SUMMARY

Coronaviruses (CoV), including SARS and mouse hepatitis virus (MHV), are enveloped RNA viruses that induce formation of double-membrane vesicles (DMVs) and target their replication and transcription complexes (RTCs) on the DMV-limiting membranes. The DMV biogenesis has been connected with the early secretory pathway. CoV-induced DMVs, however, lack conventional endoplasmic reticulum (ER) or Golgi protein markers, leaving their membrane origins in question. We show that MHV co-opts the host cell machinery for COPII-independent vesicular ER export of a short-living regulator of ER-associated degradation (ERAD), EDEM1, to derive cellular membranes for replication. MHV infection causes accumulation of EDEM1 and OS-9, another short-living ER chaperone, in the DMVs. DMVs are coated with the nonlipidated LC3/Atg8 autophagy marker. Downregulation of LC3, but not inactivation of host cell autophagy, protects cells from CoV infection. Our study identifies the host cellular pathway hijacked for supplying CoV replication membranes and describes an autophagy-independent role for nonlipidated LC3-I.

INTRODUCTION

As an early and crucial event upon infection, coronaviruses (CoV) such as the severe acute respiratory syndrome (SARS)-CoV and mouse hepatitis virus (MHV) induce the formation of double-membrane vesicles (DMVs) in host cells and target their RTCs on the limiting membranes of these structures (de Haan and Reggiori, 2008; Gosert et al., 2002; Miller and Krijnse-Locker, 2008; Salonen et al., 2005). A recent analysis of SARS-CoV- and MHV-infected cells by electron tomography has revealed that these DMVs are part of a reticular network of modified endoplasmic reticulum (ER) membranes and contain double-stranded RNA (dsRNA) in their interior (Knoops et al., 2008). The ER origin of the DMVs is supported by the finding that two nonstructural proteins (nsp3 and nsp4) with transmembrane segments that are part of the RTCs become N-glycosylated (Harcourt et al., 2004; Kanjanahaluethai et al., 2007; Oostra et al., 2008). Moreover, nsp4 localizes to the ER when separately expressed and moves to the DMVs upon viral infection (Oostra et al., 2008). Whereas previous work has shown that the early secretory pathway and CoV-induced DMV biogenesis are closely connected (Knoops et al., 2010; Oostra et al., 2007; Verheije et al., 2008), the lack of ER, ER-Golgi intermediate compartment (ERGIC), or Golgi protein markers in CoV-induced DMVs suggests that their biogenesis does not depend on the conventional routing of proteins through this transport pathway (Oostra et al., 2007; Snijder et al., 2006; Verheije et al., 2008). Thus, even though CoV must hijack ER-derived host cell membranes for replication, the precise origin of the DMV lipid bilayers, the host protein content, and the identity of the cellular factors essential for DMV formation remain mysterious (Knoops et al., 2008). The possible involvement of the autophagy machinery in the conversion of host membranes into DMVs has been reported. However, whereas Atg5, an essential component of the autophagy machinery (Mizushima et al., 2001; Yoshimori and Noda, 2008), has been shown to be dispensable for MHV replication (Zhao et al., 2007), contradictory immunofluorescence (IF) data report the presence (Prentice et al., 2004; Zhao et al., 2007) or the absence (de Haan and Reggiori, 2008; Snijder et al., 2006) of the autophagosome protein marker LC3/Atg8 on DMVs (de Haan and Reggiori, 2008). In this study, we have used MHV, the virus prototype for the CoV biology investigation, to unveil the origin of the virus-induced DMVs and to identify host cell factors essential for CoV replication. In the ER, newly synthesized, unstructured polypeptides can attract the folding as well as the degradation machineries that are operating in the lumen of this organelle (Cali et al., 2008b; Hebert and Molinari, 2007). Under normal growth conditions, therefore, the activity of the ERAD machinery must be maintained low to avoid premature interruption of folding programs and favor attainment of the native structure over degradation of immature polypeptides (Cali et al., 2008a). Consistently, it has been reported that EDEM1, a crucial regulator of ERAD (Molinari et al., 2003; Oda et al., 2003), is selectively cleared...
from the ER to tune down the ERAD activity (Calì et al., 2008a). This regulation mechanism has been named ERAD tuning. It relies on the selective sorting of EDEM1 and probably other short-living ER chaperones in 200–800 nm vesicles called EDE-Mosomes. These vesicles, coated with nonlipidated LC3/Atg8 (LC3-I) (Calì et al., 2008a, 2008b), emerge from the ER through a COPII coat-independent mechanism (Zuber et al., 2007) and deliver their content to endosomal compartments for disposal in a series of poorly characterized events (Calì et al., 2008a, 2008b; Le Fourn et al., 2009; Zuber et al., 2007).

We have discovered that MHV exploits the pathway of EDEMosome formation to generate the DMVs required for viral replication. In doing so, MHV interferes with the degradation of EDEM1 and OS-9, another short-living chaperone that we identify here as a second EDE-Mosome cargo, by trapping them into the DMVs. Our data are consistent with the model in which DMVs are generated from the host ER (Knoops et al., 2008) and explain the absence of conventional ER resident chaperones in their interior. In addition, we show that, whereas the autophagy pathway is not essential for MHV infection, nonlipidated LC3-I coats CoV-induced DMVs and is essential for MHV replication.

**RESULTS AND DISCUSSION**

**MHV Infection Does Not Require an Intact Autophagy Machinery**

To conclusively establish whether autophagy is required for MHV infection, we assessed the consequences of deleting ATG7, a gene essential for autophagy (Komatsu et al., 2005), on DMV biogenesis. IF analysis of two RTC components, nsp2 and nsp3, in MHV-infected wild-type (biogenesis. IF analysis of two RTC components, nsp2 and nsp3, in MHV-infected wild-type) and ATG7 knockout mouse embryonic fibroblasts (Atg7−/− MEF) revealed that these two proteins were similarly distributed to numerous punctuate structures in both cell lines (Figure 1A). These puncta represent the virus-induced DMVs that contain viral dsRNA (colocalization in Figure 1A; Harcourt et al., 2004; Knoops et al., 2008). The presence in both Atg7+/- and Atg7−/- MEF of these double-membrane structures with a diameter of approximately 200–350 nm (Knoops et al., 2008; Stertz et al., 2007) was confirmed by conventional electron microscopy (Figure 1B). Moreover, cells with and without Atg7 were equally susceptible to MHV infection. This was established by assessing the virus replication using a recombinant luciferase-expressing MHV (Figure 1C) and by determining the titer of a virus stock on these cells by using the mean tissue culture infection dose (TCID50) test (Figure 1D). MHV replication in Atg7+/- and Atg7−/- MEF during the course of an infection was also very similar (Figure 1E). Thus, the conventional host cell autophagy is not required for formation of MHV-induced DMVs, nor for viral replication and production of viral progeny.

**Nonlipidated LC3/Atg8 Associates with CoV-Induced DMVs**

Because contrasting data have been published on the presence (Prentice et al., 2004; Zhao et al., 2007) or the absence (de Haan and Reggiori, 2008; Snijder et al., 2006) of LC3/Atg8 on CoV-induced DMVs, we examined this issue. Our analysis by IF showed that endogenous LC3 extensively colocalized with the DMV protein markers nsp2 and nsp3 (Figures 2A and 2C). This colocalization was observed during the entire course of the MHV infection (Figures S1A and S1B available online). In contrast, ectopically expressed GFP-LC3, a conventional protein marker for autophagosome membranes (Klionsky et al., 2008; Mizushima et al., 2004), did not colocalize with nsp2 and nsp3 (Figures 2B and 2C). These apparently conflicting data were confirmed in other cell lines (e.g., in HeLa cells; Figures S1C and S1D) and explain the contradictory data in the literature.

LC3 is present in the cell predominantly in a cytoplasmic form (LC3-I) that, upon autophagy induction, is converted into an active lipidated form (LC3-II) by specific covalent linkage to the phosphatidylethanolamine present on autophagosomal membranes (Klionsky et al., 2008; Mizushima et al., 2004). The lipidation of LC3-I and the formation of LC3-II-coated autophagosomes require several proteins, including Atg7 (Komatsu et al., 2005). However, Atg7 was not necessary for the association of endogenous LC3 to DMVs (Figure 2D and 2E). Consequently, Atg7 and LC3 lipidation are not essential for the formation of LC3-positive DMVs. Analysis of the protein content in DMVs induced upon MHV-nsp2GFP infection of HeLa cells and separated on continuous density gradients as described (Calì et al., 2008a) showed the presence of LC3-I in the denser fractions containing the DMV protein marker nsp2-GFP (Figure 2F). These fractions were clearly separated from the lighter autophagosomes containing LC3-II that floated at the top of the gradient. Moreover, IF analyses revealed that ectopically expressed C-terminally HA-tagged, nonlipidable LC3 localizes on DMVs (Figure 2G). Taken all together, these data show that an intact host autophagy machinery is dispensable for the virus life cycle and that lipidation is not required for LC3 association with the DMV membranes.

**Analogs between MHV-Induced DMVs and EDE-Mosomes**

The ER origin of the MHV-induced DMVs (Knoops et al., 2008; Oostra et al., 2007), the absence of conventional ER markers in their membranes and lumen (Oostra et al., 2007; Snijder et al., 2006; Verheije et al., 2008), their association with LC3-I, and the fact that DMVs are stained with antibodies against endogenous LC3, but not with ectopically expressed GFP-LC3 (Figures 2, S1C, and S1D) are features reminiscent of those describing the EDE-Mosomes (Calì et al., 2008a). Significantly, the LC3-I coat distinguishes DMVs (this study) and EDE-Mosomes (Calì et al., 2008a; Figure S3D) from autophagosomes, which are associated with LC3-II and can be decorated with GFP-LC3 (Klionsky et al., 2008; Mizushima et al., 2004).

As in the case of formation of the ER-derived, CoV-induced DMVs, it is unclear whether an active autophagy machinery is required for formation of ER-derived EDE-Mosomes and/or for disposal of EDEM1 (Calì et al., 2008a versus Le Fourn et al., 2009). To better understand this, we compared variations in the intracellular levels of EDEM1 and of p62, a canonical substrate of autophagy (Bjerkoey et al., 2005), under conditions that either inactivate, e.g., ATG7 deletion (Figures 3A and 3B) or cell incubation with chloroquine (CQ) (Figures 3C and 3D) (Klionsky et al., 2008; Komatsu et al., 2005) or activate autophagy, e.g., rapamycin treatment (Figures 3C and 3D) (Klionsky et al., 2008). Deletion of ATG7 inhibits the p62 turnover (Waguri and Komatsu, 2009), thus substantially increasing the intracellular level of this autophagy substrate (Figure 3A). On the contrary, deletion of ATG7 did not result in substantial variations of the level of EDEM1 (Figure 3A),
thus showing that Atg7 and conventional autophagy are dispensable for EDEM1 turnover. Consistently, when wild-type and Atg7−/− MEF were metabolically radiolabeled and chased for 10–90 min, the amount of residual endogenous EDEM1 decreased with similar kinetics in the two cell lines, confirming similar rate of disposal in the presence or absence of Atg7 (Figure 3B). Cell exposure to CQ inhibited the p62 degradation, resulting in higher levels of this protein, as expected for an autophagy substrate (Figure 3C; Bjørkøy et al., 2009). CQ delayed EDEM1 turnover and resulted in intracellular accumulation of EDEM1 (Figures 3C and 3D; Calı` et al., 2008a). Finally, induction of autophagy with rapamycin reduced the intracellular levels of p62, as expected for an autophagy substrate (Figure 3C; Bjørkøy et al., 2009), but increased those of EDEM1 (Figure 3C) by delaying its turnover (Figure 3D). These results confirmed that, as reported above for CoV replication, the pathway regulating EDEM1 turnover is clearly distinct from autophagy. They also highlight another analogy between the ERAD tuning pathway and the CoV infection. Cell exposure to the autophagy-inducer rapamycin negatively affected both EDEM1 turnover (Figures 3C and 3D) and MHV replication, as shown by measuring the levels of both the N nucleocapsid levels and luciferase in cells infected with the recombinant luciferase-expressing MHV (Figure S2). All together, these observations led us to hypothesize that MHV hijacks the ERAD tuning machinery to co-opt cellular membranes for DMV generation.
MHV Infection Interferes with ERAD Tuning and Results in Accumulation of ERAD Tuning Substrates in the Virus-Induced DMVs

As mentioned above, despite their ER origin (Knoops et al., 2008; Zuber et al., 2007), CoV-induced DMVs and EDEMosomes do not contain conventional ER chaperones or protein markers of the early compartments of the secretory pathway (Calı` et al., 2008a; Oostra et al., 2007; Snijder et al., 2006; Stertz et al., 2007; Verheije et al., 2008). By IF analysis of MHV-infected wild-type and Atg7–/– knockout cells, we systematically assessed the presence in DMVs of several conventional protein markers of the early compartment of the secretory pathway, essentially confirming that none of them were in the virus-induced DMVs (Figure S3A and data not shown). Only two antibodies stained the virus-induced dsRNA+ or nsp2/nsp3-positive compartments, namely those recognizing EDEM1 and OS-9.

The presence of EDEM1 during the entire course of the infection (Figures S3B and S3C) confirmed our working model postulating that CoV hijack the ERAD tuning pathway to promote formation of their DMVs. Our model was further corroborated by the observation that cell infection with MHV substantially interfered with ERAD tuning, thus causing intracellular accumulation of EDEM1 and OS-9 (Figure 3H) due to the relocalization and confinement of these chaperones into the last MHV-induced DMVs (Figures 2F, 3E, 3F, S3B, and S3C). In noninfected cells, EDEM1 has a half-life of about 60 min (Figures 3B and 3D; Cali et al., 2008a). Because MHV infection induces a host translational shutoff (Raaben et al., 2007), the persistence of EDEM1 (and OS-9) for several hours confirms the defective clearance of this protein in infected cells (Figures 3H, S3B, and S3C). Entrapping of a fraction of cellular OS-9 in the DMVs was unexpected but significant. Like EDEM1, OS-9 is a regulator of protein disposal from the ER and it is expressed in two splice variants, OS-9.1 and OS-9.2 (Bernasconi et al., 2008; Christianson et al., 2008). Immunodetection of OS-9 in the MHV-induced DMVs (Figures 3F and 3G) led us to verify by subcellular fractionation whether OS-9 localizes to the same LC3-I-positive vesicular structures containing EDEM1 in noninfected cells (Cali et al., 2008a). Our analysis showed that, at steady state, about 20% of OS-9.1 and a smaller amount of OS-9.2 were indeed found in LC3-I-positive EDEMosomes, which sedimented in fractions 7–9 of a continuous Optiprep gradient, whereas other conventional ER chaperones were fully excluded from these fractions (Figure S3D; Cali et al., 2008a).

Despite their presence in DMVs, EDEM1 and OS-9 are not required for MHV replication. In fact, MHV infectivity was not affected by their knockdown, as measured by examining the synthesis of the viral structural N protein, the DMV formation by IF, and by assessing virus replication by either determining intracellular accumulation of EDEM1 and OS-9 (Figure 3H) due to the relocalization and confinement of these chaperones into the last MHV-induced DMVs. The inhibition of MHV replication observed in LC3 knockdown cells was caused by a defect in DMV biogenesis, as no nsp2 and nsp3 signal was detected by IF (Figure 4D). The initial DMVs and RTCs generated upon MHV infection are necessary for the massive synthesis of extra nsp proteins, which, in turn, leads to the formation of a multitude of additional DMVs and RTCs. Consequently, a defect in DMV biogenesis results in a severe block of nsp production. Crucially, back transfection of LC3 knockdown cells with the plasmid-expressing C-terminally HA-tagged, nonlipidable LC3 restored MHV replication measured by monitoring N protein synthesis (Figure 4E).

During evolution, pathogens have developed molecular devices to exploit conserved cellular pathways to optimally infect, replicate, and/or leave host cells. Until now, no host protein has been directly implicated in CoV replication. The fact that both CoV-induced DMV formation and EDEM1/OS-9 turnover rely on analog mechanisms leads us to postulate that CoV hijack the ERAD tuning machinery for the generation of DMVs, which provide the membranous support for viral RTCs. Based on our data, our current working model is that one or more CoV nsps do associate with a still elusive EDEMosome cargo receptor that normally mediates segregation and vesicular export from the ER of EDEM1 and OS-9. Accordingly to what is known about other vesicular transport pathways (Sato and Nakano, 2007), we postulate that the EDEMosome cargo receptor interacts with subunits of a cytosolic vesicle protein coat (nonlipidated LC3-I seems a good candidate). It is unlikely that the viral nsps recruit LC3-I at the cytosolic surface of DMVs because LC3-I is associated to EDEMosomes in uninfected cells (Cali et al., 2008a) and because we have not found direct interaction between nsp and LC3-I (unpublished data). Astonishingly, whereas EDEMosomes are transient structures that end their journey in late endosomes and/or lysosomes, MHV-induced DMVs are persistent cytoplasmic organelles (Ulasli et al., in press). Therefore, the presence of either nsps or (Figures 3E and 3F).
Figure 4. LC3-I Is Required for the Formation of DMVs

(A and B) HeLa-CEACAM1a cells were transfected with either siRNA directed against LC3A and LC3B (siLC3) or nontargeting (siSCR) siRNA. After 48 hr, cells were infected with MHV-2aFLS and analyzed at 7 hr p.i. This analysis has been repeated five times. (A) Cell lysates were analyzed by western blot using antibodies against the N protein, LC3, and actin. The percentage indicates the relative N protein levels in LC3-depleted cells compared to control cells and represent the average of three experiments. (B) Luciferase activity was measured as described in the Experimental Procedures, and error bars indicate the standard deviations for an experiment made in triplicate.

(C) The experiment described in (B) was repeated three times in a time course manner, and luciferase expression was determined at 5, 7, and 10 hr p.i. Error bars represent the standard deviations between experiments.

(D) Localization of nsp2/nsp3 and LC3 was examined by IF in cells treated as in (A) and (B).

(E) HeLa-CEACAM1a cells were transfected with either siRNA directed against LC3A and LC3B (siLC3) or nontargeting (siSCR) siRNA. After 24 hr, one of the samples was transfected with a plasmid expressing C-terminally HA-tagged, nonlipidable LC3, and MHV was inoculated at 48 hr. Cell lysates were prepared at 7 hr p.i. and analyzed by western blot using antibodies against the N protein, LC3, HA, and actin. Note that the higher levels of LC3-I in the siLC3+LC3-HA lane are due to LC3-HA, which run as LC3-I in the used SDS-PAGE gel.
other viral products inhibits the fusion of EDEMosomes/DMVs with the degradative compartments of the endosomal system. A main goal of future research is the identification of the elusive EDEMosome cargo receptor and the characterization of its involvement in CoV infection. It also remains to be established whether the ERAD tuning components, as well as the unconventional intervention of certain factors of the host cell autophagy machinery in the formation of CoV-induced DMVs, might provide valuable therapeutic targets.

EXPERIMENTAL PROCEDURES

Cell Culture, Viruses, and Expression Plasmid
Cell culture, viruses, construction of the expression plasmid, and statistical analyses are described in the Supplemental Experimental Procedures.

Gene Silencing with siRNA
Sets of three different siRNA duplexes targeting different sites within the coding sequences of LC3A and LC3B were designed and obtained from Applied Biosystems/Ambion (Nieuwkerk a/d IJssel). One day after seeding, the HeLa-CEACAM1a cells were transfected with 40 nM of siRNA using Lipofectamine 2000. Antibodies against LC3 (NanoTools) were used to assess by western blot the depletion of the targeted gene.

Immunofluorescence Microscopy
Cells were grown and processed for IF on coverslides as described (Verheije et al., 2008). Fluorescence signals were visualized with a DeltaVision RT fluorescence microscope equipped with a CoolSnap camera (Applied Precision). Images were generated by collecting a stack of 20 pictures with focal planes 0.20 μm apart in order to cover the entire volume of the cell and by subsequently deconvolving them using the SoftWoRx software (Applied Precision). A single focal plane is shown at each time. Primary immunological reactions were carried out with polyclonal anti-EDEM1 (Sigma), anti-OS-9 (Novus Biologicals), anti-nsp2 and nsp3 (Schiller et al., 1998), and anti-Sec3 (Affinity Bioreagents) antisera and monoclonal anti-LC3 (NanoTools), anti-HA (a kind gift of G. Bu, Washington University), anti-dsRNA K1 (English and Scientific Consultants Bt.), anti-KDEL (Calbiochem) and anti-ERGIC53 (Alexis Biochemicals) antibodies. All experiments were repeated two or three times. Selected images show a representative fluorescence profile.

Western Blots
The cell extracts were prepared with lysis buffer (200 mM NaCl, 50 mM HEPES [pH 6.8], 2% CHAPS, and protease inhibitors) and boiled for 5 min in sample buffer. Proteins were separated on a SDS-PAGE gel and transferred onto a PVDF membrane before analysis with antibodies against EDEM1, OS-9, N protein (a gift of S. Siddell, University of Bristol), Erp57 (Soldà et al., 2006), calnexin (a gift of A. Helenius, ETH Zurich), p62 (Progen Biotechnik), mouse BIP (Stressgen), tubulin (Applied Biological Materials), and actin (MP Biomedical). Alexa Fluor 680-conjugated goat anti-rabbit or rabbit anti-mouse secondary antibodies (Molecular Probes) were used for the visualization of the immunoblots using an Odyssey system (LI-Cor Biosciences). Tubulin and actin represent the loading controls.

Miscellaneous Procedures
Electron microscopy, quantification of the virus replication using firefly luciferase-carrying virosomes MHV-2aFLS, measurement of the TCID50, subcellular fractionation on Optiprep gradients, and pulse-chase radiolabeling experiments followed by immunoprecipitations are described in Calì et al., 2008a; Slot and Geuze, 2007; Verheije et al., 2008.
