Difficulties in the treatment of an infant survivor with inherited surfactant protein-B deficiency in Tunisia

Samia Hamouda1,2, Ines Trabelsi1,2, Alix de Becdelièvre3,4, Khadija Boussetta1,2

Abstract: A female-term neonate showed a severe respiratory distress syndrome (RDS) at hour 3 of life requiring her transfer to intensive care. She was intubated and started on assist-control mechanical ventilation associated with inhaled nitric oxide then high-frequency oscillation ventilation at day 12. Chest X-ray was gradually deteriorating. Chest computed tomography (CT) scan revealed diffuse interstitial lung disease. Flexible bronchoscopy excluded pulmonary alveolar proteinosis. The genetics study confirmed surfactant protein-B (SP-B) deficiency caused by the novel homozygous c.770T>C, p.Leu257Pro mutation in the SFTPB gene (NM_000542.5). Methylprednisolone pulse therapy was administered from day 20. As the infant worsened, azithromycin, sildenafil, and inhaled steroids were added at the age of 6 months and azathioprine at the age of 10 months. At the age of 12 months, chest CT showed diffuse “crazy-paving.” The infant died of respiratory failure at the age of 13 months. Unexplained neonatal RDS should raise the suspicion of SP-B disease. This novel mutation could be part of the mutations allowing partial SP-B production result in prolonged survival. Lung transplant in infants, unavailable in numerous countries, remains the unique way to reverse the fatal outcome.

Keywords: Diffuse interstitial lung disease, infant, neonatal respiratory distress, newborn, surfactant protein-B deficiency

Respiratory distress syndrome (RDS) is the most frequent cause of morbidity in newborns. Conditions such as meconium aspiration, pneumonia, and persistent pulmonary hypertension (PH) are usually suspected in a full-term newborn. Severe RDS resistant to treatment should raise the suspicion of genetic causes particularly inherited surfactant protein deficiency. ATP-binding cassette transporter A3 (ABCA3) deficiency is the most common inherited surfactant disorder, however, surfactant protein-B (SP-B) deficiency should be considered since it is potentially lethal.[1] We report on a case of an SP-B deficient infant survivor.
Hamouda, et al.: Management of a surfactant protein-B deficiency survivor infant

Echocardiography at day 2 of life showed left ventricular ejection fraction at 53%, right ventricular enlargement and paradoxical septal motion suggestive of PH. Therefore, inhaled nitric oxide (iNO) was added during 2 days. Transient improvement in respiratory parameters allowed MV to switch to noninvasive positive pressure ventilation within 5 days. However, this improvement was not sustainable. The newborn continued to have high oxygen requirements, motivating reintubation at day 12 and starting high-frequency oscillation ventilation (HFOV). CXR was gradually deteriorating with bilateral infiltrations. Chest computed tomography (CT) revealed diffuse interstitial lung disease (DILD) [Figure 1a]. Flexible bronchoscopy excluded pulmonary alveolar proteinosis. In fact, the liquid of the bronchoalveolar lavage did not have a milky appearance and the cytological examination does not show foamy macrophages with extracellular globular hyaline material positive on periodic acid–Schiff. Lung biopsy was impossible to achieve. The genetics study, performed in the Department of Biochemistry and Molecular Biology at Henri Mondor hospital in Creteil, France, confirmed SP-B deficiency caused by the novel homozygous c. 770T>C, p.Leu257Pro mutation in the SFTPB gene (NM_000542.5). This substitution affects a well-conserved amino acid within the mature form of SP-B. It was predicted by bioinformatic tools to be probably damaging (CADD score: 23.9) [Figure 2].

MV was continued for a total of 26 days, followed by high-flow nasal cannula (HFNC) oxygen therapy. Methylprednisolone pulse therapy (300 mg/m²/day, three doses monthly) was administered from day 20.

At the age of 2 months, slow weight growth (3300 g) motivated high-calorie diet. Echocardiography showed PH at 40 mmHg and 65 mmHg, respectively, at the age of 3 and 6 months. At the age of 6 months, chest CT showed DILD with less ground-glass opacities [Figure 1b]. Azithromycin, sildenafil, and inhaled steroids were added at this stage of the disease.

At 10 months, the patient had acceptable growth. She was 74 cm tall (+1SD above normal) and weighed 7.6 kg (−1SD below normal). However, she was more dyspneic and increased oxygen requirement. Azathioprine was added.

At the age of 12 months, chest CT showed diffuse “crazy-paving” [Figure 1c]. The infant kept worsening. Her peripheral oxygen saturation was around 89%–90% under 15 L/min of oxygen through HFNC. She died of respiratory failure at the age of 13 months.

One year later, the mother was pregnant again. Antenatal genetic testing showed the fetus to be heterozygous. Consequently, the newborn was healthy.

---

**Figure 1:** Patient’s chest computed tomography findings: (a) At day 12 of life: diffuse interstitial lung disease with markedly prominent interlobular septa; (b) At 6 months: diffuse ground-glass opacities associated with reticular infiltrates and posterior segmental consolidations in both upper and lower lobes; (c) At 12 months: radiologic worsening: “crazy-paving” pattern of ground-glass opacities associated with interlobular septal thickening and enlargement of the right heart.
Discussion

To our knowledge, this is the first documented case of SP-B deficiency in Tunisia with genetic confirmation. SP-B deficiency was first described in 1993 in two full-term siblings with fatal RDS. SP-B is a hydrophobic protein essential for surfactant homeostasis. SP-B deficiency is a rare autosomal recessive condition mostly fatal in homozygotes, whereas heterozygous carriers are asymptomatic. Almost 30 mutations have been identified. The c. 361delinsGAA mutation (legacy name: 121 ins 2), associated with approximately 60% of the reported cases, causes severe RDS shortly after birth, lethal within the first 6 months of life. Other less frequent mutations allowing partial SP-B production result in prolonged survival. Our novel mutation could be part of them.

Unexplained neonatal RDS should raise the suspicion of SP-B disease when associated with infiltrates at CXR and parental consanguinity. Chest CT typically reveals a diffuse “crazy-paving” pattern of ground-glass opacities and interlobular septal thickening. This should prompt consideration of genetic testing for SP-B abnormalities which might guide treatment options, prognosis debate with the parents, and adapted genetic counseling.

Recurrent surfactant replacement therapy is ineffective. The patients are often managed with high-dose steroids and maximum supportive therapy including MV, HFOV, and iNO. Extracorporeal membrane oxygenation is a bridge to lung transplant which remains the unique way to reverse the fatal outcome. Additional treatments including hydroxychloroquine and azithromycin are options usually used for other inherited surfactant protein deficiencies, such as ABCA3 and SP-C deficiencies, since cases of SP-B deficiency with prolonged survival are rare.

The five-year posttransplant survival rate is around 50%, similar to that of lung transplant recipients for other causes. However, lung transplant in neonates remains unavailable in numerous countries, as in Tunisia, which made it impossible to save our patient’s life. Gene therapy could be the hoped-for solution after promising results in animal models (viral-mediated SP-B gene delivery).

Declaration of patient consent

The authors certify that they have obtained all appropriate patient consent forms. In the form, the patient’s parents have given consent for images and other clinical information to be reported in the journal. The patient’s parents understand that her name and initials will not be published and due efforts will be made to conceal identity, but anonymity cannot be guaranteed.
