Across plant species, leaves vary enormously in their size and their venation architecture, of which one major function is to replace water lost to transpiration. The leaf hydraulic conductance (\(K_{\text{leaf}}\)) represents the capacity of the transport system to deliver water, allowing stomata to remain open for photosynthesis. Previous studies showed that \(K_{\text{leaf}}\) relates to vein density (vein length per area). Additionally, venation architecture determines the sensitivity of \(K_{\text{leaf}}\) to damage; severing the midrib caused \(K_{\text{leaf}}\) and gas exchange to decline, with lesser impacts in leaves with higher major vein density that provided more numerous water flow pathways around the damaged vein. Because xylem embolism during dehydration also reduces \(K_{\text{leaf}}\), we hypothesized that higher major vein density would also reduce hydraulic vulnerability. Smaller leaves, which generally have higher major vein density, would thus have lower hydraulic vulnerability. Tests using simulations with a spatially explicit model confirmed that smaller leaves with higher major vein density were more tolerant of major vein embolism. Additionally, for 10 species ranging strongly in drought tolerance, hydraulic vulnerability, determined as the leaf water potential at 50% and 80% loss of \(K_{\text{leaf}}\), was lower with greater major vein density and smaller leaf size (|\(r| = 0.85–0.90; P < 0.01\)). These relationships were independent of other aspects of physiological and morphological drought tolerance. These findings point to a new functional role of venation architecture and small leaf size in drought tolerance, potentially contributing to well-known biogeographic trends in leaf size.

Leaf venation architecture has common functions across plant species, serving for mechanical support (Niklas, 1999), sugar and hormone transport (Kehr and Buhtz, 2008), and the replacement of water lost to transpiration during photosynthesis (Sack and Holbrook, 2006). However, venation architecture is highly diverse across species (Uhl and Mosbrugger, 1999; Roth-Nebelsick et al., 2001; Sack and Frole, 2006; Ellis et al., 2009; Brodribb et al., 2010). In dicotyledons, the leaf venation system typically consists of three orders of major veins and up to five higher orders of minor veins embedded in the mesophyll, with the vein orders arranged in a hierarchy; lower order veins are larger in diameter, with greater xylem conduit numbers and sizes, whereas higher order veins have greater length per area (vein density; Sack and Holbrook, 2006; McKown et al., 2010). Species vary strongly in the density of given vein orders and their conductivities (Cochard et al., 2004b; Sack and Frole, 2006). The aim of this study was to test for novel functional consequences of variation in leaf venation architecture and leaf size, and particularly a role in drought tolerance. The leaf is a critical component in the plant water transport system, accounting for 30% or more of whole-plant hydraulic resistance (Sack and Holbrook, 2006). The leaf hydraulic conductance (\(K_{\text{leaf}}\); flow rate/water potential driving force, i.e. the inverse of hydraulic resistance) quantifies a complex microhydrological system, including the conductances in series of the vein xylem (\(K_x\)) and the mesophyll pathways outside the xylem (\(K_{\text{ox}}\)). The venation architecture is thus an important determinant of \(K_{\text{leaf}}\) and its dynamics. Total vein density is a determinant of both \(K_x\) and \(K_{\text{ox}}\), because, all else being equal, higher densities represent more numerous xylem flow pathways in parallel per leaf area and shorter pathways for water movement outside the xylem (Sack and Frole, 2006; Brodribb et al., 2007; McKown et al., 2010). Additionally, venation structure may contribute to the ability of \(K_{\text{leaf}}\) to withstand vein damage (Sack et al., 2008). Minor veins had been classically hypothesized to

provide “conductive overload,” consisting of many parallel pathways for water flow such that a leaf could tolerate hydraulic disruption of major veins (Wylie, 1938). However, detailed studies found that $K_{\text{leaf}}$, stomatal conductance, and photosynthesis were very sensitive to damage of the large major veins, which supply water to the downstream vein hierarchy (Nardini et al., 2001; Huve et al., 2002; Nardini and Salleo, 2003; Sack et al., 2003a; Salleo et al., 2003; Delaney and Higley, 2006). Additionally, the impact of severing the midrib near its base differed among species. The decline of $K_{\text{leaf}}$ was lower in palmately than in pinnately veined species, with greater major vein density providing flow pathways around the disrupted vein (Sack et al., 2008). The impact of midrib damage on $K_{\text{leaf}}$ also varied among pinnately veined species. Smaller leaves, with their major veins spaced more closely and thus greater major vein densities, had greater tolerance of midrib damage (Sack et al., 2008).

Just as for leaves with damaged veins, $K_{\text{leaf}}$ declines in dehydrating leaves, resulting in reductions of leaf gas exchange and whole-plant growth (Salleo et al., 2000; Brodribb and Holbrook, 2003; Sack and Holbrook, 2006; Johnson et al., 2009b). The $K_{\text{leaf}}$ decline with dehydration arises at least in part from embolism in the vein xylem (Kikuta et al., 1997; Salleo et al., 2000, 2001; Nardini et al., 2003; Trifilo et al., 2003a, 2003b; Cochard et al., 2004a; Brodribb and Holbrook, 2005; Choat et al., 2005; Brodribb et al., 2009; Johnson et al., 2009a). Cavitation in turn will depend on the intrinsic vulnerability of each vein, with major veins likely to be more vulnerable because of their long and wide conduits (Choat et al., 2005). We hypothesized that higher major vein density, by providing transport pathways around embolized major veins, would confer tolerance of $K_{\text{leaf}}$ to dehydration, i.e. more negative leaf water potential values ($\Phi_{\text{leaf}}$) at 50% and 80% loss of $K_{\text{leaf}}$ ($P_{50}$ and $P_{80}$, respectively). Such a role for leaf venation could be important in the optimization of leaf size. Leaf size is highly variable across environments, with smaller leaves more frequent in dry habitats, both within and among species (Givnish, 1987; Sultan and Bazzaz, 1993; Gibbons, 1998; Cunningham et al., 1999; Ackerly, 2003, 2004), as well as among community assemblages (Dolph and Diersch, 1980; Fonseca et al., 2000). One advantage for small leaves is their thinner boundary layer, enabling more rapid convective cooling (Vogel, 1968, 1970; Parkhurst and Loucks, 1972; Gibbons, 1998; Vogel, 2009; Nobel, 2010). Additionally, there may be a direct hydraulic benefit of small leaves, if their greater major vein redundancy protects $K_{\text{leaf}}$ from decline and thus contributes to drought tolerance. To test these hypotheses, we conducted computer simulations of the impact of vein cavitation on $K_{\text{leaf}}$. We compared theoretical results with experimentally measured relationships among leaf hydraulic vulnerability, leaf size, venation architecture, and other aspects of leaf drought tolerance for species diverse in leaf form and drought sensitivity.

**RESULTS**

**Impacts of Vein Cavitation Depend on Venation Architecture: Computer Simulations**

Simulations implemented in the program $K_{\text{leaf}}$ showed that the impacts of vein cavitation depended on vein density and leaf size (Fig. 1; Table I). Leaves were simulated of different sizes but with the same number of second-order (2$^\text{nd}$) veins; thus, larger leaves had their 2$^\text{nd}$ veins spaced farther apart, and major vein density declined geometrically with increasing leaf size (major vein density = 1.194 × leaf size$^{-0.5}$, $r_p = 0.999$, $P < 0.001$). By contrast, across the simulated leaves, minor vein density was varied independently of leaf size ($r_p = 0.02$, $P = 0.89$). $K_s$ for uncavitated leaves correlated positively with both major vein density and minor vein density ($r_s = 0.75$, $P < 0.001$ and $r_s = 0.15$, $P = 0.01$ respectively).

When major veins were reduced by 90% in cross-sectional conductivity to simulate the dysfunction of conduits due to embolism, the smaller leaves with greater major vein density showed a lesser impact on total xylem and whole-leaf hydraulic conductance per leaf area ($K_x$ and $K_{\text{leaf}}$), i.e. a lower percentage loss of conductance [PLC; Fig. 1A]. Thus, across simulated leaves, the PLC of $K_x$ resulting from major vein cavitation correlated negatively with major vein density ($r_p = −0.85$, $P < 0.001$). For the simulated leaves with cavitated major veins, the $K_x$ itself correlated strongly with minor vein density, due both to the increase of maximum $K_x$ by higher major vein density and the

![Figure 1](image-url)
The ratio of major to minor vein density (Fig. 1C; \( K \) vein density, due both to the increase of maximum major vein density, but also positively correlated with major vein density, but negatively correlated with minor vein density (\( r = -0.08; p = 0.57 \)), because the greater \( K \) conferred by higher minor vein density was counteracted by a greater sensitivity to major vein cavitation. Overall, because of the contrasting effect of major and minor vein density, the PLC of \( K \) due to the cavitation of major veins was least for leaves with highest major vein density and lowest minor vein density and correlated negatively with the ratio of major to minor vein density (Fig. 1C; \( r = -0.97; p < 0.001 \)).

When the minor veins rather than the major veins were cavitated, \( K \) and \( K_{leaf} \) had a different dependency on venation architecture. When minor veins were reduced by 90% in cross-sectional conductivity to simulate cavitation, the smaller leaves with greater major vein density showed higher PLC of \( K \) (Fig. 1B). Thus, across simulated leaves, the PLC of \( K \), resulting from minor vein cavitation was positively related to major vein density (\( r = 0.77; p < 0.001 \)). By contrast, a higher minor vein density reduced the impact of cavitation of the minor veins on the \( K \) (Fig. 1B). Thus, across the simulated leaves, the PLC of \( K \), resulting from minor vein cavitation was negatively correlated with minor vein density (\( r = -0.48; p = 0.001 \)). For the simulated leaves with cavitated minor veins, the \( K \) itself correlated positively with minor vein density, due both to the increase of maximum \( K \) by higher minor vein density and the protective role of high minor vein density (\( r = 0.66; p < 0.001 \)). For these simulated leaves with cavitated minor veins, the \( K \) also positively correlated with major vein density, but more weakly than for uncavitated leaves, because the increase of maximum \( K \) due to higher major vein density was counteracted by the greater PLC driven by minor vein cavitation in leaves with higher major vein density (\( r = 0.35 \) rather than 0.75, \( p < 0.001 \)). Overall, the PLC of \( K \) resulting from cavitation of the minor veins was strongly positively correlated with the ratio of major to minor vein density (Fig. 1C; \( r = 0.92; p < 0.001 \)).

Notably, in the model simulations, the PLC of \( K \) resulting from major vein cavitation varied widely across the entire range of tested leaves with different major and minor vein densities (22%–87%; Fig. 1, A and C). By contrast, the PLC of \( K \) resulting from minor vein cavitation was less variable and very strong across the entire range of tested leaves (62%–90% and more than 80% for most simulated leaves; Fig. 1, B and C).

### Diversity in Leaf Venation and Drought Tolerance Traits across Species of Moist and Dry Habitat

Across the 10 species diverse in drought tolerance, there were strong differences in leaf hydraulic conductance at full hydration (\( K_{max} \)) and in their vulnerability to dehydration. The species varied in \( K_{max} \), \( P_{50} \), and \( P_{90} \) by 12- to 32-fold. The \( K_{max} \) varied from 2.96 to 34.1 mmol m\(^{-2} \) s\(^{-1} \) MPa\(^{-1} \) for Comarostaphlos diversifolia and Platanus racemosa, in \( P_{90} \) from −0.09 to −2.85 MPa for \( P. \) racemosa and \( C. \) diversifolia; and in \( P_{90} \) from −0.35 to −5.25 MPa for \( P. \) racemosa and Cercocarpus betuloides (Supplemental Table S1).

The species differed strongly in leaf venation architecture and gross morphology, with substantial variation between moist and dry habitat species (Table II; Supplemental Table S1). Species varied 4-fold in major vein density, 3-fold in minor vein density, and 7-fold in the ratio of major to minor vein density. Species of moist and dry habitats did not differ significantly in minor and total vein densities (\( p = 0.11–0.74 \)), but dry habitat species had 18% higher major vein density (with 14%–18% higher midrib, 2°, and third-order [3°] vein densities) and 50% higher ratio of major to minor vein density. Moist habitat species had 24% more free-ending veinlets per area, 13% higher minor vein diameters, and 14% higher number of 2° veins than dry

| Leaf Simulation | Cavitation in Major Veins | Cavitation in Minor Veins |

habitat species (P < 0.001). Moist and dry habitat species did not differ in the diameters of their major veins (Supplemental Table S1). Species varied 18-fold in leaf area, with dry habitat species having on average 30% smaller leaves than moist habitat species. Leaf shape indices (length:width and perimeter squared: area) did not differ between habitats (P = 0.35–0.46).

Several venation traits correlated with leaf size. The densities of first-order (1ˢ), 2ⁿ, and 3ⁿ veins declined with increasing leaf size (r_p and r_s = −0.70 to −0.92, P < 0.05), as did the total major vein density (r_p = −0.95, r_s = −0.89, P < 0.001; Figs. 2A and 3) and the ratio of major to minor vein density (r_p = −0.67, r_s = −0.70, P = 0.03). Major vein density declined geometrically with increasing leaf size (i.e. with an exponent of −0.5; Fig. 2A). By contrast, minor vein density was independent of leaf size (r_p and r_s = −0.10 to −0.20, P > 0.05; Figs. 2B and 3). as were total vein density (as minor vein density accounted for 73%–95% of total vein density), vein diameters, and the number of free-ending veinlets per area (|r_p| and |r_s| = 0.02–0.43, P > 0.05; Fig. 3; Supplemental Table S2).

Species of dry habitats also had greater expression of leaf drought tolerance traits than species from moist habitats, with 14% higher leaf mass per area (LMA), 11% thicker leaves, 18% higher modulus of elasticity, 15% to 16% more negative values for osmotic potential at full turgor and at turgor loss point, and 30% lower cuticular conductance. By contrast, species of moist habitats had on average 2- to 3-fold higher saturated water content and capacitances before and after turgor loss point (Supplemental Table S1; P < 0.001).

Relationships among Hydraulic Vulnerability, Venation, and Other Drought Tolerance and Morphological Traits

Across species, P_50 and P_80 were strongly correlated, and more negative values occurred in leaves with higher major vein density and smaller leaf size (|r_p| and |r_s| = 0.78–0.90, P < 0.01; Figs. 3 and 4; Supplemental Table S2). These relationships for the major vein system also held for component vein orders; the densities of 1ˢ, 2ⁿ, and 3ⁿ veins, all intercorrelated, were greater in leaves with more negative P_50 and P_80 (|r_p| and |r_s| = 0.64–0.90, P < 0.01). Because leaf size and major vein densities were themselves negatively correlated (Fig. 2A), no correlation could be observed of leaf hydraulic vulnerability with leaf size or with major vein density independently of the other. Thus, in a partial correlation analysis, the relationships of P_50 and P_80 with leaf area were not significant after partialing out major vein density, and their relationships with major vein density were not significant after partialing out leaf area (|r_p| and |r_s| = 0.08–0.29, P > 0.05). By contrast with major vein densities, other vein traits did not correlate with P_50 or P_80, including the
minor vein density, total vein density, number of secondary veins, vein diameters, and number of free-ending veinlets per area ($r_p = 0.01–0.57$, $P > 0.05$). The ratio of major to minor vein density was positively correlated with $P_{50}$ and $P_{80}$ ($r_p$ and $r_s = 0.67–0.77$, $P < 0.05$; Supplemental Table S2).

Leaf hydraulic vulnerability also correlated with several other drought tolerance traits. The osmotic potentials at full and zero turgor, which were intercorrelated ($r_s = 0.95–0.98$, $P < 0.001$), both correlated with $P_{50}$ and $P_{80}$ ($r_p$ and $r_s = 0.71–0.85$, $P < 0.05$; Supplemental Table S2). Leaves with higher LMA values tended to have more negative $P_{80}$ ($r_p$ and $r_s = 0.71–0.73$, $P < 0.05$; Supplemental Table S2), but LMA was not correlated with $P_{50}$ ($P > 0.05$). However, both $P_{50}$ and $P_{80}$ were independent of other aspects of venation architecture and leaf morphology and physiology, including leaf shape indices (length:width and perimeter squared:area), the modulus of elasticity, capacitances at full and zero turgor, saturated water content, leaf thickness and density, and cuticular conductance ($P > 0.05$; Supplemental Table S2).

The linkage of hydraulic vulnerability ($P_{50}$ and $P_{80}$) with major vein density was independent from the relationships of hydraulic vulnerability to other leaf drought tolerance traits. The linkage of $P_{50}$ or $P_{80}$ with major vein density was apparently more fundamental. Thus, partialing out LMA or osmotic potentials at full

B, The independence of minor vein density from leaf area. Gray circles represent dry habitat species, and white circles represent moist habitat species. Fitted regression in A: major vein density = 0.32 × leaf area $^{0.35}$, *** $P < 0.001$, NS $P > 0.05$.

**Figure 3.** Relation of the vulnerability of $K_{wax}$ to major and minor vein densities for 10 species varying strongly in drought tolerance. Vulnerability curves are plotted in the left column; each point represents a different measured leaf ($n = 26–74$ per curve). For each vulnerability curve, the fitted line is the maximum likelihood function for a given species (linear for *C. sasanqua*, *C. diversifolia*, *Q. agrifolia*, and *H. arbutifolia*; logistic for *M. grandiflora*, *P. racemosa*, *H. annuus*, *H. canariensis*, and *L. camara*; and sigmoidal for *C. betuloides*; $r^2 = 0.39–0.89$, $P < 0.001$; see “Materials and Methods”) and the vertical line represents the water potential at $P_{80}$. Leaf schematics are drawn to scale with major veins (1/C and 2/C veins) and minor veins make up the rest of the network.
and zero turgor did not remove the correlation of $P_{50}$ or $P_{80}$ with major vein density ($r_{\text{partial}} = 0.68–0.78$, $P < 0.05$). However, when partialling out the effect of major vein density on $P_{50}$ or $P_{80}$, their correlations with LMA and with osmotic potentials at full and zero turgor were lost ($|r_{\text{partial}}| = 0.04–0.29$, $P > 0.05$). Notably, the $K_{\text{max}}$ did not correlate with any venation architecture or morphological trait, including leaf size or leaf drought tolerance, for this set of diverse leaves ($P > 0.05$).

DISCUSSION

The Importance of Major Vein Density and Leaf Size in Resistance to Drought

We found novel, strong correlations of $P_{50}$ and $P_{80}$ with major vein density and leaf size across 10 species with diverse leaves, consistent with findings from the computer model simulations. All else being equal, leaf and whole-plant drought resistance would be conferred by a higher major vein density, which is generally associated with small leaf size (Dunbar-Co et al., 2009; McKown et al., 2010).

Such a role for venation and leaf size in determining hydraulic vulnerability has important potential ecological and biogeographic implications. A link between leaf size and $P_{50}$ and $P_{80}$ provides a new additional mechanism for the ecological distribution of leaf sizes. Leaf size evolves relatively quickly via several independent genetic pathways (Ackerly, 2009; Gonzalez et al., 2010). Small leaves are more common in dry and exposed habitats and larger leaves in moister and/or shaded habitats (Dolph and Dilcher, 1980; Givnish, 1987; Fonseca et al., 2000), and fossil leaf size is thus used as an indicator of past climate (Wilf, 1997). A direct hydraulic benefit of small leaves in drought tolerance, and the greater risk associated with large leaves under dry conditions, should thus be considered in addition to other demonstrated roles for leaf size in determining drought tolerance. A very well-established benefit of smaller leaves in warmer environments is their thinner boundary layer and more rapid convective cooling (Nobel, 1976; Nicotra et al., 2008; Vogel, 2009; Yates et al., 2010). Another advantage of small leaves in exposed conditions is that more leaves can be packed into a smaller space to capture irradiance, although this benefit carries a greater cost in support mass; more branch allocation is needed to support many small leaves than for fewer larger leaves, and this outweighs the lower requirement for petiole and midrib support of smaller leaves (Bragg and Westoby, 2002; Niinemets et al., 2006, 2007).

Future work needs to tease apart the importance of the direct hydraulic mechanism in providing an advantage in drought tolerance for smaller leaves from these other benefits across different species sets.

Is the relationship of hydraulic tolerance of dehydration to leaf size and major vein density necessarily causal? We considered the possibility that these relationships could be coincidental, i.e. that small leaf size and high major vein density on the one hand, and more negative $P_{50}$ and $P_{80}$ on the other hand, might be independently selected in drought-tolerant species. In our study, two lines of evidence supported a causal relationship. First, the relationship was established by the computer simulations of leaves with altered sizes and venation architecture, all else being held fixed. In these simulations, cavitation of the major veins, as often observed during dehydration (see below), was better tolerated by smaller leaves with higher major vein density. Second, the partial correlation analyses of our experimental data showed that the relationship of venation architecture to leaf hydraulic vulnerability was independent of other drought tolerance traits, including turgor loss point ($\pi_{\text{TLP}}$). Indeed, $\pi_{\text{TLP}}$ is the most reliable single predictor of a species’ drought tolerance to our knowledge (Auge et al., 1998; Sack et al., 2003b; Baltzer et al., 2008); thus, if selection for drought tolerance were to result in a coincidental correlation of vulnerability and venation architecture, both should show underlying correlations with $\pi_{\text{TLP}}$. For our 10 species, $P_{50}$ and $P_{80}$ were strongly correlated with $\pi_{\text{TLP}}$ (Crombie et al., 1985; Blackman et al., 2010), but venation architecture was unrelated to $\pi_{\text{TLP}}$. Furthermore, $P_{50}$ and $P_{80}$ lost their relationship with $\pi_{\text{TLP}}$ after partialing out major vein density, whereas they remained correlated with major vein density even after partialing out $\pi_{\text{TLP}}$, indicating that the relationships of $P_{50}$ and $P_{80}$ to major vein density are more directly causal than any relationships with $\pi_{\text{TLP}}$ (Shipley, 2000).

We propose that the relationship between leaf size and hydraulic vulnerability in both simulated and real leaves supports a general mechanism, to be tested in other species sets, including closely related species within lineages in a phylogenetic context, because smaller leaves have evolved reliably in drier habitats (Ackerly et al., 2002; McDonald et al., 2003; Dunbar-Co et al., 2009). We considered the possibility that these relationships could be coincidental, i.e. that small leaf size and high major vein density on the one hand, and more negative $P_{50}$ and $P_{80}$ on the other hand, might be independently selected in drought-tolerant species. In our study, two lines of evidence supported a causal relationship. First, the relationship was established by the computer simulations of leaves with altered sizes and venation architecture, all else being held fixed. In these simulations, cavitation of the major veins, as often observed during dehydration (see below), was better tolerated by smaller leaves with higher major vein density. Second, the partial correlation analyses of our experimental data showed that the relationship of venation architecture to leaf hydraulic vulnerability was independent of other drought tolerance traits, including turgor loss point ($\pi_{\text{TLP}}$). Indeed, $\pi_{\text{TLP}}$ is the most reliable single predictor of a species’ drought tolerance to our knowledge (Auge et al., 1998; Sack et al., 2003b; Baltzer et al., 2008); thus, if selection for drought tolerance were to result in a coincidental correlation of vulnerability and venation architecture, both should show underlying correlations with $\pi_{\text{TLP}}$. For our 10 species, $P_{50}$ and $P_{80}$ were strongly correlated with $\pi_{\text{TLP}}$ (Crombie et al., 1985; Blackman et al., 2010), but venation architecture was unrelated to $\pi_{\text{TLP}}$. Furthermore, $P_{50}$ and $P_{80}$ lost their relationship with $\pi_{\text{TLP}}$ after partialing out major vein density, whereas they remained correlated with major vein density even after partialing out $\pi_{\text{TLP}}$, indicating that the relationships of $P_{50}$ and $P_{80}$ to major vein density are more directly causal than any relationships with $\pi_{\text{TLP}}$ (Shipley, 2000).

We propose that the relationship between leaf size and hydraulic vulnerability in both simulated and real leaves supports a general mechanism, to be tested in other species sets, including closely related species within lineages in a phylogenetic context, because smaller leaves have evolved reliably in drier habitats (Ackerly et al., 2002; McDonald et al., 2003; Dunbar-Co et al., 2009). We considered the possibility that these relationships could be coincidental, i.e. that small leaf size and high major vein density on the one hand, and more negative $P_{50}$ and $P_{80}$ on the other hand, might be independently selected in drought-tolerant species. In our study, two lines of evidence supported a causal relationship. First, the relationship was established by the computer simulations of leaves with altered sizes and venation architecture, all else being held fixed. In these simulations, cavitation of the major veins, as often observed during dehydration (see below), was better tolerated by smaller leaves with higher major vein density. Second, the partial correlation analyses of our experimental data showed that the relationship of venation architecture to leaf hydraulic vulnerability was independent of other drought tolerance traits, including turgor loss point ($\pi_{\text{TLP}}$). Indeed, $\pi_{\text{TLP}}$ is the most reliable single predictor of a species’ drought tolerance to our knowledge (Auge et al., 1998; Sack et al., 2003b; Baltzer et al., 2008); thus, if selection for drought tolerance were to result in a coincidental correlation of vulnerability and venation architecture, both should show underlying correlations with $\pi_{\text{TLP}}$. For our 10 species, $P_{50}$ and $P_{80}$ were strongly correlated with $\pi_{\text{TLP}}$ (Crombie et al., 1985; Blackman et al., 2010), but venation architecture was unrelated to $\pi_{\text{TLP}}$. Furthermore, $P_{50}$ and $P_{80}$ lost their relationship with $\pi_{\text{TLP}}$ after partialing out major vein density, whereas they remained correlated with major vein density even after partialing out $\pi_{\text{TLP}}$, indicating that the relationships of $P_{50}$ and $P_{80}$ to major vein density are more directly causal than any relationships with $\pi_{\text{TLP}}$ (Shipley, 2000).
et al., 2009; Santiago and Kim, 2009). In our modeled leaves and experimental species set, as across species in general, leaf size and major vein density were linked (Dunbar-Co et al., 2009; McKown et al., 2010). Future studies of species similar in leaf size but different in major vein densities are necessary to establish the role of venation independently of size in determining $P_{\text{sat}}$ and $P_{\text{sp}}$. A similar test could be conducted using Arabidopsis (Arabidopsis thaliana) vein mutants of similar leaf size with variation in major vein densities.

**The Potential Roles of Venation in Determining $K_{\text{leaf}}$ Decline**

The linkage of hydraulic vulnerability with venation architecture shown here would be expected because of the reduction of xylem conductivity, due to cavitation or collapse of conduits in the vein xylem, as shown previously by dye experiments, cryo-scanning electron microscopy, and acoustic methods (Kikuta et al., 1997; Salleo et al., 2000; Nardini and Salleo, 2003; Cochard et al., 2004a; Brodribb and Holbrook, 2005; Johnson et al., 2009a). Notably, other factors besides vein density can determine leaf hydraulic vulnerability, which is a higher-level trait influenced by multiple lower-level traits (Marks and Lechowicz, 2006; McKown et al., 2010). Thus, species may additionally differ in the air-seeding thresholds of xylem conduits and in the responses of extravascular tissues to dehydration. Some small-leaved species in moist habitats might not have the low vulnerability suggested by their leaf size, if other factors were to override the benefit of high major vein density. However, our findings from simulated leaves and from our 10 species diverse in drought tolerance indicated a strong potential role of major vein density and leaf size in determining $P_{\text{sat}}$ and $P_{\text{sp}}$ across diverse species.

Model simulations showed that the vulnerability of $K_{\text{x}}$ due to cavitation of major and minor veins was associated differently with venation architecture. Thus, loss of $K_{\text{x}}$ resulting from cavitation in the major veins correlated with lower major vein density, the same relationship found in our experiments. However, loss of $K_{\text{x}}$ resulting from cavitation in the major veins correlated with higher minor vein density. Furthermore, the opposite patterns were found for loss of $K_{\text{x}}$ when cavitation was simulated in the minor veins. These various model results can be understood according to the simple principle of the relative leverage of the major or minor veins in the overall vein system (McKown et al., 2010). The hydraulic leverage of one vein system depends inversely on its density (i.e. its redundancy) relative to the other vein system, and cavitation has a stronger impact on the overall system when the leverage of that vein system is strongest. Thus, when the major vein density is higher, it has less leverage relative to the minor vein system, and cavitation of the major veins will cause a lower decrease in $K_{\text{x}}$ and $K_{\text{leaf}}$ (Table I). By contrast, when the minor vein density is higher, the major vein system gains leverage relative to the minor vein system; thus, cavitation of the major veins would cause a greater decrease in $K_{\text{x}}$ and $K_{\text{leaf}}$ (Table I). The model indicated that a higher major vein density is more effective for reducing hydraulic vulnerability due to major vein cavitation than a lower minor vein density. The model showed that reducing minor vein density only led to a strong reduction in PLC (i.e. to a strong gain in tolerance) at high major vein density. Furthermore, a higher major vein density also increases $K_{\text{max}}$ for well-hydrated leaves, both in absolute terms and relative to vein construction cost, all else being equal, whereas a lower minor vein density leads to losses of $K_{\text{max}}$ (McKown et al., 2010). Thus, for leaves with high major vein density, a low minor vein density might be a mechanism to achieve additional drought tolerance, all else being equal, but at the cost of maximum hydraulic capacity and providing no gain in absolute conductance when the major veins are cavitated. The mechanism of achieving higher major vein density with small leaf sizes was found in the model simulations and experimental study to provide a strong benefit in reducing vulnerability and thus for drought tolerance.

Notably, the model findings indicated that leaves with higher major vein density, although less sensitive to cavitation of the major veins, were more sensitive to cavitation of the minor vein system. Thus, our empirical findings, of reduced vulnerability in leaves with higher major vein density, suggested that major vein cavitation was more important than minor vein cavitation in driving loss of $K_{\text{x}}$ and $K_{\text{leaf}}$. There are four lines of evidence that support the greater probability of cavitation in the major than minor veins. First, the major veins have wide and long xylem conduits especially vulnerable to air seeding (Choat et al., 2005). Second, in naturally dehydrated leaves, embolism is readily observed by cryo-scanning electron microscopy of major veins (Ball et al., 2004, 2006; Marenco et al., 2006; Johnson et al., 2009a), and acoustic studies have indicated cavitation in the major veins at $V_{\text{leaf}}$ values as high as −0.3 MPa (Crombie et al., 1985; Kikuta et al., 1997; Salleo et al., 2000; Johnson et al., 2009a). By contrast, the cryo-scanning electron microscopy studies published thus far have not shown cavitation of minor vein conduits (Canny, 2001). Studies of dye uptake into transpiring leaves did show less staining of minor veins in dehydrated leaves (Salleo et al., 2001; Nardini et al., 2003; Trifilio et al., 2003b); these findings are consistent with cavitation occurring principally in major veins, blocking uptake to the minor veins. Third, leaves that did not render their minor vein system resistant to cavitation would tend to be extremely sensitive to decline during drought, regardless of their venation architecture. The model simulations showed that cavitation of minor veins led to drastic declines in $K_{\text{x}}$ across leaves of all venation architectures. As previously argued by Brodribb and Holbrook (2006), it seems improbable that leaves would invest in a fine vein network that becomes embolized at high water potentials and thus decline...
strongly in function. Fourth, a study of diverse angiosperms found that the leaf \( P_{50} \) was more negative in species with thicker-walled conduits in their minor veins (Blackman et al., 2010). That finding suggested that conduits are built to resist collapse at the tensions experienced during strong dehydration. In wood, such investment to avoid collapse signifies that the xylem can withstand cavitation to close to that degree of tension, as cavitation precedes collapse (Hacke and Sperry, 2001; Hacke et al., 2001; Blackman et al., 2010). Thus, minor vein conduits too should resist both cavitation and collapse at high levels of dehydration.

The collapse of xylem conduits during leaf dehydration cannot be entirely excluded. Collapse of conduits in the major or minor veins has never yet been shown for angiosperms but has been found in conifer needles dehydrated to water potentials ranging from −1.5 to −3.5 MPa (Cochard et al., 2004a; Brodribb and Holbrook, 2005). Future studies are needed to analyze in detail the progression of cavitation and collapse in veins of different orders during leaf dehydration. Such work will also need to consider other aspects of the structure of the vein system (e.g., vessel widths and lengths and the degree that conduits span across vein orders), as these factors have been found to have great importance in stem vulnerability (Sperry, 2003; Sperry et al., 2005) and vary greatly across species (Sack and Frola, 2006). These traits may contribute to the correlation of vulnerability with low major vein density, because the major veins have especially long and wide vessels that span multiple orders. Other aspects of leaf vein arrangement in addition to vein density, such as looping in the major veins, might also influence resistance to hydraulic decline (Corson, 2010; Katifori et al., 2010).

While this discussion has focused on the decline of \( K_{\text{leaf}} \) with dehydration that is driven by declines in the xylem pathway conductivity (i.e. in \( K_{\text{v}} \)), there is also a potential role for declines in \( K_{\text{rw}} \) in the correlation of \( P_{80} \) with major vein density and leaf size. The \( K_{\text{rw}} \) may decline in dehydrating leaves due to changes in the permeability of membranes (Sack and Holbrook, 2006). Notably, given that a high major vein density would entail a large bundle sheath area by which water exits the major veins, if the lamina near the major veins accounts for a large part of transpiration (Fricke, 2002; Sack et al., 2002; Nardini et al., 2010), then leaves with high major vein density would likely maintain a greater bundle sheath area and a greater \( K_{\text{rw}} \) when cells lose turgor in dehydrating leaves (Kim and Steudle, 2007). Additionally, we note that as leaves dehydrate, it is possible that \( K_{\text{leaf}} \), the bulk leaf parameter, may not well describe the water transport pathways if sectors or “patches” of lamina become isolated, each with its own hydraulic supply (Barbour and Farquhar, 2004). Leaves with high major vein density may better provide for access of isolated leaf sectors to the lower-order vein distribution system. Future studies are needed of the impact of dehydration on the bundle sheath and mesophyll tissues and on the potential heterogeneity of water supply in dehydrating leaves. Detailed characterization of the causes of \( K_{\text{leaf}} \) decline and its dependence on xylem and mesophyll characters will contribute to an ability to predict variation in a species’ drought responses from cell- and tissue-level properties.

**Relationship of Leaf Vulnerability to Leaf and Whole-Plant Drought Tolerance**

Our results also highlighted the importance of cell properties and leaf morphology in drought tolerance. Species from dry habitats had higher LMA and modulus of elasticity, more negative osmotic potentials at full and zero turgor (\( \pi_{\text{TLP}} \)), and lower cuticular conductance than species from moist habitats, which by contrast had higher saturated water content and capacitance. Furthermore, the \( \pi_{\text{TLP}} \) correlated with \( P_{50} \) and \( P_{80} \), as shown in two previous studies (Crombie et al., 1985; Blackman et al., 2010). Given that stomata tend to close near the \( \pi_{\text{TLP}} \) (Hao et al., 2010), this linkage points to a control of stomatal aperture during drought by hydraulic vulnerability. The linkage might arise mechanistically if a low osmotic potential in leaf tissues, reflected by \( \pi_{\text{TLP}} \) acted to reduce turgor loss and the decline of membrane permeability (Canny and Huang, 2006). Alternatively, the \( \pi_{\text{TLP}} \) might be coselected with \( P_{50} \) and \( P_{80} \) in drought-tolerant leaves such that stomatal closure precedes hydraulic dysfunction. Our results were most consistent with this second possibility. In the partial correlation analysis, \( \pi_{\text{TLP}} \), had no impact on \( P_{50} \) and \( P_{80} \) when major vein density was partialed out. Thus, as found in the model simulations, leaf size and major vein density are putative causes of high \( P_{50} \) and \( P_{80} \), whereas \( \pi_{\text{TLP}} \) is apparently a structurally independent but coordinated trait that modulates the leaf and plant response to drought.

The finding that major vein density and small leaf size reduce leaf hydraulic vulnerability points to potential roles in determining whole-plant drought tolerance. These traits may be especially important because the leaf is a key locus in whole-plant vulnerability, with typically greater hydraulic sensitivity than stems and roots (Hao et al., 2008; Brodribb and Cochard, 2009; Domec et al., 2009). Thus, for three of the four chaparral species in this study, the leaf \( P_{50} \) was 2.7 to 4.7 MPa less negative than that previously reported for stems (Jacobsen et al., 2007), and with only \textit{Quercus agrifolia} having stems apparently similar to leaves in their vulnerability (−2 versus −2.4 MPa, respectively). The importance of leaf hydraulic vulnerability in whole-plant drought tolerance was further supported in this study both by the more negative \( P_{50} \) and \( P_{80} \) values for species of dry than moist habitats and by the general correlation of these traits with others related to leaf drought tolerance. It is important to recognize, however, that there can be other possible routes to leaf drought tolerance than a low hydraulic vulnerability and thus being able to maintain hydraulic...
and photosynthetic function during drought. Thus, some species can achieve substantial drought tolerance via a low cuticular conductance and water storage, with an extreme development of this mechanism in succulent plants (Ogburn and Edwards, 2009). In this study, Hedera canariensis showed this drought tolerance mechanism (Sack et al., 2003c; Metcalfe, 2005), possibly explaining its relatively high $K_{\text{leaf}}$ vulnerability for a species that can tolerate drought. Other species can achieve drought tolerance via an ability to tolerate low tissue water potentials via dehydration expression that prevents mechanical failure of the cell walls (e.g. the resurrection fern [Polypodium polyphylloides]; Layton et al., 2010). Species with these alternative mechanisms of leaf drought tolerance can achieve large leaf sizes even given dry conditions (Nobel and Jordan, 1983). Furthermore, we note that drought tolerance achieved at the level of the whole plant may not always correspond to leaf-level drought tolerance. Some species with drought-sensitive leaves can tolerate dry soil by shedding leaves or achieving deep roots, as is the case for Lantana camara (Castillo et al., 2007), which had relatively high $K_{\text{leaf}}$ vulnerability. By contrast, some species with drought-tolerant leaves may be sensitive to drought in the field due to relatively shallow roots (e.g. Magnolia grandiflora; Klos et al., 2009). Future work will establish the degree to which, even despite such complexity, key leaf traits such as major vein density, leaf size, and $P_{50}$ and $P_{80}$ contribute to drought tolerance. This work has strong potential to explain leaf function during drought from cell-, tissue-, and organ-level physiological properties and to predict the drought tolerance of diverse species and landscapes in current and extinct vegetation from their leaf traits.

**MATERIALS AND METHODS**

**Computer Simulations of the Importance of Vein Architecture in Leaf Hydraulic Vulnerability**

Simulations of the impact of cavitation in leaves with varying venation architecture were generated using the program K_leaf, version 6 (written by H. Cochard, Institut National de la Recherche Agronomique, Clermont-Ferrand, France [Cochard et al., 2004b; McKown et al., 2010]; available on request at herve.cochar@clermont.inra.fr). Based on specified parameters, K_leaf creates a spatially explicit model of a leaf with up to six vein orders represented as a square grid of xylem resistors and outside-xylem resistors (“mesophyll” resistors) branching orthogonally from each junction of the vein grid. In modeled leaves, water exits through the mesophyll resistor located at each vein junction, and the bulk of the water thus exits from the numerous minor veins. The model determines three parameters, $K_{\text{e}}$, $K_{\text{m}}$, and $K_{\text{tw}}$, where:

$$k_{\text{tw}} = \left( \frac{\pi a b^3}{6m(a^2 + b^2)} \right)$$

where $a$ and $b$ are the major and minor axes of ellipses and $n$ is the viscosity of water at 25°C (units are mm x s⁻¹ MPa⁻¹; Lewis and Boose, 1995; Cochard et al., 2004b; Sack and Fréde, 2006). The $K_{\text{e}}$, calculated by the model depends on the individual vein order conductivities and densities, and $K_{\text{m}}$ depends on the specified mesophyll conductance and the total vein density, which determines the number of junctions and thus of mesophyll resistors in parallel.

Values of $K_{\text{e}}$, $K_{\text{m}}$, and $K_{\text{tw}}$ were determined in typical units normalized by leaf area (mmol m⁻² s⁻¹ MPa⁻¹). The relative responses of $K_{\text{e}}$, $K_{\text{m}}$, and $K_{\text{tw}}$ to alteration of venation features in our simulations are expected to accurately indicate relative trends and principles of leaf venation design; however, the empirical values are not to be taken as meaningful, and units are not presented in our simulation results. For instance, the simulations based on the Juglans regia leaf anatomical data set produced a $K_{\text{e}}$ of 462 mmol m⁻² s⁻¹ MPa⁻¹, which is very high relative to experimentally measured $K_{\text{e}}$ and many times greater than measured $K_{\text{e}}$ (Cochard et al., 2004b). Cochard et al. (2004b) introduced the “xylem hydraulic efficiency” parameter in K_leaf, modeled $K_{\text{e}}$ divided by measured $K_{\text{e}}$ to calibrate the modeled $K_{\text{e}}$ with measured values and thus to account for other factors than xylem conduit numbers and diameters that cannot currently be modeled, such as pit membrane resistance (Sperry et al., 2005) or conduit blockage by embolism or tyloses (Salleo et al., 2002; Saint et al., 2005). In our simulations, xylem hydraulic efficiency was set to 1. While not significant for this study, future work should better reconcile modeled $K_{\text{e}}$ with experimentally measured values (McKown et al., 2010).

For this study, we focused on the impacts of simulated cavitation on $K_{\text{e}}$ values, which would result in a reduction of $K_{\text{e}}$ by a degree that depends on the value of $K_{\text{e}}$ relative to $K_{\text{e}}$. The ratio of $K_{\text{e}}$ and $K_{\text{e}}$ depends on species and on environmental variables that affect these compartments differently, but the available data suggest that $K_{\text{e}}$ and $K_{\text{e}}$ are of similar magnitude on average (Sack and Holbrook, 2006), and in that case, a given decline of $K_{\text{e}}$ would reduce $K_{\text{e}}$ by approximately half that amount. We also note that dehydration could also impact on the extraxylem pathways (e.g. due to cell shrinkage and/or aquaporin deactivation; Kim and Steudle, 2007), which would lead to stronger overall impacts on $K_{\text{e}}$.

The program generates leaves of a specified size and number and arrangement of 2, 5, veins, from which it determines the 2, vein density. Thus, designating leaves of larger sizes leads to the 2, veins being spaced farther apart, just as observed in real leaves (Sack et al., 2008; see “Results”). The density of the minor veins (in this model, 3, and higher) depends on the areole size, which is specified independently, and thus is manipulated independently of major vein density. We altered leaf size (and thus the density of 1, and 2, veins) and also minor vein densities, simulating a total of 42 leaves of different sizes (4.8–65.4 cm²), associated with a 3.5-fold range of major vein densities (0.15–0.53 mm mm⁻²) × seven different minor vein densities (spanning a 3.5-fold range; 2.8–8.7 mm mm⁻²). For each leaf, we additionally applied cavitation “treatments” to determine the impact on $K_{\text{e}}$: (1) to test the impact of cavitating the major veins, we reduced the cross-sectional conductivities of the 1, and 2, veins by 90%, to simulate the great majority of vessels being cavitated; and (2) to test the impact of cavitating the minor veins, we reduced the cross-sectional conductivities of the 3, 4, 5, and 6, veins by 90%. For the simulated leaves of contrasting venation architecture, we present the PLC of $K_{\text{e}}$ that resulted from these treatments (i.e. the decline relative to a control, uncavitated leaf).

**Plant Material and Leaf Hydraulic Vulnerability**

Leaf hydraulic vulnerability was determined for 10 species sampled in and around the campus of the University of California, Los Angeles, and Will Rogers State Park, in Los Angeles, in May to September 2008 (Table II). Leaves were collected from mature trees and shrubs of nine species. Leaves from sunflower (Helianthus annuus var Sunspot; Botanical Interests) were collected from greenhouse plants grown from seeds in 3.6-L pots (average minimum, mean, and maximum values for temperature, 21.1°C, 23.2°C, and 26.0°C; for humidity, 44%, 51%, and 58%). Sunflowers were irrigated every 2 d, with 200 to 400 mm (2.02±0.20/20:20 nitrogen phosphorus-potassium: the light availability measured at midday on a sunny day was up to 550 μmol photons m⁻² s⁻¹ and on average 300 μmol photons m⁻² s⁻¹ (LI-250 light meter; LI-COR Biosciences). Species spanning a wide range of drought sensitivity were selected across nine families to include phylogenetic diversity. Five species were native
to dry habitats and five species to moist habitats (Table II). Mature, healthy leaves were excised from sun-exposed branches rehydrated overnight. We used the evaporative flux method (EFM) to determine leaf vulnerability curves. We measured K_{leaf} as the light-acclimated steady-state transpirational flow rate for excised leaves (E; mmol m^{-2} s^{-1}) divided by the water potential driving force (∆Ψ_{wp}; MPa; Sack et al., 2002; Sclafani et al., 2008). The EFM was modified to allow determination of K_{leaf} at low Ψ_{wp}. Shoots were cut into segments of three or more leaves under ultrapure water and dehydrated with a fan for different periods of time to achieve a range of Ψ_{wp} values. Shoots were allowed to equilibrate for at least 30 min, and then two leaves were excised and measured for initial Ψ_{wp} (Ψ_{i}) using a pressure chamber (Plant Moisture Stress model 1000; PMS Instrument Co.). The third leaf (typically the middle leaf) was used to determine Ψ_{leaf} with the EFM. The vulnerability curve was obtained by plotting Ψ_{wp} against which ever was lowest, Ψ or Ψ_{wp} (“Ψ”), assuming this to be the most dehydrated experience during the experiment (bench drying and Ψ_{leaf} measurements). Species show different shapes in their vulnerability curve trajectories, as expected given variations in the importance of multiple mechanisms for the decline of K_{leaf} with dehydration (Brodribb and Holbrook, 2006). Thus, we determined each species’ vulnerability curve, selecting among four functions applied in the previous literature by maximum likelihood (Burnham and Anderson, 2002) using the optimum function in R 2.9.2 (http://www.r-project.org; Burnham and Anderson, 2004; Sack et al., 2006; our scripts are available on request): linear (K_{leaf} = aΨ_{leaf} + b_{ψ} + c); sigmoidal (K_{leaf} = a/(1 + e^{-b_{ψ}c})); logistic (K_{leaf} = a/(1 + e^{-b_{ψ}c})); and exponential (K_{leaf} = b_{ψ} + c_{ψ}e^{-d_{ψ}c}). We used the best-fit function for each species to estimate the maximum K_{max} for the hydrated leaf (K_{max}) and the Ψ_{leaf} at 50% and 80% loss of K_{leaf} (P_{50} and P_{80} respectively).

Quantification of Leaf Form and Venation Architecture

We determined venation traits from one leaf on an exposed branch from each of three individuals per species from the same individuals measured for hydraulic vulnerability. Leaves were collected in May to September 2007 and fixed in formalin-acetic acid solution (37% aqueous formaldehyde solution, 50% ethanol, and 13% glacial acetic acid solution). Leaves were chemically cleared with 5% NaOH in ethanol, stained with safranin, and counterstained with fast-green (Berlyn and Milsche, 1976). Leaves were mounted with water in transparent film (CG5000; 3M Visual Systems Division) and scanned (flatbed scanner; Canon Scan Lide 90; 1,200 pixels per inch). The leaf area, length, width, perimeter, and numbers and lengths of 1st- and 2nd-order veins were measured using ImageJ software (version 1.42q; National Institutes of Health). Two indices of leaf shape were calculated: the length:width ratio and the perimeter:squared area ratio (a size-independent index of edge relative to size; Sack et al., 2003b). The 3rd vein lengths were measured for three rectangles per leaf (100–300 mm², depending on leaf size) located centrally in the top, middle, and bottom thirds of the leaf. For each vein order, the vein density was calculated as length divided by leaf area; for 3rd veins, the vein densities were averaged across the three subsampled rectangles. Vein diameters, excluding the bundle sheath, were measured for each vein order by averaging six measurements (two made centrally in veins in the top, middle, and bottom thirds of the leaf).

Measurements of the minor vein system were made with a light microscope (DMRB; Leica Microsystems) with a 5X or 10X objective and digital camera (14.2 Color Mosaic; Diagnostic Instruments). Three rectangles were imaged (areas of 1.5 mm² or 6 mm²) centrally in the top, middle, and bottom thirds of the leaf, and the number of vein orders, density of minor veins (length per area), number of free vein endings per area, and vein diameters measured centrally in six segments were averaged across the rectangles. The major vein density was determined as the sum of 1st, 2nd, and 3rd order veins and the minor vein density as the sum for 4th and higher order veins. The ratio of major to minor vein density was calculated for each leaf for every species.

Quantifying Other Key Traits Related to Leaf Drought Tolerance

Morphological and physiological traits related to leaf drought tolerance were measured for six leaves taken from three to six individuals per species. Measurements were made of leaf area and of dry mass after oven drying at least 48 h at more than 70°C to allow calculation of LMA (g m⁻²). Leaf thickness was determined using digital calipers (Fowler), and leaf density was calculated as LMA divided by leaf thickness (Witkowski and Lamont, 1991). Cuticular conductance, the minimum conductance to vapor diffusion across the epidermis when the stomata are closed, was measured by weighing leaves as they dehydrated (Sack et al., 2003b; Sack and Sclafani, 2010). Parameters were determined from pressure-volume curves constructed by measuring leaf water potential and relative water content as leaves dehydrated (Tyree and Hammel, 1972; Sack et al., 2003b), including osmotic potential at full turgor (MPa) and at turgor loss point (πtLP, MPa), saturated water content (g g⁻¹), modulus of elasticity (MPa), and capacitances at full turgor and at turgor loss point (MPa⁻¹; Sack, 2010).

Statistical Analyses of Trait Differences and Correlations across Species

To test trait differences between moist and dry habitat species (Table II; Supplemental Table S1), we performed ANOVAs with species nested within habitat type (MNinstah release 15). Prior to tests, data were log transformed to improve normality and heteroscedasticity (Sokal and Rohlf, 1995). We performed t tests for leaf density, maximum K_{max}, P_{50}, and P_{80} where only species mean values were available (Supplemental Table S1). A correlation matrix was determined to reveal the intercorrelative structure of hydraulic parameters, leaf size, venation architecture, and other traits putatively related to drought tolerance. For a conservative estimation, correlations were considered significant only at P < 0.05 for both Spearman and Pearson coefficients (r and r² respectively). Because many relationships were nonlinear, we determined Pearson correlations for both raw and log-transformed data.

When three variables of interest were intercorrelated across species, we performed partial correlation analysis (Sokal and Rohlf, 1995), testing the relationship between two variables while holding the third variable constant (package in R; Schafer et al., 2007).

Supplemental Data

The following materials are available in the online version of this article.

Supplemental Table S1. Species means ± s.e. for 24 morphological, anatomical, and physiological traits and results of ANOVA testing for species differences and for differences between moist and dry habitat species.

Supplemental Table S2. Correlation matrix for the relationship of leaf hydraulic vulnerability traits with venation architecture and other traits related to leaf morphology and drought tolerance.
