Abstract. Solitary pulmonary capillary hemangioma (SPCH) is a rare type of benign lung tumor, which must be distinguished from early lung cancer and precancerous lesions of the lung that manifest in a similar way upon imaging. The current study describes a case of SPCH and a review of the literature is performed. The patient was a 40-year-old Chinese woman who was referred to the Liaoning Cancer Hospital and Institute (Shenyang, China) in October, 2015 with a cough without obvious inducement. Computed tomography (CT) demonstrated pure ground glass opacity (GGO) in the right upper lung. Following systemic anti-inflammatory therapy over 6 months, the lesion did not exhibit any change on CT and was suspected to be an adenocarcinoma in situ (AIS) or atypical adenomatous hyperplasia (AAH). Video-assisted thoracic surgery wedge resection was subsequently performed. Frozen section diagnosis revealed a benign tumor without atypical epithelial cells. Subsequent to surgery, paraffin sections demonstrated that the tumor contained narrow alveolar cavities, thickened alveolar septa and a clear boundary separating it from healthy lung tissue. Furthermore, the proliferation lumens in the alveolar septa were lined with a single layer of flat cells. Immunohistochemical staining revealed that the flat cells were positive for cluster of differentiation CD31 and CD34, and negative for thyroid transcription factor-1 and cytokeratin. The proliferation of capillary vessels lead to the thickened alveolar septa and the tumor was diagnosed as SPCH. When imaging examination demonstrates a GGO in lung, SPCH must be considered in the differential diagnosis of AIS/AAH. As the prognosis of these lesions is entirely different, a pathological examination must be conducted to ensure a correct diagnosis.

Introduction

Solitary pulmonary capillary hemangioma (SPCH) is a rare type of benign lung tumor that is difficult to diagnose due to a lack of symptoms, small lesion size and inconspicuous histological features (1). According to our search of previous literature, only 12 SPCH cases have been reported (1-10). However, each of these studies recorded only 1 or 2 cases, and thus SPCH has not been studied in depth, which may explain the absence of a description of SPCH in the World Health Organization classification of lung tumors in 2015 (11).

SPCH is a benign lesion with an unclear etiology. In the previously reported cases, all patients were asymptomatic and the lesion was discovered incidentally rather than clinically (1-10). Additionally, tumor growth was universally slow and no patients succumbed from the disease (1-10). Improvements in understanding and recognition of SPCH by radiologists, surgeons and pathologists may aid to elucidate its epidemiology.

SPCH exhibits ground glass opacity (GGO) on computed tomography (CT), and the GGO lesion may be suspected to be an adenocarcinoma in situ (AIS)/atypical adenomatous hyperplasia (AAH) and/or to have focal inflammation (1). The prognosis and treatment of these lesions vary; SPCH is a benign lesion and may be treated by complete tumor resection, while AIS/AAH may be malignant or exhibit malignant potential and require chemotheraphy and/or radiotherapy in addition to surgical resection. Meanwhile, inflammation is typically treated with anti-inflammatory therapy (1,11). Thus, a detailed pathological examination is key to ensure correct diagnosis and subsequent treatment.

In the present study, a clinicopathological study of an SPCH case has been reported alongside a review of the literature. The purpose of the study was to define the clinical
manifestation, radiological, histological and immunohistochemical features, and diagnosis of SPCH, as a currently unrecognized lesion.

**Case report**

A 40-year-old Chinese woman was referred to the Liaoning Cancer Hospital and Institute (Shenyang, China) with a cough in October, 2015 without obvious inducement. The patient had no phlegm or dyspnea chest discomfort. The chest CT indicated a pure GGO lesion (size, 19x17 mm) in the right upper lung (Fig. 1). Laboratory findings, including tumor markers, such as carcinoembryonic antigen and carbohydrate antigen 19-9 were within the normal ranges at 1.7 ng/ml (normal range 0-5 ng/ml) and 17.5 U/ml (normal range 0-37 U/ml), respectively (12). Following systemic anti-inflammatory therapy for 6 months, the size and density of the lesion had not changed according to CT. Although no abnormal uptake of fluorine-18-fluorodeoxyglucose in the lesion was observed during positron emission tomography-CT, it was suspected to be an AIS or AAH, and video-assisted thoracic surgery wedge resection was performed. Microscopically, a clear boundary between the tumor and normal lung tissue was observed in the low-power field (Fig. 2A). The tumor consisted of a narrow alveolar cavity, the alveolar septa was thickened with proliferated lumens that were various sizes and the lumens were lined with single-layer flat cells without atypical epithelial cells (Fig. 2B). Based on the above-mentioned findings, the intraoperative frozen sections demonstrated that the lesion was a benign tumor. Later, immunohistochemical staining of a paraffin section revealed the flat cells were positive for cluster of differentiation CD34 (Fig. 3A) and CD31 (Fig. 3B), and negative for D2-40, cytokeratin and thyroid transcription factor-1 (Fig. 3C). Therefore, the patient was diagnosed with SPCH and was followed up for 13 months after surgery with no recurrence.

**Discussion**

SPCH is a particularly rare type of benign tumor, characterized by the proliferation of capillary vessels. It was initially identified by Fugo et al (1) in 2006. Since then, only 13 cases have been reported (including the present case; Table I). There were seven males and six females, and the age ranged from 40 to 61 years (mean age, 52.8 years). The lesions were located on the left side in six cases and on the right side in seven cases. Two were located in the upper lobe, two in the middle lobe and nine cases were located in the lower lobe. The tumor size ranged from 7 to 20 mm (mean, 12 mm). SPCH tends to present as a single small lesion, which is located in the lower lobe without any symptoms.

Observation of GGO is typical upon imaging of cases of SPCH (1). In 13 cases, four were pure GGO, and eight were mixed GGO and one case exhibited a solid nodule. The pure GGO may represent a limited proliferation of capillary vessels in the alveolar septum, which is followed by a thickened alveolar septum and a narrowed alveolar space, although the space was preserved and still contained air. The solid aspect of the GGO may be the result of the capillary vessel congestion,

which may cause alveolar collapse and a resulting lack of space to contain air.

When GGO in the peripheral lung is observed, AIS/AAH may be highly suspected. It is difficult to distinguish AIS/AAH from SPCH by imaging examination alone. During surgery, Shimada et al (8) observed that the SPCH became impalpable following reiterative palpation. This finding may be caused by squeezing the blood in capillary vessels followed by constriction of the thickened alveolar septum and the lesion feeling the same as normal lung tissue. However, in AIS/AAH, based upon the different histopathological manifestations, the nodule would not be impalpable, as there are collagenous fibers or elastic fibers in the alveolar septa rather than capillary vessels. Therefore, when tumors are located in the peripheral lung, present with a GGO image and cannot be palpated following reiterative palpation during surgery, a diagnosis of SPCH may be determined. SPCH is a benign tumor, whereas AIS/AAH are malignant or have malignant potential. Therefore, it is critical to differentiate these lesions in the clinical setting.

Histopathology is an important method, as the histological appearance between SPCH and AIS/AAH is completely different (11). AIS often occurs in the peripheral lung, very close to the pleura. AIS is a small (≤3 cm) adenocarcinoma with growth restricted to neoplastic cells along pre-existing alveolar structure (lepidic growth), lacking stroma, vascular, alveolar space or pleural invasion. Grossly, it is a poorly defined nodule measuring up to 3 cm in size, with a tan or pale cut surface. Microscopically, AIS typically exhibits type II pneumocytes and/or Clara cell differentiation. The cells demonstrate marked cytologic atypia, such as dark and big nucleolus, coarse granular chromatin and pathologic mitosis. Alveolar septa widening is common in AIS, which is caused by sclerosis/elastosis rather than proliferation of capillary vessels (11). Macroscopically, AAH is a millimeter-sized, poorly defined, tan-yellowed nodule. It is characterized by mildly to moderately atypical type II pneumocyte and/or Clara cell proliferation along the alveolar walls. Double nuclei are common, but mitoses are extremely rare. There are gaps along the surface of the basement membrane between the cells. Alveolar septa widening is not obvious and there is no capillary vessel proliferation (11).

Pulmonary capillary hemangiomatosis (PCH) is a multiple-lesion disease with numerous GGO nodules observed on CT (13). Although the histopathological characteristics are similar between PCH and SPCH, their clinical manifestations are completely different (14). PCH is a multiple-lesion disease with numerous GGO nodules on CT and is associated with pulmonary hypertension, whereas SPCH is a solitary nodular lesion with only solitary nodules observed on CT and the patient may present with mild or no symptoms (13). However, the underlying mechanisms have not been clarified (1). Evidence indicates that the increased expression levels of vascular endothelial growth factor and platelet-derived growth factor may be associated with PCH (1). However, the association between PCH and SPCH remains unknown. Based upon the similarities in histological manifestation, whether SPCH is the precursor lesion of PCH or whether they are independent of each other requires further investigation.

Pulmonary vein fibrosis is the main histological change observed in pulmonary veno-occlusive disease (PVOD) that leads to the complete blocking of pulmonary veins, venous stagnation and alveolar wall capillary dilatation (14). The histological features of PCH are the proliferation of capillaries within the alveolar walls, as well as muscularization of arterioles and medial hypertrophy of muscular pulmonary arteries. Therefore, PCH causes pulmonary hypertension (14). PCH and PVOD are similar in clinical manifestation, though are fundamentally different diseases due to their histopathological features.

Focal inflammation also exhibits a GGO on CT (15). Clinically, it may decrease or disappear following antibiotic therapy. Histopathologically, inflammation results in different types of inflammatory cell, such as lymphocytes, plasmocytes, neutrophil granulocytes and proliferation of fibroblasts, rather than the proliferation of capillary vessels in widened alveolar septa (11).
In conclusion, different types of lesion exhibit GGO on CT, and the GGO lesion may be SPCH rather than AIS/AAH. The prognosis of these types of lesions is entirely different, therefore, a pathological examination must be conducted to ensure the correct diagnosis.
