INTRODUCTION

One classical approach in sensory neurophysiology has been to describe sensory neurons in terms of the stimuli that are most effective to drive these neurons. The stimulus that elicits the highest response is often referred to as the optimal stimulus (Albrecht et al., 1980; Stork et al., 1982; DiMattina and Zhang, 2008). Although the optimal stimulus provides a simple and intuitive means of characterizing a sensory neuron, positively identifying the optimal stimulus may be technically difficult for high-dimensional stimuli, and simply knowing the optimal stimulus without adequately exploring responses to other stimuli may provide limited information about sensory function (Olshausen and Field, 2005). Due to these practical and conceptual limitations of characterizing neurons by the optimal stimulus, many researchers have recently taken engineering-inspired approaches to studying neural coding, for example, by characterizing neurons by the optimal stimulus paradigm where the goal of experiments is to identify a stimulus which maximizes neural responses, the iso-response paradigm which finds sets of stimuli giving rise to constant responses, and the system identification paradigm where the experimental goal is to estimate and possibly compare sensory processing models. We discuss various theoretical and practical aspects of adaptive firing rate optimization, including optimization with stimulus space constraints, firing rate adaptation, and possible network constraints on the optimal stimulus. We consider the problem of system identification, and show how accurate estimation of non-linear models can be highly dependent on the stimulus set used to probe the network. We suggest that optimizing stimuli for accurate model estimation may make it possible to successfully identify non-linear models which are otherwise intractable, and summarize several recent studies of this type. Finally, we present a two-stage stimulus design procedure which combines the dual goals of model estimation and model comparison and may be especially useful for system identification experiments where the appropriate model is unknown beforehand.

We propose that fast, on-line stimulus optimization enabled by increasing computer power can make it practical to move sensory neuroscience away from a descriptive paradigm and toward a new paradigm of real-time model estimation and comparison.

In this paper, we review several lines of recent work aimed at developing practical methods for adaptive on-line stimulus generation for sensory neurophysiology. We consider various experimental paradigms where on-line stimulus optimization is utilized, including the classical optimal stimulus paradigm where the goal of experiments is to identify a stimulus which maximizes neural responses, the iso-response paradigm which finds sets of stimuli giving rise to constant responses, and the system identification paradigm where the experimental goal is to estimate and possibly compare sensory processing models. We discuss various theoretical and practical aspects of adaptive firing rate optimization, including optimization with stimulus space constraints, firing rate adaptation, and possible network constraints on the optimal stimulus. We consider the problem of system identification, and show how accurate estimation of non-linear models can be highly dependent on the stimulus set used to probe the network. We suggest that optimizing stimuli for accurate model estimation may make it possible to successfully identify non-linear models which are otherwise intractable, and summarize several recent studies of this type. Finally, we present a two-stage stimulus design procedure which combines the dual goals of model estimation and model comparison and may be especially useful for system identification experiments where the appropriate model is unknown beforehand.

We propose that fast, on-line stimulus optimization enabled by increasing computer power can make it practical to move sensory neuroscience away from a descriptive paradigm and toward a new paradigm of real-time model estimation and comparison.
models, as well as for effective model comparison. In conclusion, we suggest that adaptive stimulus optimization cannot only make the classical optimal stimulus paradigm more tractable, but can potentially move sensory neuroscience toward a fundamentally new experimental paradigm of real-time model estimation and comparison.

THE OPTIMAL STIMULUS

DEFINING THE OPTIMAL STIMULUS

In order for a sensory neuron to be useful to an organism, there must be a consistent functional relationship between the parameters of sensory stimuli and neural responses. Although this relationship may be highly complex and non-linear, for any set of stimuli defined by parameters \( x = (x_1, ..., x_n) \), we may think abstractly of the expected neural responses being described by some function \( r = f(x) \). For simplicity and definiteness, in this section we will focus our discussion of the optimal stimulus on the most common case where \( r \) is a scalar quantity which represents the firing rate of a single neuron, and will assume that the expected firing rate is entirely a function of the stimulus parameters, ignoring variables such as spiking history and stimulus-specific adaptation by assuming that they are kept constant (Ulanovsky et al., 2003; Bartlett and Wang, 2005; Asari and Zador, 2009).

Given this formulation, the problem of finding the optimal stimulus \( x_0 \) is simply the problem of maximizing the function \( f(x) \). Perhaps the simplest and most intuitive notion of the optimal stimulus is that of a firing rate peak in stimulus parameter space centered at \( x_0 \), as illustrated in Figure 1A. Here \( f \) is maximized at \( x_0 \), and for any stimulus perturbation \( \Delta x \) we have \( f(x_0 + \Delta x) < f(x_0) \). However, for high-dimensional stimulus spaces like image pixel space (Simoncelli et al., 2004) or auditory frequency space (Yu and Young, 2000; Barbour and Wang, 2003a) this intuitive notion of the optimal stimulus as a response peak is hardly the only possibility. In the example shown in Figure 1B, the neuron is tuned along one direction in the stimulus space, but is untuned along an orthogonal direction. In this case, there is not a single optimal stimulus \( x_0 \) as in Figure 1A, but rather a continuum of optimal stimuli lying along a ridge containing \( x_0 \) (Figure 1B, thick green line). Another theoretical possibility is the saddle-shaped response surface in Figure 1C, where depending on the dimension chosen for exploration, the same stimulus \( x_0 \) can be either a firing rate peak or a valley.

For high-dimensional stimulus spaces, a full factorial exploration is impossible since the number of stimuli needed grows exponentially with the dimension, a problem referred to colloquially as the curse of dimensionality (Bellman, 1961). In many experiments, stimulus spaces are explored in a restricted subset of dimensions. The behaviors of neuron in the unexplored stimulus dimensions may have various possibilities including the ones considered above. One cannot assume that the stimulus–response relationship must always be a single peak as in Figure 1A. Indeed, one of the challenges of sensory neurophysiology is that without prior knowledge about the neuron under study, there are no constraints whatsoever on the possibilities for the optimal stimulus, which must be found in a process of trial-and-error with no way to conclusively prove global optimality (Olshausen and Field, 2003). We now briefly discuss a recent theoretical study describing possible constraints on the optimal stimulus which arise from general anatomical properties of underlying functional circuitry.

CONSTRAINTS FROM UNDERLYING FUNCTIONAL CIRCUITRY

Ultimately, the stimulus–response relationship function \( f(x) \) is generated by the underlying neural circuitry connecting the sensory periphery to the neuron under study, but in general this circuitry is highly complex (Felleman and Van Essen, 1991; Shepherd, 2003) and not generally known to the experimenter. Nevertheless, recent theoretical work suggests that very basic anatomical properties of the neural circuitry may be able to provide experimentally useful constraints on the possibilities for the optimal stimulus (DiMatina and Zhang, 2008).

Consider the simple hypothetical sensory network shown in Figure 2A (left panel) which receives synaptic inputs from two

![Figure 1](hypothetical stimulus–response relationships for a sensory neuron. The red circle represents the boundary of the set of permissible stimuli. (A) Stimulus \( x_1 \) is a firing rate peak which corresponds to the intuitive notion of the optimal stimulus where any perturbation away from \( x_1 \) results in a decrease in the firing rate. (B) This neuron is tuned to one stimulus dimension but is insensitive to the second dimension. Instead of a single optimal stimulus \( x_0 \), there is a continuum of optimal stimuli (green line). (C) A neuron whose stimulus–response function around the point \( x_0 \) is saddle-shaped. Along one stimulus dimension \( x_1 \) is a firing rate maximum, and along the other stimulus dimension \( x_2 \) is a minimum.)
ADAPTIVE OPTIMIZATION OF FIRING RATE

Despite the conceptual difficulties with the notion of an optimal stimulus, it provides sensory neuroscience with an intuitive first-pass description of neural function when an appropriate quantitative model is unknown. In this section, we discuss adaptive stimulus optimization methods which have been utilized experimentally for optimizing the firing rate of sensory neurons in high-dimensional stimulus spaces where a full factorial exploration would be intractable. Mathematically, the optimization
problem may be specified as that of finding
\[ x^* = \arg \max_{x \in X} f(x) \]  
(1)
where \( x^* \) is the optimal stimulus, \( f \) is the (unknown) stimulus–response function, and \( X \) is the set of allowable stimuli. Methods to optimize firing rate fall into two general categories: those that use the local gradient of the stimulus–response function, and those which utilize genetic or evolutionary approaches. We discuss each of these approaches and their relative merits, along with issues of adaptation and constrained stimulus spaces.

**LOCAL HILL-CLIMBING**
Due to the inherent variability in neural responses (Tolhurst et al., 1983; Rieke et al., 1997), optimizing the firing rate of sensory neurons is a difficult stochastic optimization problem (Spall, 2003). Early work on adaptive stimulus optimization was performed by Harth and Tzanakou (1994), who applied a method of stochastic gradient ascent known as ALOPEX, or “Algorithm of Pattern Extraction” to neurons in the frog visual tectum (Tzanakou et al., 1979). This method works by computing correlations between random perturbations of the current stimulus and changes in firing rate and using these correlations to iteratively update the current stimulus to increase the expected firing rate, eventually converging to the optimal stimulus. More recently, related methods have been employed to optimize the responses of neurons in the primary visual (Foldiak, 2001) and auditory (O’Connor et al., 2005) cortices, providing independent verification of previously described receptive field properties like orientation selectivity (Hubel and Wiesel, 1962) or inhibitory sidebands (Shamma et al., 1993). Variations of ALOPEX have also been utilized to quickly find the best frequency for auditory nerve fibers, an essential first step in many auditory neurophysiology experiments (Anderson and Micheli-Tzanakou, 2002).

In addition to the correlation-based approaches, numerous other computational methods have been utilized for firing rate optimization. One approach is to iteratively make local linear or quadratic approximations to the neural responses around a reference stimulus (Bandypadhyay et al., 2007a; Koelling and Nykamp, 2008, 2012), which can then be used to determine a good search directions in the stimulus space. This approach has been utilized by Young and colleagues in order to determine that the optimal stimulus for neurons in the dorsal cochlear nucleus is a spectral edge centered at the neuron’s best frequency (Bandypadhyay et al., 2007b), consistent with suggestions from previous studies (Reiss and Young, 2005). An alternative optimization method which does not require estimating the local response function gradient is the Nelder-Mead simplex search (Nelder and Mead, 1965), which has been used to optimize the responses of neurons in cat auditory cortex to four-tone complexes (Nelken et al., 1994).

**GENETIC ALGORITHMS**
One limitation of the stimulus optimization methods above is that they are local searches which iteratively update the location of a single point (or simplex of points). Therefore, it is certainly possible for optimization runs to end up stuck at local firing rate maxima. Furthermore points of vanishing gradient do not necessarily indicate maxima (Koelling and Nykamp, 2012), as we can see from the examples in Figure 1. Furthermore, local search methods only identify a single optimal stimulus, and do not sample the stimulus space richly enough to fully describe neural coding. One possible alternative adaptive optimization method used in previous neurophysiological studies which can potentially surmount both of these problems is a genetic algorithm (Goldberg, 1989). A genetic algorithm works by populating the stimulus space widely with many stimuli (analogous to “organisms”), which evolve to the next generation with a probability proportional to the firing rate they elicit (analogous to their “fitness”). The parameters of the surviving stimuli are combined at random in a factorial manner (“crossing-over”) and mutated in order to produce a new generation of different stimuli based on the properties of the current generation. Over several iterations of this algorithm, a lineage of stimuli will evolve which maximizes the firing rate of the neuron under study, and since the sampling of the stimulus space is non-local, genetic algorithms are more likely to avoid the problem of local maxima than hill-climbing methods.

Genetic algorithms were applied to neurophysiology studies by Winter and colleagues, who optimized the parameters of amplitude-modulated tones defined in a four-dimensional space in order to study neural coding in the inferior colliculus (Bleeck et al., 2005). The optimal stimuli found by this method were in agreement with tuning functions found by traditional methods, thereby validating the procedure. More recently, a very powerful demonstration of genetic algorithms as a tool for adaptive optimization was given by Connor and colleagues studying the representation of two-dimensional shape in V4 (Carlson et al., 2011) and three-dimensional shape in the inferotemporal cortex (Yamane et al., 2008; Hung et al., 2012). The parameter space needed to define three-dimensional shapes is immense and impossible to explore factorially, with most of the stimuli in this space being ineffective. Nevertheless, a genetic algorithm was successful in finding shape stimuli having features which were effective at driving neurons, with the optimization results being consistent over multiple runs. Furthermore, because the genetic algorithm cross-over step generates stimuli which factorially combine different stimulus dimensions, it did a sufficiently thorough job of sampling the stimulus space to permit the investigators to fit predictive models which accurately described the tuning of the neurons to arbitrary shape stimuli (Yamane et al., 2008).

As reviewed above, the different methods developed for automatically optimizing firing rate responses of sensory neurons differ greatly, both in their general search strategy (i.e., gradient ascent versus genetic algorithms) as well as their exact methods for implementing that strategy (Nelken et al., 1994; Foldiak, 2001; Koelling and Nykamp, 2012). Furthermore, it is important to note that while genetic algorithms are a commonly chosen alternative to gradient ascent in the existing literature (Bleeck et al., 2003; Yamane et al., 2008; Chambers et al., 2012; Hung et al., 2012), a wide variety of alternative optimization methods could in principle be applied as well, such as simulated annealing (Kirkpatrick et al., 1983), and particle swarm optimization (Kennedy and Eberhart, 1995). However, without direct comparisons of algorithms on benchmark problems using numerical simulation, it is hard to
directly and fairly compare these various methods. As automated stimulus optimization becomes more widely used in physiological experiments, systematic comparison of optimization methods on benchmark problems is certainly an interesting avenue for future research in computational neuroscience.

STIMULUS SPACE CONSTRAINTS

Quite often, one may wish to optimize neuronal responses in a constrained stimulus space for constraints which are more complex than simple upper and lower bounds on stimulus dimensions. For many neurons one can always increase the firing rate simply by increasing the stimulus energy or contrast (Albrecht and Hamilton, 1982; Cheng et al., 1994; Oram et al., 2002), and it is of interest to optimize the stimulus with the constraint of fixed stimulus energy. In Eq. 1, the optimal stimulus is defined over the set of all allowable stimuli, \( \mathbf{x} \), which depends on the constraints in the stimulus space. When each component of the stimulus \( \mathbf{x} = (x_1, \ldots, x_n)^T \) is constrained between an upper bound and a lower bound (e.g., the luminance of image pixels has a limited range of possible values), the set \( \mathbf{x} \) is a hypercube:

\[
\mathbf{x} = \{ \mathbf{x} : a_i \leq x_i \leq b_i, i = 1, \ldots, n \}.
\]

With a quadratic energy constraint, the allowable stimulus set \( \mathbf{x} \) should become a hyper-sphere:

\[
\mathbf{x} = \{ \mathbf{x} : \sum_{i=1}^{n} x_i^2 = \mathbf{E} \}.
\]

For example, Levi et al. (2009) derived a fast procedure for optimization for effective model estimation under stimulus power constraints. Optimizing the stimulus in Eq. 1 subject to an energy constraint is an optimization problem for which there are many numerical methods for solutions (Douglas et al., 2000; Nocedal and Wright, 2006).

In special cases where there is prior information about the functional form of \( f(\mathbf{x}) \), the constrained optimization problem may permit numerically elegant solutions for finding optimal stimuli subject to non-linear constraints, as well as finding invariant transformations of a stimulus which leave responses unchanged. A recent study (Berkes and Wiskott, 2006, 2007) considered the problem of optimizing the responses of any neuron whose functional properties are given by an inhomogeneous quadratic form \( f(\mathbf{x}) = \mathbf{x}^T \mathbf{A} \mathbf{x} + \mathbf{b}^T \mathbf{x} + c \), subject to an energy constraint \( \mathbf{x}^T \mathbf{x} = \mathbf{E} \). This study presented a very efficient algorithm for computing the optimal stimulus \( \mathbf{x}^* \) which requires only a bounded one-dimensional search for a Lagrange multiplier, followed by analytical calculation of the optimal stimulus. In addition, they demonstrated a procedure for finding approximate invariant transformations in the constrained stimulus space, which for complex cells amount to shifts in the phase of a Gabor patch. As quadratic models have become popular tools for characterizing non-linear sensory neurons (Heeger, 1992a; Yu and Young, 2006; Simoncelli et al., 2004; Berkes and Wiskott, 2003; Bandypadhyay et al., 2007a), their algorithm offers a useful tool for sensory neuroscience.

NEURAL RESPONSE ADAPTATION

It is well known that when the same stimulus is presented repeatedly to sensory neurons, they exhibit firing rate adaptation, becoming less sensitive to that stimulus over time (Ulanovsky et al., 2003; Asari and Zador, 2009). Similarly, responses to sensory stimuli can often be non-stationary and are affected by context provided by preceding stimuli (Burtlett and Wang, 2005). Adaptation potentially presents a difficulty for stimulus optimization methods, since toward the end of the optimization run as the algorithm converges on a (locally) optimal stimulus, a series of very similar stimuli may be presented repeatedly, thereby leading to firing rate adaptation. This phenomena has been observed in studies in the published literature (Yamane et al., 2008) and presents a potential obstacle to studies of adaptive stimulus optimization (Koelling and Nykamp, 2012). Given the suppression of neural responses to stimuli which occur with high probability (Ulanovsky et al., 2005), one way of dealing with adaptation may be to intersperse random stimuli with those generated by the optimization run, so as to reduce adaptation effects. However, this may be an inefficient method for dealing with adaptation, since it increases the number of stimuli needed in an experiment (Koelling and Nykamp, 2012).

Apart from these technical considerations, the problem of firing rate adaptation illustrates a fundamental conceptual limitation of phenomenological sensory neurophysiology. In particular, it demonstrates that the act of probing a sensory neuron with stimuli can potentially change the response properties of the neuron itself, possibly including its optimal stimulus. Therefore, it may not be conceptually correct to characterize the stimulus optimization problem as it is written in Eq. 1, but rather to characterize it as a far more complicated optimization problem where the function \( f(\mathbf{x}, \mathbf{h}(t)) \) to be optimized is constantly changing, dependent on both the stimulus \( \mathbf{x} \) and response history \( \mathbf{h}(t) \). In this case, the optimal stimulus for a given neuron may only be well-defined with respect to a given history of stimuli and responses.

One solution to this problem would be to have a mathematically model of the neuron’s stimulus–response function which takes adaptation into account. Indeed, recent work has demonstrated that bilinear models of sensory neurons incorporating adaptation parameters can greatly improve predictions when compared standard linear receptive field models (Ahrens et al., 2008a). Other work has shown that the failure of spectrotimetal receptive field (STPF) models to account fully for neural responses to natural stimuli may be accounted for by rapid synaptic depression (Dawd et al., 2009), further underscoring the importance of including adaptation parameters in neural models. We discuss the issues of neural adaptation and stimulus-response history further when we discuss the estimation of neural models using active data collection.

On the whole however, the problem of adaptation does not seem to pose a fatal limitation to adapting firing rate optimization, as it has been applied successfully in many recent studies (Foldiak, 2001; O’Connor et al., 2005). Furthermore, there are many neurons in the brain for which adaptation effects are small and thus do not pose a concern (Ingham and McAlpine, 2004). These methods are potentially of great importance for investigating neural
ISO-RESPONSE SURFACES AND MODEL COMPARISON

In high-dimensional stimulus spaces, the same response from a sensory neuron can be elicited by a continuum of equally effective optimal stimuli rather than a single optimal stimulus (Figure 1). Therefore, in some experiments it may be of interest to find sets of equivalent stimuli known as iso-response surfaces which yield the same response. One possible way of formalizing an optimization problem for this class of experiments is to formulate it as finding stimuli

$$x^* = \arg \min_{x \in X} d(f(x), c),$$

which $d(\cdot, \cdot)$ is some metric measure (e.g., squared error) quantifying the discrepancy between the desired response $c$ and the neuronal response $f(x)$. Multiple optimization runs from different starting locations and for different values of the desired constant response $c$ permit the experimenter to determine families of iso-rate surfaces for the neuron under study. The geometrical shapes of the iso-rate surfaces can help to determine how stimulus variables $x_1, \ldots, x_n$ are integrated, and thus provide a useful tool for comparison of hypothetical models. For instance, linear integration of stimulus energy would yield iso-response surfaces which are hyperplanes of the form $\sum_{i=1}^n x_i = c$, whereas non-linear integration would yield non-planar iso-response surfaces. Figure 3 illustrates iso-response surfaces for two different hypothetical sensory processing models.

The iso-response surface method was used by Gollisch et al. (2002) to test several competing hypotheses about how spectral energy is integrated in locust auditory receptors. The iso-response contours to combinations of two or three pure tone stimuli with fixed frequencies and variable amplitudes were of elliptical shape, consistent with an energy-integrator model of spectral integration. Further work extended the iso-response method to incorporate temporal integration, yielding a complete cascade model of auditory transduction (Gollisch and Herz, 2005).

A more recent study applied this technique to study the integration of visual contrast over space in salamander retinal ganglion cells, revealing a threshold-quadratic non-linearity in the receptive field center as well as a subset of ganglion cells most sensitive to spatially homogenous stimuli (Bölinger and Gollisch, 2012). The iso-response surface method has also been applied fruitfully in mammalian sensory systems as well. A recent study by Horwitz and Hass (2012) utilized this procedure to study integration of color signals from the three retinal cone types in single neurons in the primary visual cortex. It was found that half of the neurons had planar iso-response surfaces, consistent with linear integration of cone signals. However, the other half showed a variety of non-linear iso-response surfaces, including cup-shaped surfaces indicating sensitivity to only narrow regions of color space.

Although the iso-response surface method has been applied successfully in stimulus spaces of low dimensionality (two or three dimensions), tracing out level hyper-surfaces in higher-dimensional spaces may pose a formidable computational challenge (Han et al., 2003; Willett and Nowak, 2007). In future research, dimensionality reduction procedures might be useful for extending the iso-response surface method to high-dimensional stimulus spaces like pixel space or auditory frequency space (Yu and Young, 2000), as well as for high-dimensional spaces defining complex naturalistic stimuli like 3D shapes or species-specific communication sounds (DiMattina and Wang, 2006; Yamane et al., 2008).

MAXIMALLY INFORMATIVE STIMULUS ENSEMBLES

It has been proposed that one of the major goals of sensory coding is to efficiently represent the natural environment (Barlow, 1961; Simoncelli, 2003). In this spirit, another class of closed-loop stimulus optimization methods has been developed to find the optimal ensemble of sensory stimuli for maximizing the mutual information between stimuli and neural responses (Machens, 2002). This method differs from efforts to find the optimal stimulus or efforts to find iso-response surfaces because the goal is not to find an individual stimulus $x^*$ which optimizes the desired criterion (i.e., Eq. 1), but rather to find the optimal distribution $p^*(x)$ which optimizes the mutual information $I(y; x)$, where $y$ denotes the observed neural response (typically the firing rate of a single neuron). Mathematically, we write

$$p^*(x) = \arg \max_{p(x)} I(y; x) = \int_{X} \int_{Y} p(y|x)p(x) \ln \frac{p(y|x)p(x)}{p(y|x)p(x)} \, dxdy,$$

where $P$ is the space of probability densities on the stimulus space $X$, and $p(y|x)$ and $p(y)$ are determined experimentally by observing neural responses to stimuli. In practice, one starts with an assumption of a uniform distribution with finite support and then applies the Blahut–Arimoto algorithm (Blahut, 1972; Arimoto, 1972) to iteratively update the sampling weights (Machens, 2002). This method has been applied experimentally to characterize grasshopper auditory receptor neurons, demonstrating optimality for processing behaviorally relevant species-specific communication sounds (Machens et al., 2005; Benda et al., 2007).

ADAPTIVE OPTIMIZATION FOR SENSORY MODEL ESTIMATION

An ideal gold standard for sensory neuroscience is to obtain a complete and accurate functional stimulus-response model of the neuron under study. In theory, once such a model is attained, one can then numerically or analytically calculate from this model the neuron’s optimal stimulus, its iso-response surfaces, and its maximally informative stimulus ensembles. That is, if one identifies the system, one gets “for free” other information one may be interested in. However, despite its conceptual appeal, the problem of system identification is of great practical difficulty. This is because one needs to specify an accurate yet experimentally tractable model whose parameters can be estimated from data obtained during the available observation time. Unfortunately, research in computational neuroscience has shown that tractable (e.g., linear and quadratic) models are not accurate, whereas more biologically accurate models (deep, multiple layer neural networks incorporating dynamics, recurrence, etc.) often pose intractable parameter estimation problems.

Looking ahead, it is likely that methods based on the principles of sensory optimization will have important applications in the auditory system.
FIGURE 3 | Examples of iso-response surfaces for two hypothetical sensory processing models. (A) Iso-response contours (left) of a sensory neuron which linearly integrates stimulus variables $x_1, x_2 \geq 0$. The response $r$ of this neuron is a summation of the outputs of two neurons in the lower layer with a threshold-linear gain function (right). Colors in the contour plot represent neural firing rates from low to high. (B) Iso-responses contours (right) of a sensory neuron which non-linearly integrates stimulus variables $x_1, x_2 \geq 0$ with a threshold-quadratic gain function (right).

It is well known from the fields of statistics and machine learning that one can more quickly and accurately estimate the parameters of a function using adaptive data collection, where new observations are generated in an iterative, adaptive manner which optimize the expected utility of the responses given the goal of estimating the model parameters (Lindley, 1956; Bernardo, 1979; MacKay, 1992). Mathematically, the optimization problem is to find at each iteration

$$x_{n+1} = \arg \max_{x \in X} U_n(x),$$

where $U_n(x)$ is the estimation utility function based on the data of the first $n$ stimulus–response pairs. There are many choices for this function, including expected squared error (Müller and Parmigiani, 1995), expected prediction error (Sugiyama, 2006), and mutual information between stimuli and model parameters (Paninski, 2005). The generic name for this strategy is optimal experimental design or OED (Fedorov, 1972; Atkinson and Donev, 1992; Cohn et al., 1996), and it is often studied in a Bayesian framework (MacKay, 1992; Chaloner and Verdinelli, 1995). Recent theoretical and experimental work has shown that such methods can potentially be fruitfully applied for high-dimensional models practical (Lewi et al., 2009), but can also make it tractable to estimate highly non-linear models which cannot be readily identified from random “white noise” data of the kind typically used in system identification experiments (DiMattina and Zhang, 2010, 2011). We first discuss the application of such methods in psychology and cognitive science, and then discuss recent theoretical and experimental work on applications of OED methods to sensory neurophysiology experiments.

ADAPTIVE STIMULUS OPTIMIZATION IN PSYCHOLOGY AND COGNITIVE SCIENCE

Psychophysics has long utilized adaptive data collection, with the classic example being the staircase method for threshold estimation (Cornsweet, 1962). More recently, an adaptive Bayesian approach to threshold estimation (QUEST) which chooses new stimuli for each trial at the current Bayesian estimate of the threshold was developed (Watson and Pelli, 1983), and subsequent work extended this approach to permit simultaneous estimation of both the threshold and slope of the psychometric function (Snoeren and Puts, 1987). Another line of work applied an information-theoretic approach to estimating the slope and threshold parameters, where stimuli were chosen at each trial to maximize the expected information gained about the slope and threshold parameters (Kontsevich and Tyler, 1999). More sophisticated methods of this kind have been utilized for psychometric
A fast information-theoretic algorithm has been developed for (McCullough et al., 2010).\footnote{fn:ir-07-00101} Variance. Simulations demonstrated that their procedure was asymptotically fast, and the calculations for finding the optimal stimulus growing only as to the posterior density, permitting fast recursive updates, with the calculations for finding the optimal stimulus growing only as the square of the stimulus space dimensionality. Numerical simulations demonstrated that their procedure was asymptotically efficient, with the empirically computed variance of the posterior density converging to the minimum theoretically possible variance.

One issue which potentially affects studies of stimulus optimization is neuronal adaptation due to the stimulus history (Ulanovsky et al., 2003; Asari and Zador, 2009). In sensory neurons, this may be manifested as the system actually changing its underlying parameters which we seek to estimate as the experiment progresses. However, the procedure developed by Lewi et al. (2009) was demonstrated to be robust to parameter drift in numerical simulations, suggesting the ability to compensate for changes in the stimulus history. The generalized linear model allows limited non-linearities, it enjoys a likelihood function with no local maxima (Paninski, 2004). Their algorithm relied on a Gaussian approximation to the posterior density, permitting fast recursive updates, with the calculations for finding the optimal stimulus growing only as the square of the stimulus space dimensionality. Numerical simulations demonstrated that their procedure was asymptotically efficient, with the empirically computed variance of the posterior density converging to the minimum theoretically possible variance.

Adaptive stimulus optimization

FIGURE 4 Example of continuous parameter confounding in a simple non-linear neural network model. Adapted with permission from DiMattina and Zhang (2010).

(A) A simple three layer neural network whose input and output weight parameters ($w$, $v$) we wish to estimate from noisy stimulus–response data. Noise is drawn from a Poisson distribution.

(B) Top: The input stimuli $x \in [-0.5, 0.5]$ only drive the hidden unit over a limited region of its gain function (black curve) which may be well approximated by a power law function (red dashed line). Bottom: The input stimuli $x \in [-2, 2]$ drive the hidden unit over a larger region of its gain function which is poorly approximated by a power law function.

(C) Top: When trained with sets of stimuli like that in the top of Figure 4B, the estimates (black dots) lie scattered along the curve predicted by the power law confounding theory. Bottom: When trained with sets of stimuli like those in the bottom panel of Figure 4B, the true parameter values (red triangle) are more reliably recovered.

Adaptive stimulus optimization methods like information-theoretic sampling (Paninski, 2005) can in principle overcome this problem of continuous parameter confounding, as we see in Figure 5D where the correct network parameters are reliably recovered when optimally designed stimuli (Figure 5B, left) are used. This simple example suggests that adaptive stimulus optimization may make it tractable to reliably recover the parameters of complex hierarchical networks needed to model non-linear neurons, whereas it is much harder to recover these networks using standard stimulus sets like white noise.

Many previous studies in the statistics and machine learning literature have demonstrated that faster convergence and smaller generalization error may be obtained when neural networks are trained adaptively using optimally designed stimuli (Lindley, 1956; MacKay, 1992; Cohn et al., 1994). Recently, we have developed a practical method for implementing the information-theoretic stimulus optimization approach derived for generalized linear models (Lewi et al., 2009) for arbitrary non-linear models like hierarchical neural networks. Although this method employs numerous approximations, it has been shown in simulated experiments to be effective at recovering non-linear neural networks having multiple hidden units, and is fast enough to utilize in real experiments (Tam et al., 2011; Dekel, 2012; Tam, 2012).

ADAPTIVE OPTIMIZATION FOR SENSORY MODEL COMPARISON

Quite often the appropriate model for describing a sensory neuron or perceptual quantity is unknown. Therefore, an important experimental goal may be to discriminate between two or more competing models. Mathematically, the optimization problem is to iteratively find stimuli

$$x^*_n+1 = \arg \max_x U_n^{\text{comp}}(x),$$

which optimize a model comparison utility function $U_n^{\text{comp}}(x)$, one choice of which may be the expected reduction in model space entropy (Cavagnaro et al., 2010; DiMattina and Zhang, 2011). This equation may be regarded as the optimal comparison counterpart of the equation for optimal estimation (Eq. 6). We now briefly discuss recent studies making use of adaptive stimulus optimization for model selection.

PSYCHOPHYSICAL MODEL COMPARISON

Although standard model comparison methods like the Bayesian Information Criterion (BIC; Schwarz, 1978) or predictive
FIGURE 5 | Stimuli which are adaptively optimized for accurate parameter estimation can be more effective than random stimuli for recovering non-linear models. Adapted with permission from DiMattina and Zhang (2011). (A) A simple center-surround neural network consisting of a narrowly integrating excitatory output unit (E-unit) which receives inhibitory input from a broadly integrating interneuron (I-unit). (B) Examples of optimally designed (left) and random (right) stimuli. Note that the optimally designed stimuli exhibit complex correlated structure. (C) Random stimuli (green dots) only drive the E-unit over a limited range of its gain function (black curve) which may be well approximated by an exponential function (red dashed line). This is due to inhibition from the I-unit, as can be seen by setting $v_I = 0$ (crosses). By contrast, optimally designed stimuli (blue dots) drive the gain function over its full range. (D) Estimates attained from training with random stimuli (green dots) exhibit continuous parameter confounding between the output weight and bias, as predicted by the exponential theory (black curve). In contrast, estimates attained from optimally designed stimuli accurately recover the true parameters (red triangle).

cross-validation may be applied post hoc (Vladusich et al., 2006; Wu et al., 2006), numerous studies suggest that performing experiments using stimuli optimized for model comparison may be far more effective (Atkinson and Fedorov, 1975a,b). One method for model comparison developed recently for psychophysical experiments is known as MAXimum Differentiation (MAD) competition (Wang and Simoncelli, 2008). Given two perceptual models which relate stimulus parameters to a perceptual quantity, this method generates a pair of stimuli which maximizes/minimizes the response of one model while holding the other model’s response fixed. Next, this procedure is repeated with the role of the two models reversed. Testing human subjects on the two pairs of synthesized stimuli can determine which model is “better” in the sense of telling us which model’s max/min pairs are simpler to
discriminate. This procedure has been fruitfully applied to compar-
ing image quality assessment models which aim to predict human perception of image quality (Wang and Bovik, 2006).

An information-theoretic method for model comparison was recently derived by Cavagnaro et al. (2010). Given a set of models with the $i$-th model having prior probability $p_i$, stimuli are chosen to maximize the mutual information between the stimulus and the model index $i$ by minimizing the expected model space entropy in a manner directly analogous to information-theoretic model estimation (Paninski, 2005), except that in this case the unknown variable is a discrete model index $i$ rather than a continuous parameter value. This method was applied to competing models of memory retention from the cognitive science literature (Rubin et al., 1999) and was shown to permit much more accurate discrimination than standard non-adaptive methods.

NEURAL MODEL COMPARISON

In general, the correct parameters of competing sensory processing models are not known beforehand. Therefore, it is of interest to consider how to conduct experiments which estimate and discriminate competing models. Typically, investigators in neu-
ropathology and neuroimaging have applied model-comparison techniques post hoc (David and Gallant, 2005; Vladu et al., 2006; Penny, 2012), particularly in the system identification literature (Prenger et al., 2004; David and Gallant, 2005; Wu et al., 2006; Sharpee et al., 2008; Rubin et al., 2012; Schinkel-Bielefeld et al., 2012). However, a fundamental limitation with post hoc analysis is that it is not possible to generate and test critical stimuli which are optimized for model comparison, as this is only poss-
ible while the system is under observation. This limitation can only be overcome by fitting multiple models to a sensory neuron during the course of an experiment and then using the fitted models to generate and present critical stimuli which are optimized to best discriminate the models. Although previous work has pre-

sented stimuli on-line to test or verify a single model (deChams et al., 1998; Touryan et al., 2002), very little work in single-unit in vivo sensory neurophysiology has presented stimuli optimized for model comparison in real-time (Tam et al., 2011).

A recent study considered a two-stage approach for combining the goals of model estimation and comparison in neurophysiology experiments, illustrated schematically in Figure 6A (DiMattina and Zhang, 2011). In the first stage, stimuli are adaptively opti-
mized for parameter estimation, with the optimal stimulus for each model being presented in turn. In the second stage, stim-
uli are generated adaptively in order to optimally discriminate competing models making use of an information-theoretic crite-

rion (Cavagnaro et al., 2010) or a likelihood-based criterion. In the special case of two models $f_i(x, h)$ and Gaussian response noise, it can be shown that under a likelihood criterion the best stimulus for model discrimination is the stimulus which maximizes the quantity $f_i(x, h) - f_j(x, h)$, and furthermore this stimulus will maximally increase the BIC in favor of the best model (DiMattina and Zhang, 2011).

Figure 6 illustrates a numerical experiment making use of this two-stage procedure for the problem of discriminating an additive and multiplicative model of neural responses (Figure 6B), where the additive model is assumed to be the true model. After the estimation phase, the BIC does not have a strong preference for either model, only being correct about half the time (Figure 6C). However, after presenting 500 stimuli optimized for discriminat-
ing the additive and multiplicative model and applying the BIC to all available data, the correct (additive) model is preferred for 24 of 25 Monte Carlo trials (red curve). As a control, presenting additional stimuli optimized for model estimation only improves final model selection moderately (blue curve), while presenting random stimuli does not at all improve model selection perfor-

mance (green curve). This procedure has now been applied in neurophysiology experiments to generate critical stimuli to dis-
tinguish between two competing models of spectral processing by single neurons in the primate inferior colliculus (Tam et al., 2011; Tam, 2012).

DISCUSSION

With increasing computer power, it is becoming practical for neuro-
science experiments to utilize adaptive stimulus optimization where stimuli are generated in real-time during the course of the experiment (Benda et al., 2007; Newman et al., 2013). Vari-
ous experiments have utilized adaptive stimulus optimization in order to break the “curse of dimensionality” and find the optimal stimulus for a sensory neuron in spaces which are too large for factorial exploration (O’Connor et al., 2005; Yamane et al., 2008). However, simply characterizing the optimal stimulus for a sen-

sory neuron provides at best only a partial description of neural coding (Olshausen and Field, 2005). Therefore, in addition to helping to find the optimal stimulus, adaptive stimulus optimization makes it possible to pursue engineering-inspired approaches to sensory neurophysiology which may yield greater functional insights, for instance finding stimulus ensembles maximizing information between stimuli (Machens, 2002; Machens et al., 2003) and neural responses or fitting and comparing multiple non-linear models to neural responses (Lewis et al., 2009; DiMat-
tina and Zhang, 2011). Table I summarizes the various closed-loop stimulation paradigms discussed in this review, and Figure 7 schematically illustrates the closed-loop experimental approach.

The vast majority of the work to date has applied closed-
loop methods to studying scalar firing rate responses measured from single neurons. However, as closed-loop approaches are con-
tinuing to develop, and as new techniques like optical imaging (Utki et al., 2005; Rock et al., 2011) are making it increasingly feasible to observe large numbers of neurons simultaneously, it is of great interest for future investigations to apply these methods to neural populations and to measurements beyond scalar firing rate. Here we briefly discuss some possible directions for future research.

While the notion of the optimal stimulus is well-defined for single neurons, it is not well-defined for neural populations. However, an alternative approach to stimulus optimization for a population of neurons is to find the stimulus at which the pop-
ulation is best at discriminating nearby stimuli, as opposed to the stimulus yielding the highest firing rate response. Indeed, it has been suggested by a number of investigators that high-
slope regions of tuning curves, where nearby stimuli are best

FIGURE 6 | Stimuli which are adaptively optimized for model comparison can lead to more accurate model selection. Adapted with permission from DiMattina and Zhang (2011). (A) A hypothetical two phase procedure for estimating and comparing multiple competing models. During the estimation (E) phase, stimuli are optimized in turn for estimating each model. During the comparison (C) phase, stimuli are optimized for comparing all of the models. (B) Two candidate models were fit to data generated by a true additive model whose input weights \( w_1 \) and \( w_2 \) were 12 \( \times \) 12 Gabor patches shown at the right. The two competing models differ only in their method of integrating subunit activities (additive versus multiplicative). (C) At the end of the estimation phase (“Start”), the BIC does not consistently prefer either model. Presenting additional stimuli optimized for model discrimination yields almost perfect model selection (red curve), while presenting additional random stimuli (green curve), or stimuli optimized for model estimation (blue curve) either does not improve or only somewhat improves model selection.

discriminated, are much more important in sensory coding than tuning curve peaks (Seung and Sompolinsky, 1995; Harper and McAlpine, 2004; Butts and Goldman, 2006; Bonnasse-Gahot and Nadal, 2008). Under reasonable assumptions of independent Poisson responses, the one-dimensional stimulus \( x \) at which a neural population can best discriminate nearby stimuli \( x + \delta x \) is the stimulus which maximizes the Fisher information

\[
I_F(x) = \sum_{i=1}^{N} \left[ f_i'(x) \right]^2 / f_i(x),
\]

where \( f_i(x) \) is the tuning curve of the \( i \)-th neuron (Dayan et al., 2001). It is relatively straightforward to extend this Fisher information formalism to higher dimensional stimulus spaces (Zhang and Sejnowski, 1999; Johnson et al., 2004; Butts and Goldman, 2006; Bonnasse-Gahot and Nadal, 2008). Under reasonable assumptions of independent Poisson responses, the one-dimensional stimulus \( x \) at which a neural population can best discriminate nearby stimuli \( x + \delta x \) is the stimulus which maximizes the Fisher information

\[
I_F(x) = \sum_{i=1}^{N} \left[ f_i'(x) \right]^2 / f_i(x),
\]

where \( f_i(x) \) is the tuning curve of the \( i \)-th neuron (Dayan et al., 2001). It is relatively straightforward to extend this Fisher information formalism to higher dimensional stimulus spaces (Zhang and Sejnowski, 1999; Johnson et al., 2004; Butts and Goldman, 2006; Bonnasse-Gahot and Nadal, 2008).

Under reasonable assumptions of independent Poisson responses, the one-dimensional stimulus \( x \) at which a neural population can best discriminate nearby stimuli \( x + \delta x \) is the stimulus which maximizes the Fisher information

\[
I_F(x) = \sum_{i=1}^{N} \left[ f_i'(x) \right]^2 / f_i(x),
\]

where \( f_i(x) \) is the tuning curve of the \( i \)-th neuron (Dayan et al., 2001). It is relatively straightforward to extend this Fisher information formalism to higher dimensional stimulus spaces (Zhang and Sejnowski, 1999; Johnson et al., 2004; Butts and Goldman, 2006; Bonnasse-Gahot and Nadal, 2008).

and this technique could readily generalize to find the stimulus which is best discriminated from nearby stimuli by a population code.

Extension of the definition of iso-response surfaces (Gollisch et al., 2002) to multiple neurons is relatively straightforward. In particular, if we can view each neuron as implementing a function \( f(x) \) on the stimulus space, then the region of stimulus space which simultaneously satisfies multiple constraints

\[
\sum_{i=1}^{N} f_i(x) = c_1, \ldots, f_N(x) = c_N
\]

should simply be the (possibly empty) intersection of the regions of stimulus space satisfying each individual constraint. It would be interesting to extend the maximally informative ensemble approach (Machens, 2002) to multiple neurons as well. One potential difficulty is that the number of possible responses which one needs to measure to compute

Table 1 | Summary of various closed-loop stimulus optimization approaches utilized in sensory systems neuroscience.

the probability distribution $p(y|x)$ increases exponentially with the number of neurons in the population. Indeed, this exponential increase in the number of symbols with the dimensionality of the response space is a well-known problem with applications of information-theoretic methods in neuroscience (Rieke et al., 1997). It would be desirable to develop more efficient computational techniques for studying neuronal populations in the future (Yarrow et al., 2012).

In addition to considering neural populations, another direction for extending the closed-loop paradigm is to consider neural responses more sophisticated than firing rates, for instance the temporal patterns of neural responses (Optican and Richmond, 1987; Victor and Purpura, 1996), first spike latency (VanRullen et al., 2005; Gollisch and Meister, 2008), or synchronous responses in neural populations (Brette, 2012). Since a temporal pattern is a vector but not a scalar, one needs to extract a scalar quantity from a temporal pattern in order to define the optimal stimulus. For example, synchrony can be defined as a scalar quantity (Steinmetz et al., 2000) and can in principle be optimized over a stimulus space in the same manner as firing rate. The iso-response paradigm (Gollisch et al., 2002) would generalize quite well to both spike pattern and synchrony measures. In this case of spike pattern, the goal would be to find the equivalence class of all stimuli which could elicit a desired pattern of spiking, and theoretical efforts have demonstrated that it is possible to design stimuli to produce a desired spike pattern (Ahmadian et al., 2011). Similarly, for iso-synchrony curves one could find equivalence classes of stimuli yielding the same degree of synchrony in the population by utilizing algorithms similar to those developed for firing rate.

One of the most powerful applications of the closed-loop paradigm is the ability to move sensory neurophysiology toward a model-based paradigm, where experiments are performed with the goal of identifying and comparing multiple competing non-linear models (Paninski, 2005; Lewi et al., 2009; DiMattina and Zhang, 2011; Tam et al., 2011). One advantage of model identification is that successful identification gives the experimenter a variety of biologically important information about the neuron or neuronal population “for free.” That is, once one has determined an accurate model for a sensory neuron, the optimal stimulus for maximizing firing rate, the iso-response surfaces, or the stimulus ensemble maximizing information transmission can be predicted from this model, and these predictions can be tested experimentally. However, the model-based approach is not without its difficulties, as many sensory neurons are poorly described by tractable linear and quadratic models and may be better described by more complex models like basis functions and neural networks. Recent work has demonstrated that in principle, adaptive stimulus optimization methods long utilized in machine learning and psychophysics can be applied in sensory neurophysiology for purposes of model estimation and comparison (Paninski, 2005; Lewi et al., 2009; DiMattina and Zhang, 2011). In particular, our recent study has presented a practical two-stage experimental
method for generating stimuli which are optimal for estimating the parameters of multiple non-linear models and then generating stimuli on-line in order to critically compare the predictions of different models (DiMattina and Zhang, 2011). This method is presently being applied in ongoing auditory neurophysiology studies (Tam et al., 2011; Deoki, 2012; Tam, 2012), and may be applicable to a broad variety of sensory systems.
