Turnover time of fluorescent dissolved organic matter in the dark global ocean

Teresa S. Catalá1, Isabel Reche1, Antonio Fuentes-Lema2, Cristina Romera-Castillo3,4, Mar Nieto-Cid3, Eva Ortega-Retuerta4, Eva Calvo4, Marta Álvarez5, Cèlia Marrasé4, Colin A. Stedmon6 & X. Antón Álvarez-Salgado3

Marine dissolved organic matter (DOM) is one of the largest reservoirs of reduced carbon on Earth. In the dark ocean (>200 m), most of this carbon is refractory DOM. This refractory DOM, largely produced during microbial mineralization of organic matter, includes humic-like substances generated in situ and detectable by fluorescence spectroscopy. Here we show two ubiquitous humic-like fluorophores with turnover times of 435 ± 41 and 610 ± 55 years, which persist significantly longer than the ~350 years that the dark global ocean takes to renew. In parallel, decay of a tyrosine-like fluorophore with a turnover time of 379 ± 103 years is also detected. We propose the use of DOM fluorescence to study the cycling of resistant DOM that is preserved at centennial timescales and could represent a mechanism of carbon sequestration (humic-like fraction) and the decaying DOM injected into the dark global ocean, where it decreases at centennial timescales (tyrosine-like fraction).
The biological pump has long been recognized as a mechanism to remove CO₂ from the atmosphere, through photosynthesis and export of particulate and dissolved organic matter (DOM) to the deep ocean. More recently, the transformation of biologically labile organic matter into refractory (long lifetime in the dark ocean) compounds by prokaryotic activity has been termed the 'microbial carbon pump' and may also constitute an effective mechanism to accumulate reduced carbon in the dark ocean. Given the large pool of refractory DOM (RDOM) in the oceans (∼656 pg C), understanding its generation, transformation and role in carbon sequestration is crucial in regards to understanding present and future CO₂ emission scenarios.

Some components of the marine RDOM pool absorb light and a fraction of them also emit fluorescence (fluorescent DOM, FDOM). These optical properties are used as tracers for circulation and biogeochemical processes in the dark ocean. Here we obtain the distribution of FDOM in the ocean interior by measuring fluorescence intensities scanned over a range of excitation/emission wavelengths during the Spanish Malaspina 2010 circumnavigation of the globe (Fig. 1). Discrete fluorescent fractions can be discriminated from the measured spectra by applying parallel factor analysis (PARAFAC) (see Methods). Four fluorescent components are isolated from the whole data set and appear to be ubiquitous and common in the dark global ocean. Two components (C1 and C2) have a broad excitation and emission spectra, with excitation and emission maxima in the ultraviolet and visible region, respectively. These are traditionally referred to as humic-like components, which accumulate and have turnover times of 435 ± 41 and 610 ± 55 years, respectively. These turnover times are longer than the ∼350 years that the dark (＞200 m) global ocean takes to renew.

The two other components (C3 and C4) have narrower spectra with excitation and emission maxima below 350 nm and are similar to the spectra of tryptophan and tyrosine, respectively. The dark global ocean appears to be a sink for fluorescent tyrosine-like (C4) component and has a turnover time of 379 ± 103 years that is comparable to turnover time of DOC pool (estimated in 370 years). Thus, we propose that the fluorescent fractions of DOM are suitable proxies for determining the cycling of the RDOM that produces (humic-like) and decays (tyrosine-like) in the dark ocean at centennial timescales.

**Results**

**Water masses across the circumnavigation.** The water mass composition of each water sample was described through the mixing of prescribed water types (WT) with a multi-parameter analysis (see Methods). We identified 22 WT (see Table 1) with 12 of them representing 90% of the total volume of water samples collected during the global cruise (Fig. 2). Circumpolar Deep Water (CDW) was widely distributed in the Indian and Pacific Oceans accounting for up to 25.6% of the total volume sampled. North Atlantic Deep Water of 2.0°C (NADW₂.₀) and 4.6°C (NADW₄.₆) accounted 21.4% of the total volume and mostly located in the Atlantic basin; Antarctic Intermediate Water of 3.1°C (AAIW₃.₁) and 5.0°C (AAIW₅.₀) accounted for 7.6% of the total volume and spread out through the South Atlantic and Indian basins; and North Pacific Intermediate Water accounted for 5.7% of the total volume sampled.

**Global distribution of fluorescent components.** The maximum fluorescence intensity (Fmax) of the two humic-like components (C1 and C2) obtained during the Malaspina circumnavigation showed a global distribution similar to the apparent oxygen utilization (AOU; Fig. 3a–c), reaching their maxima in the Eastern North Pacific central and intermediate waters and their minima in the Indian Ocean central waters. In contrast, this global trend with AOU was not evident for the two amino-acid-like components (C3 and C4; Fig. 3d,e).

**Relationships between the archetypal AOU and fluorophores.** Combining the outputs from the water mass, AOU and fluorescence analyses, we calculated WT proportion-weighted average values, hereafter referred to as archetypal, for the AOU and the fluorescence intensities of the four components (see Methods). Archetypal values retain the variability associated with the initial concentrations at the site where each WT is defined and its transformation by basin-scale mineralization processes up to the study site. Archetypal concentrations explained 81, 77, 75, 24 and 26% of the total variability of AOU, C1, C2, C3 and C4, respectively (Table 1).

In Fig. 4, we show the measured maximum fluorescence intensity (grey dots), archetypal values for each WT (white dots) and archetypal values for each sample (black dots) for the components C1, C2, C3 and C4 (Fig. 4a–d, respectively). We obtained direct relationships between the archetypal humic-like components (C1 and C2) and archetypal AOU (Fig. 4a,b) suggesting a net production of these components in parallel with the water mass ageing. The relatively high archetypal fluorescence of C1 (blue dots in Fig. 4a) for North Atlantic Deep Water (NADW) is related to the high load of terrestrial fluorescent materials transported by the Arctic, whereas the cause of the high value for the Mediterranean water (MW) is due to the low proportion of this water mass (9 ± 14%) compared to the proportion of NADW (76 ± 33%) in the same sample. Therefore, it is expectable that the archetypal concentration of C1 that our data set produces for the MW should be close to the NADW archetype. For C2, the North Pacific Subtropical Mode Water (STMW₅₉P; green dot in Fig. 4b) also departed from the general archetypal C2–AOU trend. Archetypal C1 and C2 can be modelled with archetypal AOU values using power functions (Fig. 4a,b). Given that the high fluorescence of NADW and MW in C1 and of STMW₅₉P in C2 is not related to ageing, these water masses were excluded from their corresponding regression models. It is noticeable that the power factor for C1 (0.51 ± 0.04) is almost twice than for C2 (0.31 ± 0.04), indicating a higher C1 production rate per unit of consumed oxygen. Furthermore, in hypoxic waters (dissolved oxygen concentrations <60 μM (ref. 15); orange dots in Fig. 4a,b), C1 and C2 also behave differently; whereas C1 production was enhanced, C2 did not change substantially.

In contrast, we do not observe a significant relationship between the archetypal values of the tryptophan-like fluorescence component (C3) and AOU (R² = 0.001, n = 22, P = 0.88; Fig. 4c). This lack of correlation is caused by the low archetypal
fluorescence (\(<4 \times 10^{-3}\) RU) of the relatively young (AOU < 75 \(\mu\text{mol kg}^{-1}\)) central waters of the Indian and South Pacific oceans (ICW, STMW, SAMW, SPCW, and STMWP; Table 1; purple dots in Fig. 4c). However, such low archetypal values are not observed in the tyrosine-like component (C4), leading to a weak but significant inverse power relationship with AOU (Fig. 4d). The archetypal tyrosine-like fluorescence of the aged Central waters (AOU > 200 \(\mu\text{mol kg}^{-1}\)) of the Equatorial (13EqPac) and Central North Pacific (CMWNP) exceeded the expected value from their AOU (cyan dots in Fig. 4d). These two WT were excluded from the regression model.

### Net FDOM production and turnover times

On the basis of the relationships observed between the archetypal fluorescence intensity of three out of four fluorescent components (C1, C2 and C4) and AOU, we calculated the net production rate of each component, termed net FDOM production (NFP). A positive value of NFP indicates net production, as for the case of the humic-like components C1 and C2, and a negative value indicates net decay, as for the case of the amino-acid-like C4. The NFP of each component was calculated by multiplying the WT proportion-weighted average fluorescence production values per unit of AOU by the oxygen consumption rate (OCR) for the dark ocean (see Methods). Here we have used a conservative OCR estimate of 0.827 pmol O₂ per year\(^{16}\). The net humic-like fluorescence production rate obtained was \(2.8 \pm 0.2 \times 10^{-3}\) Raman units per year (RU per year) for C1 and 1.5 \pm 0.1 \times 10^{-6} RU per year for C2, whereas C4 was consumed at a net rate of \(-1.3 \pm 0.2 \times 10^{-3}\) RU per year in the dark global ocean.

Turnover times of components C1, C2 and C4 were calculated dividing the WT weighted-average fluorescence values of the dark global ocean by its corresponding NFP rate (see Methods). These values represent the time required to produce (C1, C2) or consume (C4) a fluorescence signal of the same intensity as the actual fluorescence of the dark ocean. The resulting turnover of C2, 610 \pm 55 years, was significantly longer than the turnover of C1, 435 \pm 41 years, and both exceeded the turnover times of the bulk DOC pool—estimated in 370 years\(^{11}\)—and the terrestrial
DOC in the open ocean—estimated in <100 years\textsuperscript{17}—as well as the renewal time of the dark ocean (water depths >200 m)—estimated in 345 years\textsuperscript{9}. Conversely, the turnover time of the tyrosine-like component C4 in 379 ± 103 years was compatible with the turnover time of the bulk DOC.

Discussion
The global pattern in the dark ocean of an increase in the humic-like components concomitant to water mass ageing (high AOU values) has been previously reported\textsuperscript{5,6,18,19}. Although it has been recently hypothesized that this relationship could also be caused by further transformations of terrestrial humic-like materials in the open ocean\textsuperscript{20}, culture experiments have unequivocally demonstrated that these materials can be produced in situ in the oceans\textsuperscript{21}. In fact, we observe positive and significant relationships between the archetypes of both humic-like components (C1 and C2) and the AOU (Fig. 4a,b). The higher C1 production rate per unit of consumed oxygen in comparison with C2 could be related to different mechanisms of production\textsuperscript{6} that might be linked to the phylogenetic nature of producers (bacteria, archaea or eukarya)\textsuperscript{22} and/or the sensitivity to environmental oxygen concentration.

The particularly high archetypal fluorescence of C1 for North Atlantic Deep Water (NADW) has been previously described and appears to be clearly related to the high load of PDOF of terrestrial origin transported from the Arctic rivers to the North Atlantic Ocean\textsuperscript{6,13,14} with a relevant proportion of unaltered high molecular weight lignin\textsuperscript{23}. However, the cause of the high C2 signature for the North Pacific Subtropical Mode Water has not been previously reported. We hypothesize that it could be related to intense rainfall south of the Kuroshio extension where these materials are usually produced\textsuperscript{6} and/or the sensitivity to environmental oxygen concentration.

The percentages represent the proportion of the total volume of water sampled during the cruise that corresponds to each WT. Here the 12 most abundant WT are presented. Note that the depth range starts at 200 m. For more details see Table 1.

Methods
Sample collection. A total of 147 stations were sampled from 40°S to 34°N in the Atlantic, Indian and Pacific Oceans (Malaspina 2010 Expedition, from December 2010 to July 2011). Vertical profiles of salinity (S), potential temperature (θ) and dissolved oxygen (O\textsubscript{2}, μmol kg\textsuperscript{-1}) were recorded continuously with the
conductivity–temperature–depth (CTD) and oxygen sensors installed in the rosette sampler. Salinity and dissolved oxygen were calibrated against bottle samples determined on board with a salinometer and the Winkler method, respectively. The AOU was calculated as the difference between the saturation and measured dissolved oxygen. Oxygen saturation was calculated from salinity and potential temperature. Bottle depths were chosen on the basis of the CTD-O2 profiles to cover as much water masses as possible of the dark global ocean. Seawater samples for fluorescence measurements, collected in 12 l Niskin bottles, were immediately poured into glass bottles and stored in dark conditions until measurement within 6 h from collection. We collected 800 water samples from 200 to 4,000 m depth.

**Figure 3 | Global distribution of the AOU and fluorescence components.** The AOU (a) and the fluorescence intensity at the excitation-emission maxima of each component ($F_{\text{max}}$) of the four components (b–e) discriminated by the PARAFAC analysis in the global ocean data set of the Malaspina 2010 Expedition are plotted. Note that the depth range starts at 200 m. See Methods and Supplementary Fig. 2 for a detailed description of the four fluorescence components.
Fluorescence spectral acquisition. When the coloured fraction of marine DOM (CDOM) is irradiated with ultraviolet light, it emits a fluorescence signal characteristic of both amino-acid- and humic-like compounds, which is collectively termed FDOM10. Fluorescence excitation–emission matrices (EEMs) were collected with a JY-Horiba Spex Fluoromax-4 spectrofluorometer at room temperature (around 20°C) using 5 nm excitation and emission slit widths, an integration time of 0.25 s, an excitation range of 240–450 nm at 10 nm increments and an emission range of 300–560 nm at 2 nm increments. To correct for lamp spectral properties and to compare results with those reported in other studies, spectra were collected in signal-to-reference (S:R) mode with instrument-specific excitation and emission corrections applied during collection, and EEMs were normalized to the Raman area (RA). In our case, the RA and its baseline correction were performed with the emission scan at 350 nm of the Milli-Q water blanks and the area was calculated following the trapezoidal rule of integration.

Figure 4 | Relationships between the fluorescence components and the AOU. Measured concentrations (grey dots), archetypal concentrations for each WT (white dots) and archetypal concentrations for each sample (black dots) for the components C1 (a), C2 (b), C3 (c) and C4 (d). Orange dots represent hypoxic samples. In the right column are presented the regression models and fitting equations for the archetypal values of C1 \(R^2 = 0.90, P < 0.001, n = 19\), C2 \(R^2 = 0.79, P < 0.001, n = 21\) and C4 \(R^2 = 0.31, P < 0.05, n = 20\) with AOU. WT shown in blue, green and cyan dots were excluded from their respective regression models. Error bars represent the s.d. of the estimated archetypal values of AOU and the four fluorescent components for each WT (see Methods; equation (6)).
The average coefficient of variation between sMQ1 and sMQ2 was 1.62%. Therefore, the daily instrument shift was low and was successful in both the protein- and the humic-like regions of the EEMs.

Supplementary Figure 1a shows that the temporal evolution of the RA of the reference sealed Milli-Q was measured at the beginning (sMQ1) and at the end (sMQ2) of each session, which reveals a slight shift of the fluorescence intensity throughout each working day (Supplementary Fig. 1c). The average coefficient of variation between sMQ1 and sMQ2 was 1.62%. Therefore, no additional drift corrections were necessary. The comparison between the reference sealed Milli-Q water used on board and the reference Milli-Q water used in the laboratory was made and was validated using split-half validation and random initialization8. A four-component model was obtained (Supplementary Fig. 2), two of them of humic-like nature, peak A (at Em/Ex 270/370 nm) and peak M (at Ex/Em 320/400 nm), and two of amino-acid-like nature, attributed to tryptophan and tyrosine at 290/340 and 270/310 nm8, respectively. Here we report the maximum fluorescence (Fmax) in Raman units (RU) (refs. 31,32).

Multi-parameter water mass analysis. The dark ocean (from 200 m to the bottom) can be described by the mixing of prescribed WT, characterized by a unique combination of thermal and chemical property values. Water mass analysis quantifies the proportions of the WT that contribute to a given water sample. In our case, we have characterized the WT on the basis of their salinity (S) and potential temperature (θ), which are assumed to be conservative parameters and, therefore, do not change from the area where the WT are defined to the area where the WT are sampled that corresponds to WT i (%VOLi) can be calculated as:

% VOLi = \frac{\sum x_i}{n}

(4)

where \(n = 800\) is the number of deep samples.

Archetypal values of Fmax and AO4 for each WT. Using the measured values of fluorescence and AO4 (N) and the proportions of the 22 WT identified in this study (\(x_i\)), the water mass proportion-weighted average concentration of N in each WT, \(N_i\), termed archetypal value of N, can be calculated as:

\[ N_i = \frac{\sum x_i \cdot N_i}{\sum x_i} \]

(5)

where \(N_i\) is the concentration of N in sample \(j\).

The s.d. of the estimated archetypal value of N, was obtained by:

\[ \text{s.d. (}N_i\text{)} = \sqrt{\frac{\sum x_i \cdot (N_i - \bar{N}_i)^2}{\sum x_i}} \]

(6)

Similarly, the archetypal value of variable N in every sample (\(N_j\)) was calculated as follows:

[ N_j = \frac{\sum x_i \cdot N_i}{100} \]

(7)

The determination coefficient (\(R^2\)) and the s.d. of the residual (s.d. res) of the linear regressions of \(N_i\) (measured values) versus \(\tilde{N}_i\) (archetypal values) allows assessing the degree of dependence of variable N on WT mixing in the dark ocean.

Application of equations (5) and (6) to the collection depth of the samples (\(Z_j\)) allows obtaining the archetypal depth of each WT (\(Z_i\)) and its corresponding s.d. (\(Z_j\)).

NFP and turnover times of the components. The tight relationship between fluorescence intensity and AO4 for components C1, C2 and C4 allows estimating the rate of change of Fmax per AO4 unit (\(\text{dFmax}/\text{dAO4}\)). Using the measured values of fluorescence and AO4 (Fig. 4). Then, the total net production of each fluorescence component, NFP (in RU per year), was calculated as:

\[ \text{NFP} = \frac{\sum \text{VOLi} \cdot (\text{dFmax}/\text{dAO4})}{100} \]

(8)

Where \(\sum \text{VOLi} \cdot (\text{dFmax}/\text{dAO4})/100\) is the WT proportion-weighted fluorescence change rate per AO4 unit of the global dark ocean. The OCR was calculated by dividing 0.827 pmol O2 per year, a conservative estimate of the global oxygen demand of the dark ocean based on organic carbon sedimentation fluxes16, by 1.38 \times 10^{21} \text{kg}, which is the mass of the ocean at a depth >200 m.

Once the NFP of the three components was obtained, we calculated their respective turnover time (\(τ\)):

\[ \tau = \frac{\sum \text{VOLi} \cdot \text{Fmax}}{100 \cdot \text{NFP}} \]

(9)

Where \(\sum \text{VOLi} \cdot \text{Fmax}/100\) is the WT proportion-weighted average fluorescence of the dark global ocean.
