Convex operational models (COMs) are considered as great extrapolations to larger settings of any statistical theory. In this article we generalize the maximum entropy principle (MaxEnt) of Jaynes’ to any COM. After expressing Max-Ent in a geometrical and lattice theoretical setting, we are able to cast it for any COM. This scope-amplification opens the door to a new systematization of the principle and sheds light into its geometrical structure.

Keywords: entanglement-quantum separability-convex sets

I. INTRODUCTION

The notion of using a small set of relevant expectation values so as to describe the main properties of physical systems may be considered the leit-motiv of statistical mechanics [1]. Developments based upon Jaynes’ maximum entropy principle (MaxEnt) constitute a pillar of our present understanding of the discipline [2, 3]. This type of ideas has also been fruitfully invoked for obtaining the probability distribution associated to pure quantum states via MaxEnt (see for instance [4] and references therein). Indeed, MaxEnt constitutes a very important physical viewpoint, on the one hand, and powerful technique on the other one. This is true not only for physics, chemistry, astronomy, and engineering but for a host of other disciplines as well [5]. Thus, MaxEnt extensions that amplify its range of applicability should be regarded as significant for all branches of science.

In this communication we wish to introduce the powerful Convex Operational Models (COM) approach [6–8] into the MaxEnt domain. COM is, in turn, intimately linked to convex sets of probability measures [6–11]. Among the several extant approaches to the study of convex sets of probability measures, the above cited references deal with the COM-technique, in which physical states (understood as probability measures) and their convex structure play a key role, while other related quantities emerge in rather natural fashion. There exist generalizations of quantum mechanics, including non-linear versions, that are axiomatized using the convex structure of the set of states (see [12], [13], and [14]). Using convex sets one treats in geometrical fashion the statistical theory of systems, and can also include quantum and classical mechanics (indeed several other theories as well). Elementary (sharp) tests in quantum mechanics are represented by projection operators that form the well known von Neumann’s lattice, an orthomodular one [15]. Via the Born’s rule any projection operator defines probabilities. These are linked to measures over the von Neumann’s lattice: using Gleason’s theorem, it is possible to link in a bijective way density matrixes and non-kolmogorovian probability measures. But probability measures may also arise in quantum mechanics by means of positive operator valued measures (POVMs), which are also known as generalized measures. POVMs are also generalized easily to any COM. We will review these subjects in Section III.

We will express here Jaynes’s MaxEnt approach to a lattice theoretical form, and using this, extend it to arbitrary COM, which entails a considerable enlargement of its scope. The extension is done in such a way that includes conditions on POVMs.
This is done in Sections IV and V. Such generalization will undoubtedly be of interest to thousands of MaxEnt practitioners. Since COMs constitute important extrapolations to larger settings of any statistical theory, casting MaxEnt for any COM, after expressing Jaynes’ principle in a geometrical and lattice theoretical scenario, will hopefully open the door to a new systematization of the principle while shedding light into its geometrical structure.

II. MAXIMUM ENTROPY PRINCIPLE (MAXENT)

Statistical mechanics and thereby thermodynamics can be formulated on the basis of information theory if the density distribution $\rho(x)$ is obtained by recourse to MaxEnt [2, 3]. Jaynes’ stance asserts that assuming that your prior knowledge about the system is given by the values of physical quantities $R_j$, i.e., $(R_1), \ldots, (R_n)$, then the most unbiased probability distribution $\rho(x)$ is uniquely fixed by extremizing Shannon’s logarithmic entropy $S$ subject to the $n$ constraint

$$\langle R_i \rangle = r_i; \text{ for all } i. \quad (1)$$

This brings into the game $n$ Lagrange multipliers $\lambda_i$. In the process of employing the MaxEnt procedure one discovers that the information quantifier $S$ can be identified with the equilibrium entropy of thermodynamics if our prior knowledge $(R_1), \ldots, (R_n)$ refers to extensive quantities and lattice theoretical scenario, will hopefully open the door to a new systematization of the principle while shedding light into its geometrical structure.

$$S_{\text{max}} = \sum_i \lambda_i (r_i - \langle R_i \rangle), \quad (2)$$

where the $\lambda_i$’s are Lagrange multipliers guaranteeing that

$$r_i = -\frac{\partial}{\partial \lambda_i} \ln Z, \quad (3)$$

while the partition function reads

$$Z(\lambda_1 \cdots \lambda_n) = \text{tr}[\exp(−\lambda_1 R_1 − \cdots − \lambda_n R_n)], \quad (4)$$

and the normalization condition

$$\lambda_0 = \ln Z. \quad (5)$$

Such simple-looking algorithm constitutes one of the most powerful ones in physics’ arsenal. In a quantum setting, of course, the $R$’s are operators on a Hilbert space $\mathcal{H}$ while $\rho$ is a density matrix (operator).

III. COM-PRELIMINARIES

We recapitulate here essential aspects of convex operational models. $\mathcal{P}(\mathcal{H})$ will denote the set of all closed subspaces of $\mathcal{H}$, which are in a one to one correspondence with the projection operators. Because of the one to one link, one usually employs the notions of “closed subspace” and “projector” in interchangeable fashion. The bounded operators on $\mathcal{H}$ will be denoted by $\mathcal{B}(\mathcal{H})$. We begin the present task with reference to classical probabilities. Given a set $\Omega$, let us consider a $\sigma$-algebra $\Sigma \subseteq \mathcal{P}(\Omega)$. Then, a probability measure will be given by a function

$$\mu : \Sigma \rightarrow [0, 1], \quad (6)$$

which satisfies the well known axioms of Kolmogorov [10]. As for quantum probabilities we remind that, in the standard formulation of quantum mechanics, states may be defined as functions of the form

$$s : \mathcal{P}(\mathcal{H}) \rightarrow [0, 1], \quad (7)$$

such that:

1. $s(0) = 0$ ($0$ is the null subspace).
2. $S(P^\perp) = 1 − s(P)$
3. For any pairwise orthogonal denumerable family of projections $P_j$ one has

$$s(\sum_j P_j) = \sum_j s(P_j)$$

For a study of the differences between classical and quantum probabilities, see [11] (chapter 2). Moreover, Gleason’s theorem [18, 19] asserts that if $\dim(\mathcal{H}) \geq 3$, then the set of all measures of the form (7) can be put into a one-to-one correspondence with the set $\mathcal{C}$ of by all positive, hermitian, and trace-class (normalized to unity) operators in $\mathcal{B}(\mathcal{H})$. If $P \in \mathcal{P}(\mathcal{H})$, the correspondence between
$\rho \in \mathbb{C}$ and its induced probability measure is given by

$$s_\rho(P) = \text{tr}(\rho P),$$

(8)

where $\text{tr}(\cdot \cdot \cdot)$ stands for the trace operator in $\mathbb{B}(\mathcal{H})$, i.e., the sum of all the eigenvalues. Equation (8) is essentially Born’s rule. Any $\rho \in \mathbb{C}$ may be written as

$$\rho = \sum_i p_i P_{\psi_i},$$

(9)

where the $P_{\psi_i}$ are one dimensional projection operators on the rays (subspaces of dimension one) generated by the vectors $\psi_i$ and $\sum_i p_i = 1$ ($p_i \geq 0$). Thus, it is clear that $\mathbb{C}$ is a convex set. If the sum in (9) is finite, then $\rho$ is said to be of finite range. Remark that in the infinite dimensional case the sum in (9) may be infinite in a non-trivial sense. $\mathbb{C}$ is then a set of non-boolean probability measures, closed by convexity, that is also closed in the norm of $\mathcal{H}$. Let us remind the reader that a lattice is a partially ordered set (also called a poset) in which any two elements have a unique supremum (the elements’ least upper bound; called their join) and an infimum (greatest lower bound; called their meet). Lattices can also be characterized as algebraic structures satisfying certain axiomatic identities. Since the two definitions are equivalent, lattice theory draws on both order theory and universal algebra. Semilattices include lattices, which in turn include Heyting and Boolean algebras. These ”lattice-like” structures all admit order-theoretic as well as algebraic descriptions [22].

A very important notion for our purposes is that of $\mathcal{L}_\mathbb{C}$, the set of all convex subsets of $\mathbb{C}$. Any element of $\mathcal{L}_\mathbb{C}$ will be itself a “probability space”, in the sense that it is a set of non boolean probability measures closed under convex combinations (not to be confused with the usual mathematical notion of sample space) [22]. It can be shown that $\mathcal{L}_\mathbb{C}$ is endowed with a canonical lattice theoretical structure that can be related to quantum entanglement and positive maps [22]. The meet operation is given by set intersection, the join by convex hull and the partial order by set inclusion. We will use this lattice in order to express the Max-Ent protocol in a different (but equivalent) form. It should be also clear that the lattice operations mentioned above may be trivially defined in any COM and this will be used in Section IV.

A general (pure) state can be written as

$$\rho = |\psi\rangle\langle\psi|,$$

(10)

and we denote the set of all pure states by

$$P(\mathbb{C}) := \{\rho \in \mathbb{C} | \rho^2 = \rho\}$$

(11)

This set is in correspondence with the rays of $\mathcal{H}$ via the association

$$\mathcal{F} : \mathbb{CP}(\mathcal{H}) \to \mathbb{C} \mid |\psi\rangle \mapsto |\psi\rangle\langle\psi|,$$

(12)

where $\mathbb{CP}(\mathcal{H})$ is the projective space of $\mathcal{H}$ and $|\psi\rangle$ is the class defined by the vector $|\phi\rangle (|\phi\rangle \sim |\psi\rangle \leftrightarrow |\phi\rangle = \lambda |\psi\rangle, \lambda \neq 0)$. If $M$ represents an observable, its mean value $\langle M \rangle$ is given by

$$\text{tr}(\rho M) = \langle M \rangle$$

(13)

Notice that the set of positive operators has the shape of a cone while the set of trace class operators (of trace one) that of a hiperplane. Thus, $\mathbb{C}$ is the intersection of a cone and a hiperplane, embedded in $\mathfrak{A}$. Such structure (or geometrical convex setting) is susceptible of considerable generalization (see [0,8] for an excellent overview).

In modeling probabilistic operational theories one associates to any probabilistic system a triplet $(X, \Sigma, p)$, where $\Sigma$ represents the set of states of the system, $X$ is the set of possible measurement outcomes, and $p : X \times \Sigma \to [0, 1]$ assigns, to each outcome $x \in X$ and state $s \in \Sigma$, a probability $p(x,s)$ of $x$ to occur if the system is in the state $s$. If we fix $s$ we obtain the mapping $s \to p(\cdot \cdot \cdot, s)$ from $\Sigma \to [0, 1]^X$. We then identify in this way all the states of $\Sigma$ with maps of such a form. Focusing now attention upon their closed convex hull we obtain the set $\Omega$ of possible probabilistic mixtures (represented mathematically by convex combinations) of states in $\Sigma$. One appreciates that we also obtain, for any outcome $x \in X$, an affine evaluation-functional $f_x : \Omega \to [0, 1]$, given by $f_x(\alpha) = \alpha(x)$ for all $\alpha \in \Omega$. More generally, any affine functional $f : \Omega \to [0, 1]$ may be regarded as representing a measurement outcome and thus use $f(\alpha)$ to represent the probability for that outcome in state $\alpha$.

### A. Effects

In the special case of quantum mechanics the set of all affine functionals so-defined is called the set of effects. They form an algebra (known as the
effect algebra) and represent generalized measurements (unsharp, as opposed to sharp measures defined by projection valued measures). Effect algebras have important applications in the foundations of quantum mechanics and in fuzzy probability theory. The specific form of an effect in quantum mechanics is as follows. A generalized observable or positive operator valued measure (POVM) will be represented by a mapping \( E : \mathcal{B}(\mathbb{R}) \to \mathcal{B}(\mathcal{H}) \) such that

1. \( E(\mathbb{R}) = 1 \)
2. \( E(B) \geq 0 \), for any \( B \in \mathcal{B}(\mathbb{R}) \)
3. \( E(\bigcup_j B_j) = \sum_j E(B_j) \), for any disjoint family \( B_j \)

The first condition means that \( E \) is normalized to unity, the second one that \( E \) maps any Borel set \( B \) to a positive operator, and the third one that \( E \) is \( \sigma \)-additive with respect to the weak operator topology. In this way, a POVM can be used to define a family of affine functionals on the state space \( \mathcal{C} \) (which corresponds to \( \Omega \) in the general probabilistic setting) of quantum mechanics, as follows

\[
E(B) : \mathcal{C} \to [0, 1] \\
\rho \mapsto \text{tr}(E\rho).
\]

Effects are then positive operators \( E(B) \) which satisfy \( 0 \leq E \leq 1 \). Let us denote by \( \mathcal{E}(\mathcal{H}) \) the set of all effects in quantum theory. We appeal to effects below in order to define an special example of elements of \( \mathcal{L}_C \), and also as a generalization of conditions imposed in the Max-Ent protocol. Returning now to the general model of probability states we may consider the convex set \( \Omega \) as the basis of a positive cone \( \mathcal{V}(\Omega) \) of the linear space \( V(\Omega) \). Thus, every affine linear functional can be extended to a linear functional in \( V(\Omega)^* \) (the dual linear space). It can be shown that there is a unique unity functional such that \( u_{\Omega}(\alpha) = 1 \) for all \( \alpha \in \Omega \) (in quantum mechanics, this unit functional is the trace function). Thus, the COM approach speaks of a triplet \( (A, A^\sharp, u_A) \), where \( A \) is a space endowed with a strictly positive linear functional \( u_A \) and \( A^\sharp \) is a weak*-dense subspace of \( A^* \), ordered by a chosen regular cone \( A^+_+ \subseteq A^* \) containing \( u_A \). Effects will be functionals \( f \) in \( A^\sharp \) such that \( f \leq u_A \).

IV. A GEOMETRICAL EXPRESSION FOR MAX-ENT

Our idea is to re-discuss MaxEnt in terms of elements of \( \mathcal{L}_C \) associated to conditions on given sets of observables or effects. Consider the states

\[
C_{(E, \lambda)} := \{ \rho \in \mathcal{C} \mid \text{tr}(\rho E) = \lambda, \ \lambda \in [0, 1] \}.
\]

\( C_E \) is a convex set, and so, an element of \( \mathcal{L}_C \). \( C_{(E, \lambda)} \), represents all the states for which the probability of having the effect \( E \) is equal to \( \lambda \). Furthermore, there exists \( \mathbb{S} \), a \( \mathbb{R} \)-subspace of \( \mathcal{A} \) (the set of bounded self adjoint operators), such that

\[
C_{(E, \lambda)} = \mathbb{S} \cap \mathcal{C}
\]

and thus, \( C_E \) is also an element of \( \mathcal{L} \), the lattice induced by the intersection of all closed subspaces of \( \mathcal{A} \) and \( \mathcal{C} \). More generally, if

\[
(R) = r
\]

then the above equation may be considered as represented by the set of density matrices which serve as a solution of it. The ensuing set is obtained as the intersection of the Kernel of the functional \( F_{R}(\rho) := \text{tr}(R\rho) - r\text{tr}(\rho) \) and \( \mathcal{C} \). Accordingly, each equation of the form (17) (understood as an equation to be solved) can be represented as an element \( C \in \mathcal{L} \), and also as an element of \( \mathcal{L}_C \). \( C \) is also a closed set, because it is the intersection of the kernel of a functional (which is a closed subspace) and \( \mathcal{C} \).

With such materials at hand, we can now re-express the maximum entropy principle in lattice theoretical form. Our point here is that the set of conditions (14) can be expressed in an explicit lattice theoretical form as follows. Using a similar procedure as in (17) we conclude that each of the equations in (14) can be represented as a convex (and closed) sets \( C_R \). In this way we can now express conditions (14) with the lattice theoretical expression

\[
C_{\text{max-ent}} := \bigcap_i C_{R_i} = \bigwedge_i C_{R_i}
\]

Now, \( C_{\text{max-ent}} \) is also an element of \( \mathcal{L}_C \) (but not necessarily of \( \mathcal{L} \)) and we must maximize entropy on \( C_{\text{max-ent}} \). We have thus encountered a MaxEnt-lattice theoretical expression: given a set of conditions represented generally by convex subsets \( C_i \), one should maximize the entropy in the set \( C_{\text{max-ent}} = \bigwedge_i C_i \).
V. GENERALIZATION

A (generalized) observable in a test space \( \Omega \) will be given by a function \( F : x \mapsto F_x \) from subsets of a given outcome set \( X \) into \( A(\Omega) \) satisfying

1. \( F_x \geq 0 \)
2. \( \sum_{x \in E} F_x = u \)

This is the natural extension of the notion of POVM to any COM (extension which includes the more restricted case of projection operator valued measures for the quantum case). If \( \omega \in \Omega \), we can construct the probability function \( p_{\omega,F}(x) = F_x(\omega) \), and this pulls back a map \( F^* : \Omega \to \Delta(E) \), with \( F^*(\omega) = p_{\omega,F} \). With this at hand, we can easily generalize probabilities (and so, when they appear, mean values) as linear conditions. With this procedure we will obtain convex sets, and proceed similarly as in Section IV. For example, suppose that the outcomes of our observable \( F \) are represented with the convex set \( \mathbb{S}(E) \). Then we can write the mean value of \( F \) in the state \( \omega \) as:

\[ \langle F \rangle_\omega = \sum_i f_i F_i(\omega) \quad (19) \]

The probability functions \( F_i(\cdot) \) are linear operators defined on \( A \) taking values in the interval \([0,1]\) when restricted to states. As they are linear, we can define the functional

\[ \langle F \rangle : A \to \mathbb{R} \mid \langle F \rangle(a) = \sum_i f_i F_i(a) \quad (20) \]

If we now consider the new functional

\[ \langle F \rangle_r : A \to \mathbb{R} \mid \langle F \rangle_r(a) = \sum_i f_i F_i(a) - ru(a) \quad (21) \]

then, the Kernel of \( \langle F \rangle_r \) will be a linear subspace of \( A \), call it \( \mathbb{S}_{r,F} \). If we now restrict to the elements of \( \Omega \) (and any \( \omega \in \Omega \) satisfies \( u(\omega) = 1 \)), we will have that solutions of the Equation 19 can be represented with the convex set

\[ C_{r,F} := \mathbb{S}_{r,F} \cap \Omega \quad (22) \]

More generally, even if our measurement outcomes are just labeled by an index set and we are not interested on mean values but only on probabilities (as is generally the case for many POVM’s), conditions will have the form

\[ p_{\omega,F}(x) = F_x(\omega) = \alpha \]

and following an analogous reasoning line as above, it can also be put in the form \( \mathbb{S}_{\alpha,F} \cap \Omega \), with \( \mathbb{S}_{\alpha,F} \) a subspace which depends on the real number \( \alpha \) and the observable \( F \). In any case, the construction given above provides the path for generalization of the procedure outlined in Section IV to any COM. If \( E_i \) represent observables and the brackets \( \langle \cdot \rangle \) are meant to express either conditions of the form of Equations 19 or 23, suppose as given a set of conditions of the form

\[ \langle E_i \rangle = c_i \quad \text{for all } i. \quad (24) \]

Then, because of the above discussion, the set of conditions 24 may be expressed as a collection of convex subsets of the form \( \mathbb{S}_{c_i} \cap \Omega \). And the Jaynes method tells us that we must maximize entropy on the convex set:

\[ C_{\text{MaxEnt}} = \bigwedge_i (\mathbb{S}_{c_i} \cap \Omega) \quad (25) \]

It is important to remark here that our construction does not only restricts to projective measurements, but it includes the possibility of imposing conditions on POVMs. Thus, we provide here a generalization of the Max Ent protocol for generalized measurements.

We notice that the specific form of the entropy to maximize depends on the specification COM which is being used. For example, for the particular cases of quantum theory and a classical model, von Neumann and Shannon entropies are used respectively in a natural way. The election of the particular function to maximize on \( C_{\text{MaxEnt}} \), does not depend on the general formulation but in the specific characteristics of the model. An interesting question would be to set up general conditions for entropies in any model, but the existence of such conditions is hard to believe, because of the proliferation of entropies and contexts.

VI. CONCLUSIONS

In this work we reviewed the celebrated E. T. Jaynes max-ent principle. After that, we studied generalizations of probabilistic models, the COM
In Section IV we gave a new expression for max-ent using a lattice theoretical fashion, expressing conditions as convex sets and taking the maximum in their set theoretical intersection, i.e., lattice conjunction. In Section V, we used the key fact that the probability function of COM preserves convexity in order to link the COM approach with the results of Section IV, and gave a generalization for max-ent. This generalization also includes a max-ent protocol for conditions on POVMs in any COM. This kind of generalizations may be useful to extend the powerful max-ent approach for more general theories and also yields light into its mathematical and geometrical structure/background.
