the wealthy and their association with diverse sexual networks. According to previous studies, people with higher socioeconomic status in developing countries tend to have a higher rate of sequential partners, which increased their susceptibility risk of becoming infected with HIV. Positive associations between HIV infection and higher SES have been observed in other countries in SSA. 

Our findings suggest that the Muslim religion is a protective factor against HIV infection in Ghana. This finding corroborates with a previous study that also found a significant association between religious affiliation and knowledge of HIV in Ghana. However, religious affiliation was not found to be associated with changes in specific protective behavior, particularly the use of condoms. Some studies have attributed the reduced rates of HIV infection in Muslim men due to the protective effect of circumcision, which is practiced and required by the Muslim religion. However, the explanation of the lower risk of HIV rates in Muslim women is not well understood. Our study findings also suggest increasing age to be positively associated with a higher risk of HIV infection. Although it is not possible to know precisely when the infection of HIV occurred in this study due to its cross-sectional nature, this finding could be explained by increased unprotected sexual behaviors among older adults, such as having multiple sexual partners and the lack of consistent condom use during sex. It is also possible that women who are approaching menopause may not have the motivation to use condoms more frequently to protect themselves, which puts them at a higher risk of getting infected by HIV. The higher prevalence of HIV among older women found in this study could reflect infections at a younger age. This study showed that knowledge of HIV risk factors does not always translate into practicing preventative behaviors to reduce the risk of acquiring or transmitting HIV infection. Therefore, effective theoretical frameworks such as Bandura’s social learning theory; theory of reasoned action; and the health belief model (HBM) are needed to create effective public health education strategies that can help translate HIV knowledge into HIV preventative behavior. In a study in which Reinecke and colleagues evaluated the effect of the theory of planned behavior in influencing condom use with a new sexual partner among 650 German youths, they found that beliefs, attitudes, and intentions concerning condom use changed over a relatively short period after this theory was employed. They explained that an effective intervention in HIV prevention would not only have to persuade young people of the attractiveness of the behavior (use of condoms) but also provide skills and the means to perform the behavior. In addition, a recent literature review showed that the constructs of the HBM (perceived susceptibility to HIV/

STI – sexually transmitted infection, - not applicable

AIDS, perceived severity of HIV/AIDS, perceived benefit of condom use, perceived barriers to condom use, cues to action for condom use and condom use self-efficacy) are the most commonly used theory components in health education, health promotion and disease prevention. By employing both HBM and theory of planned behaviors in influencing condom use, behavioral change in condom use may be obtained and sustained.

LIMITATIONS
One of the major limitations of this analysis is that the survey was based on the self-report of sexual and other related behaviors. Previous studies have shown that women tend to underreport and men tend to exaggerate their premarital and extramarital sexual activity. Some of the findings for this analysis may be biased because some women and men may not correctly report their number of sexual partners, use of condoms, and other related risk behaviors. Another limitation is that the cross-sectional nature of the survey does not allow for the determination of a temporal relationship between the explored variables and HIV infection. Besides these limitations, this study provides a better understanding of the current prevalence and the associated risk factors of HIV among women and men in Ghana. The findings are significant in identifying factors related to the prevalence of HIV infection in Ghana, which can be used to better tailor HIV prevention and intervention strategies at the national, regional, and individual levels.

CONCLUSION
This study documents the current prevalence and related factors of HIV infection in Ghana. The findings are useful in identifying high-risk populations and strengthening prevention and treatment programs. HIV control and prevention programs should target all levels of the social-ecological model (policy, community, organization, interpersonal, and individual) in order to be successful at reducing the risk factors associated with HIV in Ghana. Further investigation is needed to determine the temporal relationship between risk factors and HIV infection to determine effective intervention strategies for reducing the burden of HIV in Ghana.
