Abstract
Transition metal phosphides as ideal anodes have been attracted a large number of interests due to their excellent performance for lithium-ion batteries. Nevertheless, CoMoP$_2$ materials were rarely reported as lithium-ion battery anode materials. Thereupon, to excavate their ability in LIBs, a sandwich-like architecture was employed as anode material, in which heterostructured CoMoP$_2$ and MoP nanoparticles were coated on N, P co-doped carbon matrix. Notably, doped micro-lamellated carbon sheets could not only allow boosted lithium ion and electron transport but also alleviate the volume changes of active material to sustain anode integrity during the discharge/charge processes. More importantly, the combination of CoMoP$_2$ and MoP nanoparticles could synergically strengthen the electrochemical activities of the anodes, and their built-in heterojunction facilitated the reaction kinetics on their interfaces. This research may offer a rational design on both heterostructure and doping engineering of future anodes for lithium-ion batteries.

1 Introduction
From the creation of Leyden jar to here various batteries, the unceasing evolution of energy storage system was a witness for the entire human modern civilization [1–3]. Owing to relatively stable cycle performance, high energy and operating voltage, and sufficient range of use, safety, and no memory effect, lithium-ion batteries (LIBs) realized extensive commercialization, which has already occupied the market of cars, mobile phones, laptops, and most energy equipment [4–6]. It is evident that carbon as current commercial anode material, however, allows only one lithium-ion intercalated in six carbon atoms, and this could result in battery performance instability as a result of the volume expansion during lithium-ion insertion/extraction processes and inferior electrical conductivity, although not as serious as silicon [7], apparently hindering its electrochemical performance. Therefore, a quite low theoretical capacity of about 372 mAh g$^{-1}$ was delivered, which is far away from the increasing pressure of fuel crisis and the emerging demand of future applications [8–11]. Such as it is, by the way of loading other active materials with rational architecture design, the
carbon-based materials are expected to exhibit extraordinarily electrochemical performance in LIBs to address the aforementioned issues.

Because of their high theoretical capacities (500–1800 mAh g$^{-1}$), low polarization, and comparatively low intercalation potentials vs. Li/Li$^+$ [12–14], numerous research efforts have been devoted to transition metal phosphides (TMPs) as anode materials for LIBs in recent years. To be honest, they could react completely with lithium ions via conversion reaction formula of $\text{M}_x\text{P}_y + 3\text{yLi}^+ + 3\text{ye}^- \leftrightarrow y\text{Li}_3\text{P} + x\text{M}^0$ during the discharge process, and it is obvious that one P atom could offer three positions for lithium-ion combination, which delivers a much higher specific capacity than that of carbon anode [15]. In addition, as a result of their electrochemical nature, TMPs typically exhibit triangular prism structure, where their metal atoms occupy in the apex positions and phosphorus atoms take the inner spaces of triangular prism [16], and this unique structure is believed to provide more active sites to improve electrochemical properties of TMP anodes. Although such a lot of merits the TMPs feature, two major shortcomings restrict the practical application of TMP materials in LIBs. One is their inferior intrinsic electrical conductivity, resulting in a poor kinetics in the electrochemical reactions. Another is the volume changes in the charging/discharging processes, leading to severe pulverization and exfoliation of the active material within limited cycles. Decorating TMPs onto a carbon-based matrix is an effective way to deal with these matters, mainly because carbon matrix could relieve the volume changes and shorten the pathway of lithium-ion transition during shuttling. For instance, Wang et al. found that FeP could ameliorate the ionic conductivity and alleviate the volume changes in the processes of ion insertion and desertion, benefiting from the fact that Fe–P distance is larger than that of the lithium-ion diameter, and their hollow FeP@carbon nanocomposite encapsulating in graphene could provide more active sites, thus delivering excellent electrochemistry performance in both lithium-ion and sodium-ion batteries [14]. Except for this, it is evident that fruit of research on metal phosphides have also been conducted in power source fields, including Ni$_2$P immobilized on reduced graphene oxide [17], hollow carbon nanosheet encapsulated Cu$_3$P [18], CoP@C intertwined with N-doped carbon nanotubes [19], and MoP/Mo$_2$C@C [20]. Interestingly, metal-rich TMPs with the formula of $\text{M}_x\text{P}_y$ ($x/y \geq 1$) normally display a character of metal materials, because of the existence of strong intensive M-M interactions [21]. On the contrary, with regard to phosphorus-rich TMPs ($x/y \leq 1$), most of their bonds are P-P or M-P. The more P atoms exist, the easier the P atoms gather together, leading to inferior properties in electrical conductivity and poor material stability [22].

It is worth noting that unitary TMPs can only offer single anionic active sites, while binary TMPs could provide more active sites to remarkably activate the lithium-ion insertion/extraction processes. Moreover, metal atoms in binary TMPs tend to form a triangular structure in an ordered way, and the center positions accommodate P atoms, which endows TMPs abundant electronic transmission channels [23] and good accommodated ability of lithium ions [24]. As an example of binary phosphides, Chen et al. reported that the Co substitution for Fe in FeP could result in increased density of states near Fermi level, significantly improving the intrinsic electrochemical activity of Co–Fe–P composite [25].

Among binary TMPs, CoMoP$_2$ and CoMoP have been intensively studied in hydrogen evolution reaction (HER) [26–30], oxygen evolution reaction (OER) [29], and oxygen reduction reaction (ORR) [24]. To the best of our knowledge, they have not been functioned as anode materials for LIBs up to now, and such binary TMP materials, honestly, could enable desired atom distribution of Co, Mo, and P, which is expected to deliver an impressive effect for enhancing LIB performance.

Recently, heterostructures have been attracted a lot of attention in the research fields of photocatalysis [31], HER [32], water splitting [33], and microwave absorption [34]. It has been widely proved that with the distinct band gaps compounded in different components, the differences in Fermi energy levels combined together could build up an equilibrium of equal Fermi energy levels [35], thereby generating a space charge region, which could accelerate the charge transport and the interface reaction kinetics [36–38]. According to the reports from Shen et al. [39], the heterostructures consisting of MoO$_2$ and MoP could increase the flat band potentials as a result of their Mott-Schottky defects, promoting the electron/hole separation and modulating electron migration between two pure materials to enable superior electrical conductivity. Enlightened by the unique architecture construction with different materials via physical and chemical combinations, heterostructures are desired to perfect the electrochemical properties for LIBs.

Herein, sandwich-like CoMoP$_2$/MoP heterostructures coupling N, P co-doped carbon nanosheet (CoMoP$_2$–MoP@NPC) composites were successfully prepared through the process of solution evaporation and calcined treatment with regulating the addition contents of urea. It is believed that the NPC matrix with a multilayered micro-/nano-architecture could not only supply a highly conductive network for facilitated transformation of lithium ions and electrons but also promote the effective penetration of electrolyte and aid in easing the volume changes of the active CoMoP$_2$/MoP heterostructures during cycling, beneficial for realizing their full electrochemical activities for lithium-ion storage.
2 Experimental section

2.1 Synthetic procedures

200 mg of glucose, different amount of urea, 131 mL H$_3$PO$_4$, 275 mg of Co(NO$_3$)$_2$·6H$_2$O, and 170 mg of (NH$_4$)$_6$Mo$_7$O$_24$ were first dispersed into 40 mL deionized water under vigorously stirring. Afterwards, the solutions were then dried in an oven at 80 °C until all the solvent evaporated. Finally, the purple resultant was transferred into a tube furnace and heated in argon flow at 900 °C for 2 h with a ramp of 3 °C min$^{-1}$. After cooling down to room temperature, CoMoP$_2$/MoP@NPC composites were achieved, which are denoted as CMP@PC, CMP-2@NPC, and CMP-4@NPC, with the urea addition amounts were 0, 2, and 4 g, respectively. NPC was also fabricated as the same preparation route without employing Co(NO$_3$)$_2$·6H$_2$O and (NH$_4$)$_6$Mo$_7$O$_24$. The synthesis digital photos are seen in Fig. S1.

2.2 Physical characterizations

The crystalline and phase structures of as-prepared samples were studied by X-ray diffraction (XRD, Rigaku D/Max-r B) with monochromatic Cu-Kα (λ = 1.5418 Å) line as the radiation source. The sample morphologies were inspected using field emission scanning electron microscope (FESEM, SU-70) and transmission electron microscope (TEM, JSM-7800F), and element information was collected by energy dispersive X-ray spectrometer (EDX) with an accelerating voltage of 20 kV equipped on the FESEM. The sample components were characterized by Raman spectroscopy (LabRam HR Evolution) with a 532 nm excitation laser. X-ray photoelectron spectroscopy (XPS, ESCALAB 250XI) was performed to analyze the surface chemical environment and composition, and all the XPS spectra were calibrated by C 1 s = 284.8 eV. ASAP 2020 Micrometrics analyzer was utilized to research the N$_2$ adsorption/desorption characteristics. The mass ratio of Co/Mo was acquired through the inductively coupled plasma (ICP, Agilent 5110).

2.3 Electrochemical measurements

To test the electrochemical performance, a slurry consisting of 20 wt% Super P as the conductive agent, 10 wt% polyvinylidene fluoride (PVDF) as the binder, and 70 wt% active materials were dispersed in N-methylpyrrolidone as the solvent. It was then homogeneously bladed on the copper foil and sent into a vacuum oven at 120 °C overnight. Using these as-prepared anodes, CR2032 cells were assembled with a Li disk as the counter and reference electrode in an argon-filled glovebox. The electrolyte is composed of 1 M LiPF$_6$ in ethylene carbonate (EC) and diethyl carbonate (DEC) with a volume ratio of 1/1. The electrochemical performance of Li-ion cells was tested on a LANHE CT2001A battery tester at room temperature with the cutoff voltage between 0.01 and 3 V. Cyclic voltammetry (CV) and electrochemical impedance spectroscopy (EIS) data were recorded by using an electrochemical workstation (PARSTAT 2273).

3 Results and discussion

As depicted in Fig. 1, the synthetic process of CoMoP$_2$-MoP@NPC composites was performed via a simple and effective route. Specifically, glucose, urea, H$_3$PO$_4$, Co(NO$_3$)$_2$·6H$_2$O, and (NH$_4$)$_6$Mo$_7$O$_24$ were added in deionized water under continuous stirring to form a reaction solution. After evaporating the solvent, the resultant was transferred into tube furnace for annealing activation, and composite material could be successively achieved.

FESEM observation of precursors were conducted, as shown in Fig. S2, and it could be seen that the morphology of NPC precursor seems like a cheese. With the increase of
urea addition contents, precursors of CMP@PC, CMP-2@NPC, and CMP-4@NPC presented apparent porous composition with more particles.

It was observed that NPC exhibit a lamellated structure in Fig. 2a, and CMP-2@NPC show a sandwich structure fully loaded with nanoparticles inside in Fig. 2b. Similar structure of CMP-4@NPC is seen in Fig. S3, inferring that the NPC could play a vital role in homogenizing distribution of nanoparticles, and as for CMP@PC, the nanoparticles formed uneven clusters. As depicted in Fig. 2c, the TEM image indicates that these nanoparticles uniformly distributed throughout the layered nanosheets, and HRTEM results are also recorded and shown in Fig. 2d. It could be clearly seen that the interplanar distances of two contiguous lattice fringes labeled by the purple and blue squares are 0.210 and 0.232 nm, corresponding to the (103) planes of the CoMoP₂ and (101) planes of the MoP, respectively, and interplanar distances of 0.334 nm are attributed to (002) planes of the graphitic matrix. These results turn out the existence of the heterostructures containing CoMoP₂ and MoP nanoparticles loaded on the carbon sheets. The selected area electron diffraction (SAED) pattern of the CMP-2@NPC is shown in Fig. 2e, demonstrating the diffraction rings matched well with lattice planes of (103) and (104) for CoMoP₂, (101) for MoP, and (002) for graphitic matrix, respectively. The elemental mapping images are collected and presented in Fig. 2f–k, manifesting the uniform distribution of Co, Mo, N, and P elements on the composite material. In order to learn the proportion of different ingredients in CMP-2@NPC, EDX measurement was performed, and the relative data is provided in Fig. S4. It is calculated that the mass ratio of CoMoP₂/MoP is 1.53/1, and the carbon matrix accounts for 25.94 wt% of the total composite material. According to the ICP result in Table S1, the mass ratio of Co/Mo is 37.68/62.32, and it was deduced that the mass ratio of CoMoP₂/MoP is 1.51/1, which is close to EDX result.

Depicted in Fig. 3a, XRD patterns exhibit the crystalline structures of different samples. XRD pattern of the NPC shows a wide peak alone at about 26°, accorded with the (002) planes of graphitic material. Notably, with the change of urea contents, three samples display different compositions. Specifically, the phases of CMP@PC, CMP-2@NPC, and CMP-4@NPC were identified with CoMoP₂-MoP, CoMoP₂-MoP, and CoMoP₂, respectively, and all these peaks could be indexed by CoMoP₂ (JCPDS, No. 33–0428), CoMoP (JCPDS, No. 32–0299), and MoP (JCPDS, No. 24–0771). XRD results of NPC, CMP-2@NPC, and CMP-4@NPC precursors in Fig. S5 demonstrate that their main crystal phase is urea, and the precursor of CMP@PC appears a wide peak, owing to the absence of urea.

To investigate the degree of defects and graphitization on carbon matrix, Raman spectra of as-synthesized samples
were employed, as shown in Fig. 3b. Two characteristic peaks could be seen at about 1346 and 1590 cm\(^{-1}\), assigned to the D band and the G band, respectively, verifying carbon materials existed in these composites. As it is well known that the D band is associated with the disorders and defects in the graphene, caused by the point defects like nitrogen, phosphorus doping, displacements, and distortions in the crystal faces, while the G band is related to the in-plane stretching vibration of sp\(^2\)-bonded carbon [40, 41]. Consequently, the intensity ratio of the D band and the G band (\(I_D/I_G\)) reveals the degree of defects and disorders on the carbon matrix. It was traced that \(I_D/I_G\) of NPC, CMP@PC, CMP-2@NPC, and CMP-4@NPC are 0.765, 0.639, 0.932, and 0.849, respectively, and the largest \(I_D/I_G\) value of CMP-2@NPC illustrates the formation of more active sites and defects on the carbon matrix, which could improve its electrochemical performance in a certain degree.

The specific surface area and pore size distribution of CMP-2@NPC was tested through the Brunauer–Emmett–Teller (BET) \(N_2\) isothermal adsorption–desorption measurement. As can be seen in Fig. 3c, the isotherm curve is corresponding to type H3 hysteresis loop in the \(P/P_0\) range of 0.4–1.0, which shows a saturated adsorption platform and demonstrates the formation of uniform mesopores. It is calculated that the specific surface area of CMP-2@NPC is 75.368 m\(^2\) g\(^{-1}\), and the pore volume is 0.069 cm\(^3\) g\(^{-1}\). The pore size distribution curve analyzed by the BJH method inserted in Fig. 3c suggests a sharp peak located within 3–10 nm. This unique structure with sandwiched nanoparticles in the multilayered N, P co-doped carbon nanosheets is deem as a perfect accommodation to ease the volume expansion of CMP-2@NPC material during the lithiation/delithiation processes, shortening the lithium-ion transition distances and advancing the battery reversibility.
XPS measurement of CMP-2@NPC was conducted to investigate the surface elemental chemical compositions and the bonding configurations. The survey spectra in Fig. 3d overview the elements existing in CMP-2@NPC, and based on which, the N and C weight ratio on the NPC matrix could be roughly estimated to be 6.97%. The weight ratio of doped P and C can be affirmed to 3.43% according to the high-resolution XPS spectra of C 1 s in Fig. 3e, and the peaks at binding energies of 284.8, 285.8, and 289.6 eV are matched well with C–C, C–N, and C–P signals, implying the co-doped nature with N and P on carbon matrix [24]. As shown in high-resolution XPS spectra of Co 2p in Fig. 3f, doublets of Co 2p3/2 at 779.1 and 782 eV are ascribed to the Co-P and Co–O bonds, respectively, with a satellite peak located at 786.6 eV, well with C binding energies of 284.8, 285.8, and 289.6 eV are matched.

To elucidate the reactions at different potentials, CV curves of CMP-2@NPC was conducted to investigate the surface oxidation of MoP. In the following cycles, the SEI layer peak disappeared, and a series of redox pairs located at 0.65 and 1.28 V appeared, which can be attributed to the reversible phase transition of Li2CoMoP2 and Li2MoP in the lithium-ion insertion and disembedding processes. Additionally, the subsequent cycles display a similar characterization in the oxidation and reduction reactions, and the peaks overlapped and their positions almost unchanged, indicating an excellent reversible behavior and excellent stability.

Rate performance of the CMP-2@NPC anode for LIBs was researched, as given in Fig. 4b. It is revealed that at current densities of 100, 200, 400, 800, and 1500 mA g−1, its specific capacities are 581, 524, 470, 407, and 360 mA h g−1, respectively. Even at a high current density of 2000 mA g−1, the corresponding reversible specific capacity still remained 344 mA h g−1, and this specific capacity retention is 59.2% relative to that at 100 mA g−1. When the current density returned back to 100 mA g−1, the specific capacity recovered to 626 mA h g−1, even higher than that of the initial cycles. This highly reversible specific capacity was stable in the following cycles, resulting in favorable retention capability of CMP-2@NPC anode.

An oxidation peak raised at about 1.25 V in the first anodic sweep, which could be assigned to the transformation from Li3P to CoMoP2 and MoP. In the following cycles, the SEI layer peak disappeared, and a series of redox pairs located at 0.65 and 1.28 V appeared, which can be attributed to the reversible phase transition of Li2CoMoP2 and Li2MoP in the lithium-ion insertion and disembedding processes.
slight increase in cycling process, which could mainly be attributed to the robust structure of carbon matrix, as well as the important role of doped N [56–58].

Even at 500 mA g⁻¹ in Figs. 4e and S6, the CMP-4@NPC, CMP-2@NPC, and CMP@PC anodes delivered the retentive specific capacity of 607.6, 689.3, and 514.3 mAh g⁻¹ after 700 cycles, respectively. Besides, the cycling performance of CMP-2@NPC anode at 1 A g⁻¹ is also included in Fig. S7, and it still exhibited about 530 mAh g⁻¹ after 900 cycles with the similar phenomenon occurred. This enhanced specific capacity was mainly as a result of the activation processes, which has been widely reported in other conversion-type and transition metal phosphide anodes for LIBs [19, 52, 59]. Table. S2 provides the electrochemical performance of various TMPs anode for LIBs, and it could be seen that the CMP-2@NPC outperforms most of TMPs anodes under similar conditions, illustrating it an efficient material for LIBs.

In order to excavate the transport kinetics of the CMP-2@NPC anode, its EIS data were provided with the equivalent circuit model inserted. Fig. S8 shows the EIS profiles of CMP-2@NPC anode monitored after 200, 400, and 600 cycles. Normally, the semicircle seated at middle-frequency region is assigned to the charge transfer resistance ($R_c$) with the double-layer capacitance ($C_d$). It is worth noting that $R_c$ after 200, 400, and 600 cycles gradually become smaller. These results are well consisted with the discharge/charge profiles showing an obvious specific capacity increase, and this phenomenon could also be attributed to the activation treatment, which greatly improved the cycling performance [19]. The electrochemical function of heterostructure between the two lattice planes were schematically presented in Fig. 5.
4 Conclusion

In summary, CoMoP$_2$-MoP@NPC composites were successfully synthesized through a facile strategy of directly annealing the evaporated reactants, in which the heterostructures consist of CoMoP$_2$ and MoP nanoparticles were sandwiched in NPC nanosheets. Thanks to the unique architecture, the transportation acceleration of lithium ions and electrons was realized, and the volume changes during the lithiation duration was released. Therefore, the composite anode delivered a surpassed specific capacity of 693.2 mAh g$^{-1}$ after 150 cycles at 100 mA g$^{-1}$, and similar electrochemical performance occurred even at 500 mA g$^{-1}$, attributed to the activation processes during cycling. These superior electrochemical properties demonstrate CoMoP$_2$-MoP@NPC composites can be served as efficient anode materials for LIBs, with the expectation for other transition metal phosphides applied in various energy-related fields.
