(Dated: June 11, 2018)

Critical current was recently measured near the transition from 0 to \(\pi\)-contact in superconductor/ferromagnet/superconductor Josephson junctions. Contrary to expectations, it does not vanish at the transition point. It shows instead a tiny, though finite, minimum. The observation of fractional Shapiro steps reenforces the idea that the vanishing of the main sinusoidal term in the Josephson relation gives room to the next harmonics. Within quasiclassical approach we calculate the Josephson relation taking into account magnetic scattering. We find that the observed minimum is compatible with the value of the second harmonics expected from the theory.

PACS numbers: 74.50.+r

According to textbooks equilibrium supercurrent, \(I\), in a tunnel-barrier Josephson junction depends sinusoidally on the phase difference, \(\phi\), between the superconducting leads: \(I = I_c \sin \phi\), where \(I_c > 0\) is the so-called critical current of the junction. In his seminal work of late seventies Bulaevskii et al predicted [1] that the sign of \(I_c\) can change (or, equivalently, a shift of \(\pi\) appear in the argument of the sine) in the presence of magnetic impurities within the tunnel barrier. Soon after, Buzdin et al. [2,3] suggested that such a junction, conventionally called now the \(\pi\)-junction, can be realized in a hybrid structure where the tunnel barrier is replaced with the ferromagnetic metal. While predicted theoretically, experimental realizations of \(\pi\)-junctions remained long unobserved. Indeed, superconductivity and magnetism compete; thus conventional ferromagnets would strongly suppress supercurrent. The first recent successful realization of a \(\pi\)-junction [4,5] utilized the so-called weak ferromagnets, and the observation of a non-monotonic dependence of \(I_c\) as a function of the temperature [4,5] and on the thickness of the ferromagnetic layer [5] served as the first evidences of the actual realization of \(\pi\)-junctions. Moreover in the former case, the existence of the temperature \(T^\ast\), where \(I_c\) reached a minimum with the vanishing magnitude, allowed for a precise identification of the transition point.

These spectacular observations of \(\pi\)-junction behaviors remarkably confirmed original predictions of [1,2,4,5] and yet posed new puzzling questions. The first was that the observed amplitude of the current in the junctions appeared two orders of magnitude smaller than that expected from the theory. H. Sellier et al [6] proposed that magnetic impurities in the ferromagnet could be the origin of this effect, and indeed it was recently shown for the \(\sin \phi\) component [7] that magnetic impurities can lead to a noticeable reduction of the critical current if one assumes somewhat artificial uniaxial distribution of magnetic disorder. It remains however to understand the effect of a more realistic disorder distribution.

Another puzzle concerns the form of the phase-current relation at the transition point \(T^\ast\). Quite generally, the phase relation has to be periodic in \(\phi\). This does not rule out the possibility of the second or even higher harmonics: \(I = I_1 \sin \phi + I_2 \sin 2\phi + \ldots\), which indeed appear in Josephson junctions formed by point contacts, constrictions, or non-equilibrium normal metals [8,9]. Only in the non-equilibrium case was the \(I_2\) component observed [12]. However the amplitude of higher order components in the magnetic Josephson junctions was long considered too low for being observed. Note now that at \(T^\ast\) the coefficient of the first harmonics \((I_1)\) vanishes and, therefore, the higher harmonics become dominant. In Ref. [13] the measured critical current (the maximum of the absolute value of the current-phase relation) does not vanish at \(T^\ast\), but passes through a minimum. This fact, together with the observation of fractional Shapiro steps, indicates that the observed current is in fact the \(I_2\) component. A phenomenological decoherence time has been proposed in Ref. [14] to fit both \(I_1\) and \(I_2\) amplitudes at zero temperature. On the other hand no \(I_2\) component was detected in Ref. [15].

In this Letter we develop a microscopic theory enabling the quantitative derivation of the full current-phase relation in the regimes corresponding to actual experiments of Refs. [4,13,15]. We solve the resulting equations numerically without restriction on the values of the parameters. Extracting the exchange field and magnetic scattering time from the published data on the temperature dependence of \(I_c\), we estimate the expected magnitude of \(I_2\). We find that the predicted values agree favorably with those observed in Ref. [13], while the expected magnitude of \(I_2\) for the sample of Ref. [15] is too small to be observable. Note that thickness inhomogeneities in the ferromagnetic layer could give an alternative explanation [10] of the experimental result of Sellier et al. [12]. A powerful and microscopic approach...
to superconductivity in disordered metals is offered by the quasiclassical theory in a form described in Refs. \[10, 21\]. The non-magnetic disorder leads to the usual form of the self energy \(\Sigma_1(\mathbf{r}, \omega_n) = (2\pi \nu r)\tau_z \bar{G}(\mathbf{r}, \mathbf{r}, \omega_n)\tau_z\). The magnetic disorder gives instead:

\[
\Sigma_2(\mathbf{r}, \omega_n) = \sum_{\alpha=x,y,z} (2\pi \nu r_m^\alpha)\tau_z S_\alpha \bar{G}(\mathbf{r}, \mathbf{r}, \omega_n) S_\alpha \tau_z. \tag{3}
\]

Here \(S = (\sigma_x, \sigma_y, \sigma_z)\), \(\sigma_x\) and \(\tau_x\) are Pauli matrices in spin and Nambu spaces, respectively.

Now we define the quasiclassical Green’s function \(g(\mathbf{r}, \omega_n) = (i/\pi \nu r)\tau_z \bar{G}(\mathbf{r}, \mathbf{r}, \omega_n)\) which, in the diffusive limit, obeys the equation

\[
-D\nabla^2 (g \nabla g) + [\omega_n \tau_z - i\hbar \tau_z \sigma_z + \sum_{\alpha} \frac{1}{2} \overline{\alpha} g S_\alpha g S_\alpha, g, h] = 0,
\]

with \(D\) the diffusion coefficient, and the normalization condition \(g^2 = 1\). Symmetry properties of the Hamiltonian further constrain the form of \(g\). Specifically: (i-a) By the invariance under the rotation around the average magnetization axis \(\hat{z}\), we find that \(g\) is block diagonal in spin space; we thus define the two matrices in Nambu space, \(g_+\) and \(g_-\), as the two non-vanishing upper and lower components, respectively. (i-b) From the invariance under the rotation over an angle \(\pi\) around the \((x\) or \(y)\) axis and simultaneously change of sign of \(h\), we find \(g_+(h) = \tau_z g_-(\tau) \tau_z\). (ii) By time-reversal symmetry, we find \(g_\pm(\mathbf{r}, \omega_n) = -\tau_z g_\pm(\mathbf{r}, -\omega_n)^\dagger \tau_z\). Finally, the 16 correlation functions introduced in Eq. \((??)\) are not independent, since the representation is redundant. This gives: (iv) \(g_+(\mathbf{r}, \omega_n) = -\tau_z g_-(\mathbf{r}, \omega_n)^\dagger \tau_z\).

Exploiting these properties, we parameterize the complete Green’s function in terms of \(g_+\), which in its turn is completely determined by complex functions, \(\theta\) and \(\eta\):

\[
g_+ = \begin{pmatrix} \cos \theta & \sin \theta e^{i\eta} \\ \sin \theta e^{-i\eta} & -\cos \theta \end{pmatrix}. \tag{5}
\]

Then, Eq. \((??)\) yields:

\[
0 = D\nabla^2 (\sin^2 \theta \nabla \eta) + \frac{2}{\tau_m^\eta} \sin \theta \sin \theta^* \sin(\eta - \eta^*) \tag{6a}
\]

\[
0 = -D\nabla^2 \theta + D \cos \theta \sin \theta (\nabla \eta)^2 + 2(\omega_n - i\hbar) \sin \theta + \frac{2}{\tau_m^\eta} \sin \theta \cos \theta
\]

\[
+ \frac{2}{\tau_m^\eta} [\sin \theta \cos \theta^* + \cos \theta \sin \theta^* \cos(\eta - \eta^*)]. \tag{6b}
\]

These equations constitute the main analytical result of our work. Note that in non ferromagnetic superconductors, symmetry properties (i-b) and (iv) for \(h = 0\) imply that \(\theta\) and \(\eta\) are real. Then Eqs. \((??)\) only depend on the effective magnetic scattering time \(1/\tau_m = 1/\tau_m^\eta + 2/\tau_m^\eta\), in agreement with Abrikosov-Gor’kov theory for magnetic impurities \[21\]. By contrast, in ferromagnetic superconductors, magnetic disorder can be characterized by two scattering times: \(\tau_m^\eta\) \[22\] and \(\tau_m^\eta\). In
Ref. [5] the uniaxial disorder was considered. In our notation this corresponds to $\tau^x_m = \tau^y_m = \infty$, $\tau^z_m = \tau_m$. This hypothesis simplifies greatly the solution of Eq. (6), since $\theta$ and $\eta$ are no more coupled to $\theta^*$ and $\eta^*$. The physical reason for this simplification is that magnetic scattering does not couple the spin up and spin down populations. However it seems more realistic that the magnetic disorder is also able to flip the spin of conduction electrons. In this sense the opposite limit is to consider a completely isotropic disorder: $\tau^x_m = \tau^y_m = \tau^z_m = \tau_m$. In the following we thus concentrate on this case. We shall also discuss briefly the uniaxial one for comparison.

In order to determine the Josephson relation, we assume that the ferromagnet is a layer of the length $L$ along the $\hat{x}$-axis. We thus need to solve Eqs. (6) with appropriate boundary conditions $2\Delta$ at $x = \pm L/2$:  

$$\sin \theta \nabla \eta = \mp \frac{\gamma_b}{\sigma_f} \frac{\Delta}{\sqrt{\omega_n^2 + \Delta^2}} \sin(\eta \mp \frac{\phi}{2}),$$  

$$\nabla \theta = \mp \frac{\gamma_b}{\sigma_f} \frac{\omega_n \sin \theta - \Delta \cos \theta \cos(\eta \mp \frac{\phi}{2})}{\sqrt{\omega_n^2 + \Delta^2}}.$$  

(7a)  

(7b)

Here, $\sigma_f$ is the conductivity of the ferromagnet, and $\gamma_b$ is the barrier resistance per unit area at the contacts (taken to be identical for simplicity) between the ferromagnet and the superconducting leads. We also assume that temperature dependence of the superconducting gap in the leads, $\Delta$, is simply given by conventional BCS theory. The supercurrent is given by  

$$I = \frac{2\pi G_f L T}{e} \sum_{\omega_n > 0} \text{Re} \left[ \sin^2 \theta \nabla \eta \right],$$  

(8)  

where $G_f$ is the conductance of the ferromagnetic metal.

We use now the above equations for fitting the experimental data of Ref. [13, 14]. For a given set of parameters, namely the Thouless energy $D/L^2$, $\Delta(T = 0)$, $T$, $\gamma_b$, $h$, $\tau_m$, we obtain the current-phase relation by solving numerically the system of differential equations [6] and calculating the current through Eq. (8). One can then extract the first two harmonics, $I_1$ and $I_2$. (Higher harmonics near $T^*$ are much smaller than $I_2$). We begin with the data of Ref. [13], Fig. 2, concerning a sample with a ferromagnetic layer of $L = 17$ nm. The length $L$, the superconducting gap, and the temperature are known experimentally. The interface resistance is more difficult to measure. The authors of Ref. [13] give an estimate of 30% of the total resistance of the junction in its normal state, $R_f$.

For a given value of $\gamma_b$ one can find the pairs of values $(h, \tau)$ that satisfy the two equations $I_1(h, \tau, T^*) = 0$ and $I_1(h, \tau, T_1) = I_1^{\text{exp}}$, where $T_1$ is a temperature different from $T^*$ and $I_1^{\text{exp}}$ is the corresponding experimental value for $I_1$. We find that only three pairs of values satisfy this constraint. We order them by increasing value of $h$. One can show that the $n$-th solution refers to a junction where, as a function of the length of the sample, other $n - 1$ zeros are predicted for $L < 17$ nm. We optimize then this first estimate of the parameters by including $\gamma_b$ as a fitting parameter for the full experimental curve. The solutions are given in Table I. For comparison fitting parameters for uniaxial magnetic disorder are also given.

In all cases we have a good fit to data (see Fig. 4). Thus, the quality of the fit is not a sufficient criterium to discriminate between the three possibilities (for each model). One argument in favor of the first solution (for isotropic model of magnetic disorder) is the agreement of the fitting parameter $\theta^*$ with the data of Ref. [13], Fig. 2, concerning a sample with a ferromagnetic layer of $L = 17$ nm. The length $L$, the superconducting gap, and the temperature are known experimentally. The interface resistance is more difficult to measure. The authors of Ref. [13] give an estimate of 30% of the total resistance of the junction in its normal state, $R_f$.

**FIG. 1:** Fit to experimental data for the critical current of Ref. [13] (boxes), for the three solutions reported in the table of the isotropic model. The three solutions gives nearly indistinguishable curves. Inset: temperature dependence near $T^*$ of the calculated $I_c = \max_{\phi}(I(\phi)\phi)$, $I_1$ (dashed), and $I_2$ (dotted), for the first solution. The minimum of $I_c$ coincides with $I_2$.  

| model          | order | $h$ (meV) | $1/h\tau_m$ | $\rho$ (%) | $RI_2$ (nV) |
|----------------|-------|-----------|-------------|------------|------------|
| $\tau^x_m = 3\tau_m$ | 1     | 4.6       | 9.3         | 25         | 1.08       |
| (isotropic)    | 2     | 49        | 1.1         | 8          | 0.25       |
| $\tau^y_m = \tau_m$ | 3     | 83        | 0.3         | 10         | 0.07       |
| $\tau^z_m = \infty$ | 2     | 15        | 2.7         | 12         | 0.10       |
| (uniaxial)     | 3     | 61        | 0.8         | 0          | 0.16       |

**TABLE I:** Parameters of the fit (shown in Fig. 1 for the isotropic case). We took for the sample $\Delta = 1.3$ meV, $D/L^2 = 1.13$ meV for $L = 17$ nm, $T^* = 1.1$ K. $\rho = \sigma_f/(2\tau_f + \gamma_b L)$ is the ratio of the barrier resistance to the total resistance $R$ of the junction in its normal state.
FIG. 2: Length dependence at $T = 4.2$ K of $I_1$ (full line) and $I_2$ (dashed line) for the parameters obtained with the fit with the isotropic model. We show the solution 1 (upper panel) and 2 (lower panel). The zero at $L = 17$ nm is visible in both cases. Solution 2 displays a second zero for $L < 17$ nm.

experiment, where incertitude on $L$ is about 1 nm, and $\pi$-contacts were observed for $L = 17 - 19$ nm. We consider now the second component, $I_2$.

In Ref. [13] the minimum value of $RI_2$ is 0.5 nV, and it falls between the first and the second predicted value for isotropic model (cf. Tab. 1). In both cases we thus find that the amplitude of the second harmonics is compatible with the observed one. We also find a strong temperature dependence of $I_2$, the values presented in the table at $T^* = 1.1$ K, are reduced by a factor 10 at 5 K. This dependence can explain the much smaller value for $RI_2$ observed in the 19 nm sample of Ref. [13]. In comparison, the uniaxial model gives a much smaller value for $RI_2 \approx 0.1$ nV for all three solutions.

We repeated the fitting procedure on the data of Frolov et al. [6], where no second harmonics is observed at $T^*$. We found again that the data can be compatible with either a second or a first zero, but in both cases $RI_2 < 10^{-10}$ mV, thus below the observation threshold.

We finally discuss the length dependence of the first and second harmonics for the fitted values of the parameters (see Fig. 2). As anticipated, $I_1(L)$ displays an oscillating behavior. One can clearly see in Fig. 2 that $I_1$ for solution 1 and 2 vanishes once and twice, respectively, for $L \leq 17$ nm (solution 3 is not shown). A more unexpected result is the oscillatory behavior for $I_2(L)$, that shows a remarkable doubled periodicity with respect to $I_1(L)$: Between two zeros of the first harmonics we always observed two zeros of the second harmonics. This means that the sign of $I_2$ remains always positive when $I_1$ vanishes. Therefore we find that the transition from 0- to $\pi$-contact is always discontinuous. We cannot rule out, however, that $I_2$ may be negative at $T^*$ in some other region of the parameters space. This would imply that the transition from 0 to $\pi$-contact is continuous as a function of the temperature.

In conclusion, we have presented a development of the quasiclassical theory of superconductivity taking into account magnetic scattering in the presence of an exchange field. We have used our model to extract the exchange field and scattering times from the temperature dependence of the critical current in superconductor/ferromagnet/superconductor junctions. With these parameters we have calculated the second harmonics at the vanishing value of the first component which agree favorably with the experimental findings.

Note added: after the completion of this work we became aware of related work by A. Buzdin [20] where $I_2$ is calculated near the critical temperature.

We are pleased to thank A. Buzdin for illuminating and important discussions. This work was supported in part by the U.S. Department of Energy office of Science under the contract W-31-109-Eng-38.
