Within many-body perturbation theory we apply vertex corrections to various closed-shell atoms and to jellium, using a local approximation for the vertex consistent with starting the many-body perturbation theory from a DFT-LDA Green’s function. The vertex appears in two places – in the screened Coulomb interaction, $W$, and in the self-energy, $\Sigma$ – and we obtain a systematic discrimination of these two effects by turning the vertex in $\Sigma$ on and off. We also make comparisons to standard $GW$ results within the usual random-phase approximation (RPA), which omits the vertex from both. When a vertex is included for closed-shell atoms, both ground-state and excited-state properties demonstrate little improvement over standard $GW$. For jellium we observe marked improvement in the quasiparticle band width when the vertex in $\Sigma$ on $W$ is turned on, whereas turning on the vertex in $\Sigma$ leads to an unphysical quasiparticle dispersion and work function. A simple analysis suggests why implementation of the vertex only in $W$ is a valid way to improve quasiparticle energy calculations, while the vertex in $\Sigma$ is unphysical, and points the way to development of improved vertices for $ab$ initio electronic structure calculations.

I. INTRODUCTION

Many-body perturbation theory (MBPT) is a leading method for computing excited-state electronic properties in solid-state physics. Within many-body perturbation theory, Hedin’s $GW$ method is the most widely used approximation for the self-energy, $\Sigma$. The exact one-body Green’s function, $G$ (which contains information about ground and excited-state properties of the system) can be written, using a Dyson equation, in terms of a suitable Green’s function of a “zeroth-order” system of non-interacting electrons, $G_0$ (constructed from that system’s one-particle wavefunctions and energies), and the self-energy operator $\Sigma$. The approximation is defined by the choice of zeroth-order system and by the expression (typically a diagrammatic expansion in terms of $G_0$) used to approximate $\Sigma$. The self energy, $\Sigma$, contains all the information of many-body interactions in the system and can be obtained by using Hedin’s set of coupled equations:

$$\Sigma(12) = i \int W(1^{+}3)G(14)\Gamma(23; 3)d(34)$$  \hspace{1cm} (1)$$

$$W(12) = v(12) + \int W(13)P(34)v(42)d(34)$$  \hspace{1cm} (2)$$

$$P(12) = -i \int G(23)G(42)\Gamma(34; 1)d(34)$$  \hspace{1cm} (3)$$

and the Dyson equation, where $P$ is the polarization, $W$ the screened and $v$ the unscreened Coulomb interaction and $\Gamma$ the vertex function. The notation $I \equiv (x_1, \sigma_1, t_1)$ is used to denote space, spin and time variables and the integral sign stands for summation or integration of all of these where appropriate. (1$^+$) denotes $\Gamma_1 + \eta$ where $\eta$ is a positive infinitesimal in the time argument. Atomic units are used in all equations throughout this paper. These are four coupled integro-differential equations where the most complicated term is the vertex, $\Gamma$, which contains a functional derivative and hence, in general, cannot be evaluated numerically. The vertex is the usual target of simplification for an approximate scheme.

The widely used $GW$ approximation is derived with the Hartree method as a starting point, and hence has a rigorous foundation only when started from a non-interacting Green’s function, $G_0$, made from eigenstates of the Hartree Hamiltonian. This is because the initial self-energy, $\Sigma_0 = 0$ and the vertex function is correspondingly set to $\Gamma(12; 3) = \delta(12)\delta(13)$ since $\delta \Sigma(12)/\delta G(45) = 0$.

Solving Hedin’s equations with the vertex fixed in this expression yields the so-called self-consistent $GW$ approximation. In this approach, the self-energy operator is formed from a product of a Green’s function and a screened Coulomb interaction, where the Green’s function used is consistent with that returned by Dyson’s equation. Since the self-energy depends on $G$, this procedure should be carried out self-consistently, beginning with $G = G_0$.

In practice, it is customary to use the first iteration only, often called $G_0^W W_0^{\text{RPA}}$, to approximate the self-energy operator. Here, $W_0^{\text{RPA}}$ is perhaps the simplest possible screened interaction, which involves an infinite geometric series over

$\Gamma(12; 3) = \delta(12)\delta(13)$

$$+ \int \frac{\delta \Sigma(12)}{\delta G(45)} G(46)G(75)\Gamma(67; 3)d(4567),$$  \hspace{1cm} (4)$$

$\Gamma(12; 3)$ is perhaps the simplest possible screened interaction, which involves an infinite geometric series over
non-interacting electron-hole pair excitations as in the usual
definition of the RPA. It is important to make this one iteration
as accurate as possible, so an initial $G_0$ calculated using
Kohn-Sham density-functional theory in the local-density
approximation (DFT-LDA) is normally used. This choice of $G_0$
generally produces much more accurate results for quasipar-
ticle energies (the correct electron addition and removal en-
ergies, in contrast to the DFT-LDA eigenvalues). However,
because this choice of $G_0$ corresponds to a non-zero $\Sigma$, there
is no longer a theoretical justification for the usual practise of
setting the vertex to a product of delta functions and different
choices for the exchange-correlation functional may lead to
different Green’s functions $\Sigma$.\footnote{1}

Using the static exchange-correlation kernel, $K_{xc}$, (which is
the functional derivative of the DFT exchange-correlation po-
tential, $V_{xc}$, with respect to density, $n$) Del Sole et al.\footnote{2}
demonstrated how $G_0W_0^{\Gamma\text{LDA}}$ may be modified with a vertex function
to make $\Sigma$ consistent with the DFT-LDA starting point. They
added the contribution of the vertex into both the self-energy,
$\Sigma$, and the polarization, $P$. The result is a self-energy of the
form $G_0W_0^{\Gamma\text{LDA}}$.\footnote{3} The $G_0W_0^{\Gamma\text{LDA}}$ approximation is obtained
when the vertex function is included in $P$ only. As com-
mented by Hybertsen and Louie\footnote{4} and Del Sole et al., both
these results take the form of $GW$, but with $W$ representing the
Coulomb interaction screened by respectively the test-charge-
electron dielectric function and the test-charge-test-charge di-
electric function, in each with electronic exchange and cor-
relation included through the time-dependent adiabatic LDA
(TD-LDA).

Del Sole et al. found that $G_0W_0^{\Gamma\text{LDA}}$ yields final results
almost equal to those of $G_0W_0^{\text{RPA}}$ for the band gap of crys-
talline silicon and that the equivalent results from $G_0W_0^{\text{LDA}}$
were worse when compared to $G_0W_0^{\text{RPA}}$. It should perhaps be
mentioned that the inclusion of other types of vertex correc-
tions have been studied before as well, most notably correc-
tions based on various approximations of a second iteration
of Hedins equations, starting with $G_0W_0^{\text{RPA}}$.\footnote{5,6} However,
these have usually been applied with initial Kohn-Sham (KS)
Green’s functions, which are still not theoretically consistent
with that starting point. The correct theoretical treatment of a
second-iteration vertex from KS Green’s functions is quite
complicated and still absent in the literature.

The purpose of the present work is to make a systematic
study, for both localized and extended systems, of a simple
ab initio vertex correction whose form is determined by the
starting approximation for the self-energy ($\Sigma_0 = V_{xc}$ for DFT-
LDA). Related vertex corrections, including others derived
from $K_{xc}$, have been investigated in earlier work. For ex-
ample, Northrup et al.\footnote{7} used LDA bulk calculations as a starting
point and a plasmon-pole calculation of the response func-
tion in conjunction with a $G_0W_0^{\text{LDA}}$-like vertex correction in
the screened interaction. They found a narrowing of the band
widths of Na, Li and K\footnote{8} in agreement with the experiments
of Jensen and Plummer\footnote{9,10} who had noted that the experimental
band width was significantly narrowed ($\sim 23\%$) compared to
the free-electron result. Hedin’s $G_0W_0^{\text{RPA}}$ calculations only
gave a narrowing of about $10\%$ for an homogeneous electron
gas of the same mean density, indicating a large impact of

II. METHOD

Hybertsen and Louie\footnote{11} comment that it is possible to
start a $GW$ calculation from an initial self-energy, $\Sigma_0(12) =
\delta(12)V_{xc}(1)$. This approach gives a theoretical basis for be-
inning a $G_0W_0$ calculation from DFT-LDA orbitals. Adopt-
ing this idea, we see from Eq. (4) that the second term is now
non-zero, unlike in the $GW$ approximation. Since the electron
density is $n(1) = -iG(11^{+})$ then,

$$\frac{\delta \Sigma(12)}{\delta G(45)} = \frac{\delta \Sigma(12)}{\delta n(4)} \frac{\delta n(4)}{\delta G(45)}$$

(5)

$$= -i\frac{\delta V_{xc}(1)}{\delta n(4)} = -iK_{xc}^{\text{LDA}}(1)$$

(6)

where delta-functions are to be understood in all other vari-
ables. In an appendix Del Sole et al.\footnote{12} show how to add this ap-
proximate vertex to both $W$ and $\Sigma$, and into $W$ only, by form-
ing two different effective $W$s. Our method follows that of Del
Sole et al.\footnote{12} by modifying the dielectric function, $\epsilon$, from its
form in the RPA. The screened Coulomb interaction in MBPT
is written as

$$W = \epsilon^{-1}v,$$

(7)

where $\epsilon^{-1}$ is the inverse dielectric function. We use the full
polarization without recourse to plasmon-pole models. The
random phase approximation (RPA) dielectric function is

$$\epsilon = 1 - \chi^0.$$

(8)
Del Sole et al. show that adding the form of the vertex from Eq. (6) into both $\Sigma$ and $W$ modifies the RPA dielectric function to,

$$\tilde{\varepsilon} = 1 - (v + K_{xc}) \chi^0,$$  \hspace{1cm} (9)

which leads to the introduction of an effective screened Coulomb interaction $\tilde{W}$. This is trivial to implement into a GW computer code as it requires a simple matrix addition, once $K_{xc}$ is calculated. The result of this modification is that $\tilde{W}$ contains not only the screened Coulomb interaction but also an exchange-correlation potential. We shall refer to this method as $G_0W_0\Gamma_{LDA}$ as we have added the correct DFT-LDA vertex to the GW method, hence the method is a one-iteration GW ($G_0W_0\Gamma_0$) calculation beginning with a DFT-LDA Green’s function.

An alternative choice for the effective dielectric function,

$$\tilde{\varepsilon} = 1 - (1 - K_{xc}) \chi^0 v \chi^0$$  \hspace{1cm} (10)

corresponds to adding $K_{xc}$ into $W$ only. We term this method $G_0W_0\Gamma_{LDA}$ as the LDA vertex is inserted into the screened Coulomb interaction, $W$, only. This is equivalent to the one-iteration GW approximation, $G_0W_0$ but with $W$ calculated using the adiabatic LDA.

The vertices presented are thus dynamical, i.e., frequency dependent, due to the inclusion of $\chi^0$, and must include the excitonic effects of the corresponding jellium due to the appearance of $K_{xc}$. Another way of looking at it is that this corresponds to a treatment beyond $G_0W_0$ where at the level of the vertex corrections, the system is modelled by the homogenous electron gas. It is not likely, however, that these methods would be able to capture any satellite structure beyond that provided by $K_{xc}$ as the calculations are non-self-consistent.

### III. COMPUTATIONAL APPROACH

The quasiparticle energies, $\epsilon_i$, and wavefunctions, $\psi_i$, are formally the solution of the quasiparticle equation,

$$\{-\frac{1}{2} \nabla^2 + V_{ext}(\mathbf{r}) + V_H(\mathbf{r})\} \psi_i(\mathbf{r}) = \epsilon_i \psi_i(\mathbf{r}).$$  \hspace{1cm} (11)

where $V_{ext}$ and $V_H$ are the external and Hartree potential, respectively.

In the case of a spherically symmetric system it is sufficient to describe all non-local operators in the GW formalism by two radial coordinates and one angular coordinate, $\theta$, that denotes the angle between the vectors $\mathbf{r}$ and $\mathbf{r}'$. The self-energy, $\Sigma$, then assumes the much simpler form,

$$\Sigma(\mathbf{r}, \mathbf{r}', \theta; \epsilon) = \sum_{l=0}^\infty [\Sigma_l(\mathbf{r}, \mathbf{r}'; \epsilon)] P_l(\cos \theta),$$  \hspace{1cm} (12)

where $P_l(\cos \theta)$ is a Legendre polynomial of order $l$.

The Legendre expansion coefficients of the self-energy, $\Sigma$, are calculated directly, thereby circumventing the need for a numerical treatment of the angular dependence. We use a real-space and imaginary time representation to calculate the self-energy from the non-interacting Green’s function $G_0$. The self-energy on the real frequency axis, required for solving the quasiparticle equation, is obtained by means of analytic continuation. The current implementation has been successfully applied to jellium clusters and light atoms.

To obtain the quasiparticle energies and wavefunctions the quasiparticle equation is fully diagonalized in the basis of the single particle orbitals of the non-interacting Kohn-Sham system. For localized systems the quasiparticle wavefunctions can differ noticeably from the wavefunctions of the non-interacting system or in certain cases even have a completely different character, as was demonstrated for image states in small metal clusters.

Ground-state total energies were calculated using the Galitskii-Migdal formula transformed to an integral equation over imaginary frequency. This avoids analytic continuation of the self-energy, which would be unreliable for large frequencies.

For jellium, the homogenous electron gas, we solve Hedin’s equations in wavevector and real-frequency space. This avoids analytic continuation and enables accurate and easy extraction of spectral properties. Again, we do not use plasmon-pole models, but the full frequency-dependent polarization.

### IV. TOTAL ENERGIES

| Method     | He     | Be     | Ne    |
|------------|--------|--------|-------|
| HF         | $-1.4304^a$ | $-3.6433^a$ | $-12.8547^a$ |
| DFT-LDA    | $-1.4171$ | $-3.6110$ | $-12.8183$ |
| $G_0W_0^{\Gamma_{LDA}}$ | $-1.4117(5)$ | $-3.5905(9)$ | $-12.777(1)$ |
| $G_0W_0^{\Gamma_{LDA}}$ | $-1.4120(2)$ | $-3.590(1)$ | $-12.775(15)$ |
| $G_0W_0^{\Gamma_{LDA}}$ | $-1.3912(2)$ | $-3.573(1)$ | $-12.745(10)$ |

**TABLE I**: Total energy data (Hartrees/electron). See Fig. I — A comparison of various methods for total energy calculations. Hạt-tree-Fock, Density-Functional Theory, one-iteration GW ($G_0W_0^{\Gamma_{RPA}}$), the two approximate vertex GW’s, variational Monte Carlo, diffusion Monte Carlo and configuration interaction. (CI usually yields the most accurate estimate of the ground-state energies for localized systems.)

The MBPT total energy results are compared against configuration interaction (CI) and quantum Monte Carlo methods (variational Monte Carlo (VMC) and diffusion Monte Carlo (DMC)). The CI and QMC family of methods usually yield the most accurate estimates of ground-state energies and are
variationally bound, meaning that the lowest energy is the most accurate.

The $G_0 W_0$ result with $G_0$ constructed from DFT-LDA eigenstates, $(G_0 W_0^{\text{RPA}})$ is in poor agreement with CI in all three cases. It is known that there is a large self-interaction error in the LDA, especially noticeable in smaller atoms. Hartree-Fock, which is self-interaction free by construction, is more accurate than DFT-LDA. Hence the self-interaction error is introduced via the LDA orbitals into the Green’s function, $G_0^{\text{DFT}}$, which gives rise to the $G_0 W_0^{\text{RPA}}$ total energy’s consistent poor agreement with CI. (By way of illustration, using a $G_0$ from the superior KLI, an optimized effective potential that is formally free of self-interaction error for a two-electron system, greatly improves the DFT and $GW$ total energies. The $G_0 W_0^{\text{RPA}}$ results for He, Be and Ne are $-1.4550(3), -3.6780(2)$ and $-12.843(1)$ respectively.)

For all three atoms the vertex in $W$ alone ($G_0 W_0^{\text{LDA}}$) shows little difference to $G_0 W_0^{\text{RPA}}$ (Table II and Fig. 1), whereas $G_0 W_0^{\text{LDA}}$ raises the total energy with respect to $G_0 W_0^{\text{RPA}}$. This change is due not to the LDA self-interaction but to the nature of the vertex. The result of adding the LDA vertex to $G_0^{\text{KLI}} W_0$ mirrors that of adding it to $G_0^{\text{DFT-LDA}} W_0$. There is an increase of the total energy when the vertex is applied in both $W$ and $\Sigma$ ($G_0^{\text{KLI}} W_0^{\text{LDA}}$) but the vertex in $W$ only, ($G_0^{\text{KLI}} W_0^{\text{LDA}}$), results in a similar total energy to $G_0^{\text{KLI}} W_0^{\text{RPA}}$. (The $G_0^{\text{KLI}} W_0^{\text{LDA}}$ and $G_0^{\text{KLI}} W_0^{\text{RPA}}$ for He are $-1.4235(10)$ and $-1.4475(5)$ respectively.)

In jellium the trend is the same for all densities in the region from $r_s = 2$ to 5 ($r_s$ is the density parameter, where $r_s = (3/(4\pi n))^{1/3}$ and $n$ is the electron density in atomic units) as can be seen in Table II. $G_0 W_0^{\text{LDA}}$ lowers the total energy of jellium slightly as compared to $G_0 W_0^{\text{RPA}}$ and $G_0 W_0^{\text{LDA}}$ makes the energy too high. $G_0 W_0^{\text{RPA}}$ is on average $\sim 5\%$ lower than the QMC result. $G_0 W_0^{\text{LDA}}$ is $\sim 10\%$ too high and $G_0 W_0^{\text{LDA}}$ $\sim 6\%$ lower than the QMC result.

For jellium, neither method leads to a result more accurate than $G_0 W_0^{\text{RPA}}$. It is apparent, however, that the vertex added solely in the polarization has the minor effect of lowering the total energy. When the vertex is subsequently added into the self-energy there is a major positive shift in the total energy as seen in the atomic results as well. Self-consistent $GW$ calculations \cite{41} for jellium show that the self-consistent total energy is about 4 – 5\% higher than the $G_0 W_0^{\text{RPA}}$ ones in the range of $r_s = 2$ to 5 and the essentially exact QMC energies are about 0.5 – 1\% lower than the self-consistent $GW$ values. Assuming to a first approximation that the vertex corrections are independent and additive corrections to self-consistency, this would indicate that the $G_0 W_0^{\text{LDA}}$ energies would still be much too high, but the $G_0 W_0^{\text{LDA}}$ energies might end up very close to the QMC results if self consistency is achieved, since they lower the $G_0 W_0^{\text{RPA}}$ energies to roughly the same extent as the difference between QMC and self-consistent $GW$ energies.

V. QUASIPARTICLE ENERGIES

The quasiparticle energy corresponding to the first ionization energy is presented for helium, beryllium and neon in Fig. 1. The MBPT methods are consistently more accurate than DFT-LDA Kohn-Sham eigenvalues. However,
again $G_0W_{0}\text{LDA}$ is roughly equivalent to $G_0W_{0}\text{RPA}$ for helium and beryllium and in all cases $G_0W_{0}\Gamma_{\text{LDA}}$ causes an increase in quasiparticle energy, in agreement with Del Sole et al. In general, $G_0W_{0}\Gamma_{\text{LDA}}$ worsens QP energies as compared to $G_0W_{0}\text{RPA}$.

For jellium, different quantities are accessible at different stages of the iteration of Hedin’s equations. The pair-correlation function $g(r)$ for example, can be obtained from the (isotropic) inverse dielectric function, $\varepsilon^{-1}(k, \omega)$, by the integration

$$g(r) = 1 + \frac{3}{2rk_F^3} \int_0^\infty dk k \sin(kr) \left[S(k) - 1\right],$$

(13)

where the static structure factor,

$$S(k) = -\frac{k^2r^3}{3} \int_0^\infty d\omega \frac{1}{\pi} \sum_{\varepsilon} \left[\varepsilon^{-1}(k, \omega)\right].$$

(14)

$g(r)$ is shown in Fig. 3 for $r_s = 1.0$. The RPA displays the well-known failure to be positive definite for $r_s \gtrsim 0.78$. This is remedied by the local vertex, but the result appears to be an overcorrection (note that $G_0W_{0}\text{LDA}$ and $G_0W_{0}\text{Gamma LDA}$ are equivalent at this stage since $\Sigma$ has not yet been calculated).

The tendency of $G_0W_{0}\Gamma_{\text{LDA}}$ to overshoot – the reason for which, we will defer to the closing discussions – is apparent in all subsequent results. Once $\Sigma$ has been calculated, the QP dispersion can be extracted. Presented in Fig. 4 is the real part of the self-energy evaluated at the self-consistent eigenvalues, i.e. the correction $Re\left\{\Sigma_k(\varepsilon_k)\right\}$ to the quasiparticle dispersion as found by the formula

$$\varepsilon_k = \varepsilon_k^0 + Re\left\{\Sigma_k(\varepsilon_k)\right\},$$

(15)

where $\varepsilon_k^0$ is the non-interacting dispersion. Care has been taken to align the Fermi energy of non-interacting and interacting systems so that the Dyson equation is consistent and all quantities are calculated in real frequency. The self-consistent quasiparticle energy should be used when one has a self-consistent $\Sigma$, but for a $G_0W_{0}$ calculation there is still controversy about whether the self-consistent eigenvalues $\varepsilon_k$ or the zeroth-order eigenvalues $\varepsilon_k^0$ are best used as the argument of $\Sigma_k$ in equation (13). The self-consistent approach was chosen in this paper.

The difference between the quasiparticle energies at $k = k_F$ and $k = 0$ is known as the band width, which therefore takes the form of the free-electron value ($k^2_F/2$) corrected by the change in Fig. 4 between $k = k_F$ and $k = 0$. This band width is shown in Table IV and Fig. 5. It consistently seems that vertex corrections applied in the screened Coulomb interaction only give the best results. This is corroborated by the fact that this quasiparticle dispersion has a better band width and that the $G_0W_{0}\Gamma_{\text{LDA}}$ introduces little change to the band width. These results are in agreement with those of Mahan and Sernelius.
VI. THE CHEMICAL POTENTIAL OF JELLIIUM

To get another indication of whether the large absolute positive shift of the quasiparticle dispersion is physical, we compare with experimental work functions of Al (100), (110) and (111) surfaces (see Table V). We assume that the electron density of the surface region, and therefore the electrostatic energy approximation of the bulk Fermi level, which we use here as a discriminator between self-energy approximations in the bulk. Treating the bulk metal as jellium, we obtain a shift in the work function due to the new chemical potential,

\[ \phi = \phi^{\text{LDA}} + \Delta \mu = \phi^{\text{LDA}} - (\Re \{ \Sigma_k(\epsilon_F) \} - V_{xc}). \]

where \( \Delta \mu \) is the correction due to the shift of the bulk Fermi energy for a GW jellium calculation. The LDA work function is defined as the shift between the vacuum potential, \( \phi_{\text{vac}} \), and the chemical potential from the LDA surface calculation, \( \mu^{\text{LDA}} \). Since the exact self-energy for jellium must fulfill the condition

\[ \Re \{ \Sigma_k(\epsilon_F) \} = V_{xc}, \]

we see that the LDA (taken from highly accurate QMC calculations) corresponds to the exact result if one assumes that the bulk is accurately modelled by jellium. Comparing with Table V and Fig. 6 we see that \( G_0W_0^{\text{RPA}} \) is closest to the exact result and \( G_0W_0^{\text{LDA}} \) is slightly further away, while \( G_0W_0^{\Gamma^{\text{LDA}}} \) is even worse.

This leads us to conclude that \( G_0W_0^{\Gamma^{\text{LDA}}} \) is unphysical in the sense that a vertex correction derived from a self-energy

| \( r_s \) | \( G_0W_0^{\text{RPA}} \) | \( G_0W_0^{\Gamma^{\text{LDA}}} \) | \( G_0W_0^{\text{LDA}} \) | Experiment |

FIG. 6: (Color online) The workfunction of aluminium ($r_s = 2.07$) — Compared to experiment. The LDA surface calculation corresponds to the exact result if jellium is used to model the bulk Fermi energy. $G_0 W_{0}^{\text{RPA}}$ and $G_0 W_{0}^{\text{LDA}}$ are closer, while $G_0 W_{0}^{\Gamma_{\text{LDA}}}$ is much worse compared to experiment. The colored lines are there to guide the eye. The black line corresponds to perfect agreement with experiment (error bars indicate experimental uncertainty).

approximation with a completely local dependence on the density (like the LDA) will have pathological features. This is most probably due to improper behaviour of the spectral function of the screened interaction, as is demonstrated in the final section of this paper.

VII. DISCUSSION AND CONCLUSIONS

We have presented $G_0 W_{0}^{\text{LDA}}$ and $G_0 W_{0}^{\Gamma_{\text{LDA}}}$ calculations for isolated atoms and jellium. We see that $G_0 W_{0}^{\Gamma_{\text{LDA}}}$ worsens results in all cases compared to the common $G_0 W_{0}^{\text{RPA}}$ approximation.

A proper $ab$ initio vertex correction for calculations on an arbitrary system should be derived from the starting approximation for the self-energy. In this work we have shown that in practice, vertex corrections derived from a local density approximation to the self-energy (like the LDA) are pathological when applied to both the self-energy and the screened inter-

action. The work function of aluminium was used to confirm that the value of the chemical potential in $G_0 W_{0}^{\Gamma_{\text{LDA}}}$ is far from the correct result.

An indication of why a local correction in both $W$ and $\Sigma$ performs so poorly has been discussed previously by Hindgren and Almbladh and investigated in excitonic effects on wide-bandgap semiconductors by Marini et al. Both types of vertex corrections lead to a modified screened interaction $\tilde{W} = \tilde{E}^{\text{inc}}$. The spectral function of this, which is required to be positive semidefinite for $\omega \leq 0$ and negative semidefinite otherwise, is given by

$$ B_q(\omega) = -\frac{\text{sgn}(\omega)}{\pi} \text{Im} [\tilde{W}_q(\omega)] $$

$$ = \frac{\text{sgn}(\omega)}{\pi} \text{Im} [\tilde{\Sigma}_q(\omega)] |\tilde{\xi}_q(\omega)|^2 v_q, $$

so it inherits whatever properties of definiteness the imaginary part of the dielectric function has. Now for $G_0 W_{0}^{\Gamma_{\text{LDA}}}$ this is given by,

$$ \text{Im} [\tilde{\xi}_q(\omega)] = -(v_q + K_{xc}) \text{Im} \left[ \chi_q^0(\omega) \right]. $$

Since the RPA response function, $\chi_0$, will have the correct analytical properties by construction, this expression will obviously change sign whenever $K_{xc}$ - which is strictly negative for all densities and a negative constant for jellium - is larger in magnitude than $v_q$, which decays as $1/q^2$. This will thus lead to a spectral function with the wrong sign, which is entirely unphysical. For jellium, isolated atoms, or any sparse enough condensed state, this is guaranteed to happen, because $K_{xc} \to -\infty$ for low densities. Inspection of the dielectric function in $G_0 W_{0}^{\Gamma_{\text{LDA}}}$,

$$ \text{Im} [\tilde{\xi}_q(\omega)] = -\frac{v_q \text{Im} \left[ \chi_q^0(\omega) \right]}{1 - K_{xc} \chi_q^0(\omega)^2}, $$

illustrates that it cannot suffer from the same pathology. Since Eq. (20) ensures that the static structure factor has the correct pair-correlation function of jellium when $r \to 0$, except that it must depend on the high $k$ behavior of the denominator. We note that none of the calculations have been carried out self-consistently; it is possible that the vertices presented here go some way to improve self-consistent $GW$ results.

One possibility of the failure of the LDA starting point with the inclusion of the theoretically consistent vertex is the self-interaction error the LDA orbitals carry with them. Any starting point with an inherent self-interaction error should lead to correcting terms in the diagrammatic expansion. It is possible that the first-order correction, like $G_0 W_{0}^{\Gamma_{\text{LDA}}}$, is not enough and higher order corrections must be applied. A vertex derived from a second iteration of Hedin’s equations does indeed lead to further and more complicated diagrams than the equivalent vertex from a Hartree starting point. Unfortunately these diagrams are of prohibitive complexity for practical calculations.

It is still not understood why a correction in $W$ only (in a TDDFT-like manner) seems to work as well as it does. There
is a similarity here with the way that the Bethe-Salpeter equation (BSE) is usually applied for the calculation of optical spectra. There too it is well known that, in theory, inclusion of a screened interaction in electron-hole excitations should be accompanied by an inclusion of the double-exchange term in $\Sigma$ but this has been proven to worsen results. Recently, Tiago and Chelikowsky have used a $G_0W_0^{\text{LDA}}$ vertex in conjunction with an efficient numerical implementation of the BSE for isolated molecules and have shown that the inclusion of a TDLDA vertex gives very good results over a wide range of structural configurations in excited states.

For atomic helium and beryllium $G_0W_0^{\text{LDA}}$ is very similar to the $G_0W_0^{\text{RPA}}$ result but slightly worse in neon. While in jellium the band width is improved. Hence $G_0W_0^{\text{LDA}}$ may be a local and easily implementable way to improve quasiparticle results in extended systems.

Overall, vertices based on the local density clearly have their limitations, arriving in part from the wavevector independent character of $K_{xc}$. It should be fruitful to explore vertices that incorporate non-local density-dependence and reflect the non-local character of the original self-energy operator.

Acknowledgments

The authors would like to thank Ulf von Barth, Carl-Olof Almbladh, Peter Bokes, Arno Schindlmayr, Matthieu Verstraete, Steven Tear and John Trail for helpful discussions. This research was supported in part by the European Union (contract NMP4-CT-2004–500198, “Nanoquanta” Network of Excellence), the Spanish MEC (project FIS2004-05035-C03-03) and the Ramón y Cajal Program (PGG).

We compute quantities for the non-relativistic, all-electron Hamiltonian 

Recently Fleszar and Hanke\textsuperscript{61} have also used the $G_0W_0\Gamma^{\text{LDA}}$ vertex and noted improvement in band gaps and the energy positions relative to the valence band minimum for the computationally difficult II$^B$-VI semiconductors when the $G_0W_0\Gamma^{\text{LDA}}$ method is used in conjunction with $G$ and $W$ partially updated through one previous iteration of Hedin’s equations.
