It is commonly thought that thermal photons with transverse electric polarization cannot exist in a planar metallic cavity whose size $a$ is smaller than the thermal wavelength $\lambda_T$, due to absence of modes with $\lambda < 2a$. Computations based on a realistic model of the mirrors contradict this expectation, and show that a micron-sized metallic cavity is filled with non-resonant radiation having transverse electric polarization, following a non-Planckian spectrum, whose average density at room temperature is orders of magnitudes larger than that of a black-body. We show that the spectrum of this radiation can be measured by observing the transition rates between hyperfine ground-state sub-levels $1S_{1/2}(F,m_F) \rightarrow 1S_{1/2}(F',m_F')$ of D atoms passing in the gap between the mirrors of a Au cavity. Such a measurement would also shed light on a puzzle in the field of dispersion forces, regarding the sign and magnitude of the thermal Casimir force. Recent experiments with Au surfaces led to contradictory results, whose interpretation is much controversial.

I. INTRODUCTION

The study of the spectrum of the electromagnetic (em) fluctuations in a cavity in thermal equilibrium is at the roots of quantum mechanics. The fundamental importance of this problem was recognized after Kirchhoff showed that the energy density of thermal radiation is a universal function of the frequency and of the temperature, independent of the material properties of the walls. This discovery stimulated intense efforts to work out theoretically the analytical expression of this universal function, which was finally found by M. Planck [1].

The famous theorems of Kirchhoff are valid in a large box, and at distances from the walls much larger than the wavelength. This observation naturally leads one to wonder how the Planck spectrum gets modified in a small cavity, and/or in proximity of its walls. The study of this important problem was initiated by Rytov [2], the founder of the modern theory of em fluctuations, who computed the thermal field in proximity of a dielectric slab. Since then, Rytov’s theory turned into a vast field of research that goes by the name of fluctuational electrodynamics, with many diverse applications extending from heat radiation to heat transfer, as well as to Casimir and van der Waals forces both in and out equilibrium [3, 4].

The fundamental result of fluctuational electrodynamics is the following formula for the correlator of the em field in a vacuum region of space, surrounded by any number of dielectric bodies at temperature $T$, which can be derived by linear-response theory [5]:

$$\langle \hat{E}_\alpha(r,t)\hat{E}_\beta(r',t') \rangle_{\text{sym}} = \hbar \int_{-\infty}^{\infty} \frac{d\omega}{2\pi} \coth \left( \frac{\omega}{2k_B T} \right) \times \text{Im}[\xi_{\alpha\beta}(r,r',\omega)] e^{-i\omega(t-t')} ,$$

(1)

where $\xi_{\alpha\beta}(r,r',\omega)$ is the Fourier transform of the classical Green function of the electric field, obtained by solving the macroscopic Maxwell Equations in the background of the bodies. The correlator of the magnetic field has an analogous form, in terms of the magnetic Green function $H_{\alpha\beta}(r,r',\omega)$. The subscript sym in the average symbols denotes symmetrized products of field operators [1]. We stress that Eq. (1) describes both zero-point (i.e. quantum) and thermal fluctuation of the em field. The validity of Eq. (1) is only subjected to the condition that the length scales of the relevant fluctuations should be large compared to atomic distances, in such a way that the em material properties can be described by macroscopic response functions.

A wealth of quantum em phenomena can be studied using the correlator in Eq. (1). For example, starting from the free-space Green function, it is easy to derive from Eq. (1) Planck’s law, and to compute the coefficient of spontaneous emission of an atom in vacuum [6]. The most spectacular applications of Eq. (1) are however in bounded geometries. Consider for example a planar cavity consisting of two mirrors separated by a vacuum gap. By evaluating the difference among the averages of the Maxwell stress tensor at a point inside the gap and a point just outside the cavity, one can obtain the celebrated Lifshitz formula [7] for the Casimir pressure between two dielectric slabs at finite temperature, which generalized to real media the famous formula of Casimir for ideal mirrors at zero temperature [8]. Other classic cavity-QED problems that can studied with the help of Eq. (1) include the Casimir-Polder interaction of an atom...
with one or more material walls [9] [10], and suppression of spontaneous decay of an atom in a cavity [6] [11] [12]. Applications of Eq. 1 are endless, being limited only by one’s ability to work out the classical Green functions in more complex geometries.

In this paper we use fluctuational electrodynamics to study the thermal radiation existing in a micron-sized planar metallic cavity, and we describe the scheme of an experiment with spin-polarized D atoms to observe its spectrum.

On general grounds, the spectrum of the thermal radiation of a narrow cavity is expected to deviate strongly from the Planckian form. Our analysis shows that the properties of the obtained radiation depend dramatically on whether the mirrors are modeled as lossy or rather as dissipation-less. When dissipation is neglected, the radiation is mostly constituted (for moderately high temperatures) by em fields with transverse magnetic (TM) polarization, while barely any radiation with transverse electric (TE) polarization is present. This is consistent with one’s expectation that no photons with TE polarization are present. This is consistent (up to 99 % c.l.) with the theoretical analysis of [10]. Surprisingly, the data are instead consistent (up to 90 % c.l.) with Lifshitz theory; provided that conductive electrons are modeled as a dissipation-less plasma. When the latter model is used to compute the Casimir force, the obtained thermal correction is attractive for all separations, and for \( a \gg \lambda_p \) it is indistinguishable from that for a perfect conductor (more details can be found in the book [24]). To explain the findings of these experiments, it has been conjectured [25] that when two conductors are brought into close proximity, saturation effects may lead to suppression of thermal fluctuations of the em field, which might explain why the repulsive thermal Casimir force predicted by the Drude model has not been seen in the experiments. Agreement with the Drude model has been reported in a single torsion-balance experiment [20], which probed the Casimir force in the range from 700 nm up to the large separation of 7.3 \( \mu \)m. The interpretation of the latter experiment is, however, obscured by the fact that the Casimir force was not measured directly, but rather estimated indirectly after subtracting from the data a much larger force (up to one order of magnitude), supposedly originating from electrostatic patches, by a fit procedure based on a phenomenological model of the unknown electrostatic force.

We point out that an attempt to measure the thermal Casimir force in a plane-parallel Al setup at separations larger than three micron was reported earlier in [27], but observation of the Casimir force turned out impossible due to the presence of large unexplained forces, presumably of electrostatic origin. Finally, we note that a new experiment to probe the gradient of the Casimir force between two parallel plates at large separations is presently under way [28].

These considerations show that it would be of great interest to directly observe the spectrum of the thermal radiation of a metallic cavity, to make sure that the Drude model provides the correct description. We show that this could be done using a spin-polarized beam of D atoms passing in the gap between the mirrors of a micron-sized cavity.

The plan of the paper is the following: in Sec. II we compute the thermal radiation existing in a micron-sized metallic plane-parallel cavity, and work out its non-Planckian spectrum. In Sec III we discuss the connection between the thermal radiation of the cavity and the thermal Casimir force. In Sec. IV we show that the spectrum of this radiation can be measured by observing the transition rates among hyperfine ground-state sub-levels of spin-polarized D atoms passing between the mirrors. Finally in Sec. IV we present our conclusions.
II. THERMAL RADIATION IN A PLANE-PARALLEL CAVITY

According to intuition, very few thermal photons with transverse electric (TE) polarization can exist in the cavity if its width $a$ is smaller than the thermal wavelength $\lambda_T$, since their wavelengths $\lambda \simeq \lambda_T$ are just too long to fit in the narrow gap between the mirrors. The absence of photon states with TE polarization for $\lambda < 2a$ is indeed the main reason for the suppression of spontaneous emission by excited Cs atoms with maximal angular momentum normal to the mirrors reported in [12]. These considerations lead one to expect that for $a \ll \lambda_T$ there should be very little thermal energy in the cavity, in the form of em fields with TE polarization. Surprisingly, this expectation appears to be incorrect. Let us see how this comes about.

To be definite, let us set a cartesian coordinate system $(x, y, z)$ such that the $z$ coordinate spans the axis of the cavity $0 \leq z \leq a$, while $x$ and $y$ are assigned as the coordinates of the two mirrors. The absence of photon states with TE polarization for $\lambda \simeq \lambda_T$ is smaller than the thermal wavelength $\lambda_T \simeq (2a)^{-1}$.

After the identity is substituted into Eq. (3), one further notes that the representation of the cavity Green function as the sum of the free-space Green function plus a scattering contribution (see Eqs. (A.1) and (A.2)) allows to decompose the unrenormalized energy density $u_{\text{unr}}(z)$ as the sum of four terms:

$$ u_{\text{unr}}(z) = u_{z,p}^{(0)} + u_{z,p}^{(sc)}(z) + u_{\text{BB}} + u^{(sc)}(z) , \quad (5) $$

where

$$ u_{z,p}^{(0)} = \frac{\hbar}{2} \coth \left( \frac{\hbar \omega}{2k_B T} \right) \left( \frac{\hbar}{2} + \exp(\hbar \omega/k_B T) - 1 \right) , \quad (4) $$

The $\hbar/2 \coth (\hbar \omega / 2k_B T)$ term on the r.h.s. of the above Equation is interpreted as describing the contribution of quantum zero-point fluctuations of the em field, while the Bose-Einstein term represents the contribution of thermally excited em fields. After the above identity is substituted into Eq. (3), one further notes that the representation of the cavity Green function as the sum of the free-space Green function plus a scattering contribution (see Eqs. (A.1) and (A.2)) allows to decompose the unrenormalized energy density $u_{\text{unr}}(z)$ as the sum of four terms:

$$ u_{\text{unr}}(z) = u_{z,p}^{(0)} + u_{z,p}^{(sc)}(z) + u_{\text{BB}} + u^{(sc)}(z) , \quad (5) $$

where

$$ u_{z,p}^{(0)} = \frac{\hbar}{2} \coth \left( \frac{\hbar \omega}{2k_B T} \right) \left( \frac{\hbar}{2} + \exp(\hbar \omega/k_B T) - 1 \right) , \quad (4) $$

The $\hbar/2 \coth (\hbar \omega / 2k_B T)$ term on the r.h.s. of the above Equation is interpreted as describing the contribution of quantum zero-point fluctuations of the em field, while the Bose-Einstein term represents the contribution of thermally excited em fields. After the above identity is substituted into Eq. (3), one further notes that the representation of the cavity Green function as the sum of the free-space Green function plus a scattering contribution (see Eqs. (A.1) and (A.2)) allows to decompose the unrenormalized energy density $u_{\text{unr}}(z)$ as the sum of four terms:

$$ u_{\text{unr}}(z) = u_{z,p}^{(0)} + u_{z,p}^{(sc)}(z) + u_{\text{BB}} + u^{(sc)}(z) , \quad (5) $$

where

$$ u_{z,p}^{(0)} = \frac{\hbar}{2} \coth \left( \frac{\hbar \omega}{2k_B T} \right) \left( \frac{\hbar}{2} + \exp(\hbar \omega/k_B T) - 1 \right) , \quad (4) $$

The $\hbar/2 \coth (\hbar \omega / 2k_B T)$ term on the r.h.s. of the above Equation is interpreted as describing the contribution of quantum zero-point fluctuations of the em field, while the Bose-Einstein term represents the contribution of thermally excited em fields.
where metals display little dissipation. This consideration suggests that for a realistic modeling of the cavity, which takes into account the finite skin depth of em fields in real metals, it is sufficient to model the mirrors by the dissipation-less plasma model of infrared optics, according to which:
\[
\epsilon(\omega) = 1 - \frac{\omega_p^2}{\omega^2} + \epsilon_{\text{core}}(\omega),
\]
where \(\omega_p\) is the plasma frequency and \(\epsilon_{\text{core}}(\omega)\) is the contribution of bound electrons. When the dissipation-less model in Eq. (11) is used, the obtained spectrum actually confirms the initial expectation, showing that in the cavity there are barely any thermal photons with TE polarization. For example, at the center of a 2 \(\mu\)m Au cavity at 300 K the energy density \(u_{\text{TE}}^{(\text{cav})}\) associated with TE photons turns out to be seven hundred times smaller than the energy density \(u_{\text{BB}}\) of a (large) black-body (BB) cavity at the same temperature (see the dotted line in the upper panel of Fig.2).

Real metals however do display dissipation at all frequencies, and one thus considers that a more accurate picture of the spectrum of the cavity would be obtained by using the Drude dielectric function for the conduction electrons:
\[
\epsilon(\omega) = 1 - \frac{\omega_p^2}{\omega^2} + \frac{i\gamma}{\omega + i\gamma} + \epsilon_{\text{core}}(\omega),
\]
where \(\gamma\) is the (temperature-dependent) relaxation frequency. The results are surprising, for one finds that dissipation does not engender, as one would expect, just a small correction to the energy density \(u_{\text{TE}}^{(\text{cav})}(z)\) obtained by using the plasma model, but instead leads to a huge increase of the energy density. This can be seen from Fig.1, where the energy \(u^{(\text{cav})}(z)\), normalized by the BB energy \(u_{\text{BB}}\), is displayed for values of \(z\) corresponding to points whose minimum distance from the walls if larger than 50 nm. The solid and the dotted lines correspond to inclusion and to neglect of dissipation, respectively.

As we see, the energy density for dissipation-less mirrors is about twice \(u_{\text{BB}}\), and is nearly constant for the considered values of \(z\), while the energy density of the lossy cavity is everywhere larger than \(u_{\text{BB}}\) by orders of magnitudes, and increases enormously as \(z\) approaches the mirrors. We observe that both \(u^{(\text{cav})}(z)\) and \(u^{(\text{cav})}(z)|_{\text{pl}}\) diverge on the surface of the mirrors. One should recall however that the macroscopic theory loses its validity at points whose separation from the mirrors is not large compared to atomic distances. It turns out that the contribution \(u_{\text{TM}}^{(\text{cav})}\) of em fields with transverse magnetic (TM) polarization is unaffected by the inclusion of dissipation, \(u_{\text{TM}}^{(\text{cav})} \approx u_{\text{TM}}^{(\text{pl})}\), and therefore the huge increase of the energy caused by dissipation is due to modes with TE polarization. This is explicitly shown by Fig.2, where the energy densities of TE modes (upper panel) and TM modes (lower panel) at the center of the cavity are plotted as a function of the temperature \(T\) (in K). In both panels the upper red and the lower blue solid lines correspond, respectively, to lossy mirrors made of Au or Pt, while the dotted lines correspond to neglect of dissipation in a Au cavity, and the dot-dashed lines show the BB energy density. The lower panel demonstrates that the energy of TM modes is practically independent of the conductivity of the plates. The upper panel shows that the energy of TE modes increases by many orders of magnitude as one includes the effect of dissipation.

A better insight into the origin of the large energy \(u_{\text{TE}}^{(\text{cav})}\) can be obtained by looking at its spectrum \(\rho_{\text{TE}}^{(\text{cav})}(\omega)\), say at the centre of the cavity. Plots of \(\rho_{\text{TE}}^{(\text{cav})}(\omega)\) are shown in the lower panel of Fig.3 for two lossy mirrors made of Au (solid line) or Pt (dotted line) (in the upper panel we show for comparison the Planck’s spectrum). The corresponding spectrum from dissipation-less mirrors is negligibly small, and is not displayed in the Figure. The plot in Fig.3 shows that \(u_{\text{TE}}^{(\text{cav})}\) has a broad spectrum extending from zero-frequency up to a maximum frequency \(\tilde{\omega} \approx \omega_c/4\pi\sigma\), where \(\omega_c = c/2a\) is the characteristic cavity frequency and \(\sigma\) is the conductivity. In micron-sized cavities \(\tilde{\omega} \ll \omega = k_BT/h = 3.9 \times 10^{13} \times (T/300)\) rad/s. Indeed for a Au cavity \(\tilde{\omega}|_{\text{Au}} = 6.4 \times 10^9 \times (1\mu\text{m}/a)^2\) rad/s, while for a Pt cavity \(\tilde{\omega}|_{\text{Pt}} = 4.3 \times 10^{10} \times (1\mu\text{m}/a)^2\) rad/s. It is interesting to note that the spectrum of \(\rho_{\text{TE}}^{(\text{cav})}(\omega)\) has a tail extending up to frequencies as large as \(\omega = (10 \pm 100)\) \(\tilde{\omega}\), which contribute significantly to the energy density \(u_{\text{TE}}^{(\text{cav})}\). The tail explains why the energies \(u_{\text{TE}}^{(\text{cav})}\) of Pt and Au are not much different (see Fig.2), despite the factor of 6 difference in their spectral densities for low \(\omega\) visible in Fig.3. Inspection of the magnitudes of the in-plane wave-vectors \(k_{\perp}\) contributing to \(u_{\text{TE}}^{(\text{cav})}\) reveals that \(u_{\text{TE}}^{(\text{cav})}\) is associated with evanescent TE modes, consisting predominantly of magnetic fields. The latter property is demonstrated by the coincidence of the solid and dashed lines in Fig.3 with the full circles and the triangles, respectively, which show the magnetic contribution
FIG. 2: Energy density of TE (upper panel) and TM (lower panel) modes at the center of a 2 µm cavity, versus temperature (in K). In both panels, the upper and lower solid lines are for two lossy mirrors made of Au and Pt, respectively. The lower dotted line is for a Au cavity with dissipation neglected. The dot-dashed curve shows the energy density of a black-body. The upper dashed line in the upper panel shows the universal energy density in Eq. (13).

FIG. 3: Spectrum of the room temperature energy density of TE modes at the center of a 2 µm cavity (lower panel) made of Au (solid line) or of Pt (dotted line), versus angular frequency ω. The full circles and the triangles show the spectrum of the magnetic energy. The mirrors are modeled as lossy conductors. The corresponding spectrum for loss-less mirrors is negligibly small and is not displayed in the Figure. For comparison, the upper panel shows the spectrum of a black body at the same temperature.

to \( \rho_{TE}^{(cav)}(ω) \). Fig. 3 shows that differently from Planck’s law, the spectrum \( \rho_{TE}^{(cav)}(ω) \) is not a universal function of the frequency and of the temperature, for it depends on the conductivity of the mirrors (and also on their thickness). Quite remarkably, though, it can be shown that if the width \( a \) of the cavity and the mirror thicknesses \( w \) satisfy the conditions \( λ_p ≪ a ≪ λ_T \) and \( w ≫ λ_p \), where \( λ_p = c/ω_p \) is the plasma length (\( λ_p = 22 \) nm for Au), at points \( P \) in the gap whose (minimum) distance \( d \) from the mirrors satisfies the condition \( d \gg λ_p \), the energy density \( u_{TE}^{(cav)}(P) \) of the TE modes attains the universal value:

\[
u_{TE}^{(cav)}(z) = \frac{k_B T}{16πa^2} [ζ(3, z/a) + ζ(3, 1 - z/a)], \tag{13}
\]

where \( ζ(s, a) \) is generalized Riemann zeta function. This Equation indicates that the fluctuations contributing to \( u_{TE}^{(cav)}(z) \) are classical, and that the energy of the TE modes grows linearly with the temperature, differently from the \( T^4 \) behavior of the BB energy \( u_{BB} \). A plot of \( u_{TE}^{(cav)}(z) \) is shown by the upper dashed line of Fig. 1 and by the (upper) dashed line in the upper panel of Fig. 2.

Summarizing, we have shown that when the mirrors of a cavity are modeled as lossy conductors, the cavity gets filled with thermal magnetic fluctuations whose energy density is larger by orders of magnitudes than that of a BB at the same temperature (at least for moderately high temperatures). The physical source of these magnetic fields can be traced back to the thermal electronic noise (Johnson-Nyquist noise) of an ohmic conductor at finite temperature. According to the fluctuation-dissipation theorem [29] the power spectrum of the Johnson-Nyquist noise is in fact proportional to the imaginary part of the permittivity \( ε(ω) \), which explains why the phenomena described here become manifest only when the mirrors are treated as dissipative.

III. THE PUZZLE OF THE THERMAL CASIMIR FORCE

The thermal spectrum shown in Fig. 3 has never been tested experimentally, and so it is legitimate to wonder if the theoretical framework which led to it is right. The question is not idle, because indirect evidence from recent Casimir experiments raises more than a doubt. Casimir experiments indeed probe the mechanical effects of thermal em fields on the mirrors. We said earlier that Lifshitz computed the Casimir pressure between two mirrors by
The expressions of the scattering contributions that for a integral over the real frequency axis \([32, 33]\). One finds starting from the representation of Lishitz formula as an

\[
\Delta P_C(a; T) = \int_0^\infty \left[ 1 - 6 \frac{\lambda_p}{a} + O \left( \frac{\lambda_p}{a} \right)^2 \right] \, d\omega,
\]

where \(\xi(3) = 1.202\) is Riemann zeta function. It can be verified that \(\Delta P_C(a; T)\) coincides with the Maxwell stress associated with the thermal magnetic fields contributing to \(u_{(cav)}^{(cav)}\), that we described earlier. The repulsive thermal force has been indeed interpreted as the effect of the magnetic coupling among the Johnson-Nyquist thermal currents with the eddy currents induced by them in the opposite plate \([30, 31]\). The existence of a repulsive thermal correction to the Casimir force between two lossy mirrors, was noted for the first time in \([16]\, and gave rise to intense efforts to observe it. As we pointed out earlier two series of precise experiments \([17, 23]\) found no evidence of the repulsive force in Eq. \((14)\) predicted by the lossy model of the mirrors, and were instead consistent with a loss-less model of the mirrors.

The comindrum of the missing repulsive thermal Casimir force raises the suspicion that the picture of thermal magnetic noise of a lossy cavity, composing \(u_{(cav)}^{(cav)}\), is not entirely right. This prompted us to investigate whether it is possible to observe the spectrum depicted in Fig. \([3]\, to establish which among the lossy Drude and the loss-less plasma model provides the correct description. To provide useful information on the thermal Casimir force, the band-width of the probe should fall in the region of frequencies which contribute significantly to the unobserved thermal Casimir force. To this end, we computed the spectrum \(T_{zz}(\omega)\) of the thermal Casimir pressure \(\Delta P_C(a; T)\). The spectrum \(T_{zz}(\omega)\) can be obtained starting from the representation of Lishitz formula as an integral over the real frequency axis \([32, 33]\). One finds that for \(a \ll \lambda_T\), \(T_{zz}(\omega)\) is well described by the formula:

\[
T_{zz}(\omega) = \frac{\hbar}{2\pi} \left( \frac{2H_{\parallel}^{(sc)}(\omega; z) - H_{\perp}^{(sc)}(\omega; z)}{\exp(h\omega/k_BT) - 1} \right),
\]

where we set

\[
H_{\parallel}^{(sc)}(\omega; z) = \text{Im}[H_{xx}^{(sc)}(\rho, \rho, \omega)] - \text{Im}[H_{yy}^{(sc)}(\rho, \rho, \omega)],
\]

\[
H_{\perp}^{(sc)}(\omega; z) = \text{Im}[H_{zz}^{(sc)}(\rho, \rho, \omega)].
\]

The expressions of the scattering contributions \(H_{\alpha\beta}^{(sc)}(\rho, \rho, \omega)\) to the magnetic Green functions \(H_{\alpha\beta}(\rho, \rho, \omega)\) can be found in the Appendix. Equation \((15)\) shows explicitly the magnetic character of the thermal force. A plot of \(T_{zz}(\omega)\) is shown in Fig. \([4]\, By comparing Fig. \([4]\) with Fig. \([3]\, we see that from the point of view of the Casimir force, the relevant frequencies are those towards the high end of the thermal spectrum, corresponding roughly to angular frequencies in the range from \(10^7\, \text{rad/s}\) to \(10^{11}\, \text{rad/sec}\).

**IV. EXPERIMENTAL SCHEME**

The above considerations suggest that atomic hyperfine transitions could be used to probe the thermal spectrum of the cavity. There are three distinct reasons supporting this belief. First of all, atoms are small and therefore they do not appreciably perturb the thermal field of the cavity. Second, since a magnetic field couples to atomic magnetic moments, hyperfine transitions are sensitive to magnetic field fluctuations. Third, and more importantly, the frequencies of hyperfine atomic transitions typically belong to the GHz region, which coincides with the peak of the spectrum of the thermal Casimir force of a micron-sized cavity (see Fig. \([4]\). We underline that the magnetic trap experiment \([15]\) does not provide much information on the problem of interest for the present work, because the frequencies probed by this experiment are in the MHz region, which are two to three orders of magnitude smaller than the frequencies of interest for the thermal Casimir force. In addition to that, the experiment involved a single metallic surface, and therefore it
is not clear to what extent its results can be extrapolated to a Casimir system of two closely spaced metallic surfaces. The possible existence of saturation effects in a cavity makes it desirable to observe the spectrum of the thermal em field in the gap of a micron-sized metallic cavity, an enterprise that has never been attempted so far. In principle, one might consider an experimental scheme similar to that used in the experiment Ref. [3], based on the observation of the shift of the hyperfine spectral lines of the atoms passing between the mirrors, caused by the Casimir-Polder interaction of the atoms with the fluctuating magnetic field of the cavity. Unfortunately, estimates of the shifts of hyperfine levels suffered by atoms placed near a metallic surface indicate that the effect is too small to be measurable. Thus, a different approach is needed.

The scheme of the experiment we propose is in its general lines similar to that of Ref. [12], and is illustrated in Fig. 4. A plane parallel Au cavity of width \(a = 2 \mu m\) is placed in a uniform magnetic field \(B\) directed in the \((y, z)\) plane, forming an angle \(\theta\) with the \(z\)-axis. A spin-polarized beam of D atoms prepared in a single Zeeman hyperfine \(1S_{1/2}(F, m_F)\) state, traverses the cavity in the \(x\) direction. Thermally excited magnetic fields inside the cavity cause transitions \((F, m_F) \rightarrow (F', m'_F)\) among ground state hyperfine sublevels. Only atoms passing within a narrow channel of width \(H\) across the center can traverse the cavity without being deflected onto the mirrors by the Casimir-Polder interaction. The populations of the hyperfine sublevels by the atoms that escape the cavity are measured by the detector A.

![FIG. 5: Experimental scheme. A plane parallel Au cavity of width \(a = 2 \mu m\) is placed in a uniform magnetic field \(B\) directed in the \((y, z)\) plane, forming an angle \(\theta\) with the \(z\)-axis. A spin-polarized beam of D atoms prepared in a single Zeeman hyperfine \(1S_{1/2}(F, m_F)\) state, traverses the cavity in the \(x\) direction. Thermally excited magnetic fields inside the cavity cause transitions \((F, m_F) \rightarrow (F', m'_F)\) among ground state hyperfine sublevels. Only atoms passing within a narrow channel of width \(H\) across the center can traverse the cavity without being deflected onto the mirrors by the Casimir-Polder interaction. The populations of the hyperfine sublevels by the atoms that escape the cavity are measured by the detector A.](attachment:figure5.png)
Substituting the above relation into Eq. (17), and using Eq. (1), one obtains the following formula for the rate:

\[
\Gamma_\alpha = \frac{2}{\hbar (1-e^{-\hbar \omega/k_B T})} \left| \mu_\alpha^0 \right|^2 \text{Im}[\mathcal{H}_{\alpha\beta}(r_0, r_0, \omega)]. 
\] (20)

From the above formula, one can get the total transition rate \( \Gamma_i = \sum_{\alpha \neq \beta} \Gamma_\alpha \). Substituting the imaginary part of the free space Green function \( \text{Im}[\mathcal{H}_{\alpha\beta}(r_0, r_0, \omega)] = (2/3)(\omega/c)^3 \delta_{\alpha\beta} \) into the r.h.s. of Eq. (20), one can verify that the rates \( \Gamma_i^{(\text{free})} \) outside the cavity are extremely small. For example, for \( T = 300 \text{ K} \) and \( B = 10 \text{ G} \) the rate of the highest hyperfine state (\( F = 3/2, m_F = 3/2 \)) is \( \Gamma^{(\text{free})}_{(3/2,3/2)} = 1.1 \times 10^{-12} \text{ s}^{-1} \). The transition rates inside the gap are obtained by substituting into the r.h.s. of Eq. (20) the Green functions of the cavity. By a simple computation, one finds:

\[
\Gamma_i^{(\text{cav})} = \frac{2}{\hbar (1-e^{-\hbar \omega/k_B T})} \times \left\{ \left| \mathcal{H}_{\perp}^{(\text{cav})}(\omega; z_0) (1 + \cos^2 \theta) + \mathcal{H}_{||}^{(\text{cav})}(\omega; z_0) \sin^2 \theta \right| \mu_i^0 \right|^2 
\]

\[
+ \left| \mathcal{H}_{\perp}^{(\text{cav})}(\omega; z_0) \sin^2 \theta + \mathcal{H}_{||}^{(\text{cav})}(\omega; z_0) \cos^2 \theta \right| \mu_i^0 \right|^2 , 
\] (21)

where \( \mu_i^0 = \mu_i^0 \cdot \hat{B}/|B| \). The coefficients \( \mathcal{H}_{\perp}^{(\text{cav})}(\omega; z_0) \) and \( \mathcal{H}_{||}^{(\text{cav})}(\omega; z_0) \) are defined in a similar manner as \( \mathcal{H}_{\perp}^{(\text{sc})}(\omega; z_0) \) and \( \mathcal{H}_{||}^{(\text{sc})}(\omega; z_0) \):

\[
\mathcal{H}_{\perp}^{(\text{cav})}(\omega; z) = \text{Im}[\mathcal{H}_{xx}^{(\text{cav})}(r, r, \omega)] = \text{Im}[\mathcal{H}_{yy}^{(\text{cav})}(r, r, \omega)] ,
\]

\[
\mathcal{H}_{||}^{(\text{cav})}(\omega; z) = \text{Im}[\mathcal{H}_{zz}^{(\text{cav})}(r, r, \omega)] .
\] (22)

The two sets of coefficients are related to each other by the following Equations:

\[
\mathcal{H}_{\perp}^{(\text{cav})}(\omega; z) = \mathcal{H}_{\perp}^{(\text{sc})}(\omega; z) + 2 \omega^3/3c^3 ,
\]

\[
\mathcal{H}_{||}^{(\text{cav})}(\omega; z) = \mathcal{H}_{||}^{(\text{sc})}(\omega; z) + 2 \omega^3/3c^3 .
\] (23)

We note that the formula for \( \Gamma_i^{(\text{cav})} \) involves the same coefficients \( \mathcal{H}_{\perp}^{(\text{sc})} \) and \( \mathcal{H}_{||}^{(\text{sc})} \) that enter into \( \mathcal{T}_{zz}(\omega) \) (see Eq. (15)). It is apparent from Eqs. (21) that by appropriate measurements of \( \Gamma_i^{(\text{cav})} \) it is in principle possible to determine the coefficients \( \mathcal{H}_{\perp}^{(\text{cav})} \) and \( \mathcal{H}_{||}^{(\text{cav})} \), and then to obtain an estimate of the density of the thermal Casimir pressure \( \mathcal{T}_{zz}(\omega) \).

Figure 6 shows that the transition rates \( \Gamma_i^{(\text{cav})}(z_0) \) depend on the atoms’s coordinate \( z_0 \) inside the cavity, increase rapidly as the atoms approach the mirrors, and diverge at each mirror surface. At first sight, it would seem that the \( z_0 \) dependence of the decay rates introduces a large uncertainty in the final state of the atoms exiting the cavity. Fortunately, this potential source of uncertainty is actually negligible, if one recalls that only atoms passing in the narrow channel of width \( H = 100 \text{ nm} \) across the cavity center can escape it, without being pulled onto the mirrors by the CP attraction. Since the \( z_0 \)-dependence of the rates \( \Gamma_i^{(\text{cav})}(z_0) \) is flat around the center (see Fig. 7), the 50 nm uncertainty on the coordinate \( z_0 \) of the atoms entails an uncertainty much smaller than one percent in the decay rates \( \Gamma_i^{(\text{cav})} \), showing that the atoms that escape the cavity have almost identical rates.

The radiative rates \( \Gamma_i^{(\text{cav})} \) depend dramatically on the used model for the low-frequency electric permittivity \( \epsilon(\omega) \) of the Au mirrors. If the mirrors are described by the plasma model, the rates turn out to be unmeasurably small, and of similar magnitudes as those in free space. For example, for \( T = 300 \text{ K} \) and with a field \( B = 10 \text{ G} \) directed along the \( y \) axis, one finds \( \Gamma_i^{(\text{cav})}_{(3/2,-1/2)} m = 5 \times 10^{-15} \text{ s}^{-1} \). If the mirrors are modeled as Drude conductors, the transition rates increase by many orders of magnitude. In Fig. 8 we shall show plots of the Drude-model radiative rates \( \Gamma_i^{(\text{cav})} \) at the center of the cavity, versus \( B \) (in G). The magnetic field is directed along the \( z \) axis (top panel) or along the \( y \) axis (lower panel). In Fig. 9 the radiative rates are plotted as a function of the angle \( \theta \), for fixed \( B = 20 \text{ G} \). In both figures, the
solid lower red, dashed, dotted, long dashed and the upper solid blue lines correspond, respectively, to the Zeeman hyperfine levels of Fig. 6 from top to bottom. We see that the Drude-model values of the rates differ by more than thirteen orders of magnitudes from the plasma model ones. Since the Larmor frequencies can be tuned by varying the strength of the magnetic field $B$ (see Fig. 6), it is possible in this way to scan a large part of the frequency interval that contributes to the thermal Casimir force (see the colored bands in Fig. 4). Figures 8 and 9 show that the hyperfine state with the largest transition rate is $(F = 3/2, m_F = -1/2)$, which suggests to prepare the atoms in this state.

A precise determination of the probability distribution of the atoms exiting the cavity can be obtained by solving the master equation [37], which describes the evolution of the probabilities $(p_1(t), \cdots p_{2(2I+1)}(t))$ to find an atom in any of the $2(2I+1)$ hyperfine sublevels, during the time interval $0 < t < \tau$ it spends in the cavity:

$$\frac{dp_n}{dt} = -p_n \sum_{k \neq n} \Gamma_{kn}^{(cav)} + \sum_{k \neq n} \Gamma_{nk}^{(cav)} p_k.$$  (24)

By solving this Equation one finds for example that for a $10$ G field directed along the $y$-axis, D atoms prepared in the state $(3/2, -1/2)$ decay into other hyperfine states with a total probability of about 5 $\%$. The final probability distribution among the states $(F', m_{F'})$ is the following: $p_{1/2,1/2} = 0.57\%$, $p_{1/2,-1/2} = 1.07\%$, $p_{3/2,-3/2} = 1.57\%$, $p_{3/2,-1/2} = 94.9\%$, $p_{3/2,1/2} = 1.84\%$ and $p_{3/2,3/2} = 0.02\%$.

Larger transition probabilities can be clearly achieved, if necessary, by considering atoms of lower velocity. The price to pay in that case is however that less atoms shall be able to traverse the cavity, without getting deflected onto the mirrors before reaching the exit. It is not easy to tell a priori what is the best compromise among these

FIG. 7: Radiative rate $\Gamma_{(3/2,-1/2)}^{(cav)}$ in a $2 \mu m$ Au cavity at $T = 300$ K, as a function of the atom coordinate $z_0$. The cavity is placed in a $10$ G magnetic field, directed along the $z$ axis (solid line) or along the $y$ axis (dashed line). The Au mirrors are modeled as lossy conductors. If dissipation is neglected, both rates become smaller than $10^{-12}$ s$^{-1}$ for all displayed values of $z_0$.

FIG. 8: Radiative rates $\Gamma_{(F,m_F)}^{(cav)}$ at the center of a $2 \mu m$ Au cavity for $T = 300$ K, as a function of $B$ (in G). The Au mirrors are modeled as lossy conductors. The magnetic field is directed along the $z$-axis (top panel) or along the $y$-axis (lower panel). The lower solid red, dashed, dotted, long dashed and the upper solid blue lines correspond, respectively, to the Zeeman hyperfine levels of Fig. 6 from top to bottom. If the mirrors are modeled as dissipation-less all rates are negligibly small.

FIG. 9: Radiative rates $\Gamma_{(F,m_F)}^{(cav)}$ at the center of a $2 \mu m$ Au cavity for $T = 300$ K, as a function of $\theta$ (in rad) for $B = 20$ G. The Au mirrors are modeled as lossy conductors. The lower solid red, dashed, dotted, long dashed and the upper solid blue lines correspond, respectively, to the Zeeman hyperfine levels of Fig. 6 from top to bottom. If the mirrors are modeled as dissipation-less all rates are negligibly small.
V. CONCLUSIONS

In conclusion, we have shown that a micron-sized metallic cavity is filled with non-resonant radiation having transverse electric polarization, following a non-Planckian spectrum, whose average density at room temperature is orders of magnitudes larger than that of a black-body at the same temperature. Differently from the typical $T^4$ dependence of the energy of a large black-body cavity, the energy density of a narrow cavity whose width $a$ is smaller than the thermal length $\lambda_T$, displays an almost linear dependence on the temperature. Computations show that the existence of this radiation is strictly dependent on the dissipative properties of real mirrors, an that no such radiation exists in an ideal cavity with no losses. The mechanical pressure exerted by this radiation on the mirrors coincides with the repulsive thermal correction to the Casimir force, predicted by Lifshitz theory for two lossy plates at finite temperature [10]. The actual existence of this thermal force is much debated, since several precision Casimir experiments with metallic surfaces failed to observe it.

We have shown that the spectrum of this radiation can be measured by observing the transition rates between hyperfine ground-state sublevels $1S_{1/2}(F, m_F) \rightarrow 1S_{1/2}(F', m'_F)$ of D atoms passing in the gap between the mirrors. Apart from providing a test of the extension of Planck’s law to the sub-wavelength regime, such a measurement would shed much light on the puzzle of the missing thermal Casimir force, which remains unsolved after twenty years. The availability of optical techniques which allow to manipulate and observe with exquisite precision cold atoms in well determined Zeeman hyperfine states [35][40] makes us hopeful that the experiment described in this work is feasible with current apparatus.

Appendix: Green function of a planar cavity

In this Appendix we provide the explicit formulae for the Green functions of a cavity, that are needed for the computations described in the present work.

At points $\mathbf{r}$ and $\mathbf{r}'$ in the gap between two parallel dielectric slabs at distance $a$ in vacuum, the electric Green function $\mathcal{E}_{\alpha\beta}(\mathbf{r}, \mathbf{r}', \omega)$ can be decomposed as:

$$\mathcal{E}^{(\text{cav})}_{\alpha\beta}(\mathbf{r}, \mathbf{r}', \omega) = \mathcal{E}^{(0)}_{\alpha\beta}(\mathbf{r}, \mathbf{r}', \omega) + \mathcal{E}^{(\text{sc})}_{\alpha\beta}(\mathbf{r}, \mathbf{r}', \omega), \quad (A.1)$$

where $\mathcal{E}^{(0)}_{\alpha\beta}(\mathbf{r}, \mathbf{r}', \omega)$ is the free-space Green function, and $\mathcal{E}^{(\text{sc})}_{\alpha\beta}(\mathbf{r}, \mathbf{r}', \omega)$ is a scattering contribution. The magnetic Green function has an analogous decomposition:

$$\mathcal{H}^{(\text{cav})}_{\alpha\beta}(\mathbf{r}, \mathbf{r}', \omega) = \mathcal{H}^{(0)}_{\alpha\beta}(\mathbf{r}, \mathbf{r}', \omega) + \mathcal{H}^{(\text{sc})}_{\alpha\beta}(\mathbf{r}, \mathbf{r}', \omega). \quad (A.2)$$

The free-space Green function has the expression:

$$\mathcal{E}^{(0)}(\mathbf{r}, \mathbf{r}', \omega) = \mathcal{H}^{(0)}(\mathbf{r}, \mathbf{r}', \omega) = \left(3\mathbf{R} \otimes \hat{R} - 1\right) \left(\frac{1}{R^2} - \frac{i\omega}{cR^2}\right) + (1 - \hat{R} \otimes \hat{R}) \frac{\omega^2}{c^2R^2} - \frac{4\pi}{3}\delta(\mathbf{R})1, \quad (A.3)$$

where $\mathbf{R} = \mathbf{r} - \mathbf{r}'$. Note that the imaginary part of the free-space Green function is non-singular for $\mathbf{r} \rightarrow \mathbf{r}'$:

$$\lim_{r \rightarrow r'} \text{Im}[\mathcal{E}^{(0)}(\mathbf{r}, \mathbf{r}', \omega)] = \lim_{r \rightarrow r'} \text{Im}[\mathcal{H}^{(0)}(\mathbf{r}, \mathbf{r}', \omega)] = \frac{2\omega^3}{3c^3}1. \quad (A.4)$$

In the limit $\mathbf{r} \rightarrow \mathbf{r}'$, the scattering part of the Green tensor $\mathcal{E}^{(\text{sc})}_{\alpha\beta}(\mathbf{r}, \mathbf{r}', \omega)$ attains a finite limit, and its non-vanishing components are:

$$\mathcal{E}^{(\text{sc})}_{zz} = 4\pi i \int \frac{d^2k}{(2\pi)^2} k_z^2 \left( \frac{R_p^{(1)} R_p^{(2)}}{A_p} + \frac{\omega^2 R_p^{(1)} R_p^{(2)}}{A_s} \right) e^{2ik_z a} + \frac{1}{2} \left( \frac{\omega^2 R_p^{(1)} R_p^{(2)}}{A_s} \right), \quad (A.5)$$

and

$$\mathcal{E}^{(\text{sc})}_{zz}(\mathbf{r}, \mathbf{r}, \omega) = 4\pi i \int \frac{d^2k}{(2\pi)^2} k_z^2 \left( \frac{R_p^{(1)} R_p^{(2)}}{A_p} e^{2ik_z a} + \frac{R_p^{(1)}}{2A_p} e^{2ik_z a} + \frac{R_p^{(2)}}{2A_p} e^{2ik_z(a-z)} \right), \quad (A.6)$$

where $k_z$ is the in-plane wave-vector, $k_z = \sqrt{\omega^2/c^2 - k_{\perp}^2}$, the indices $s$ and $p$ denote TE and TM polarizations, respectively, $R_{\alpha}^{(k)}$ is the reflection coefficient of the $k$-th mirror for polarization $\alpha = s, p$ and $A_{\alpha} = 1 - R_{\alpha}^{(1)} R_{\alpha}^{(2)} e^{2ik_z a}$. The corresponding formulae for the magnetic Green tensor $\mathcal{H}^{(\text{sc})}_{\alpha\beta}(\mathbf{r}, \mathbf{r}, \omega)$ can be obtained from those of the electric Green tensor, by interchanging the reflection coefficients $R_s^{(k)} \leftrightarrow R_p^{(k)}$ into Eqs. (A.5) and (A.6).
