Rational design of a promising oxychalcogenide infrared nonlinear optical crystal†

Yansong Cheng, Hongping Wu, Hongwei Yu,* Zhanggui Hu, Jiyang Wang and Yicheng Wu

Oxychalcogenides with the performance-advantages of both chalcogenides and oxides are emerging materials class for infrared (IR) nonlinear optical (NLO) crystals that can expand the wavelength of solid-state lasers to IR regions and are of importance in industrial and civil applications. But rationally designing a high-performance oxychalcogenide NLO crystal remains a great challenge. Herein, we chose the melilite-type Sr$_2$ZnSi$_2$O$_7$ as the structure template. Through part isovalent substitution of S$^{2–}$ for O$^{2–}$ anions, the first hetero-anionic thionannate Sr$_2$ZnS$_2$O$_S$ with wide IR transmission has been synthesized. More importantly, compared to the maternal oxide, Sr$_2$ZnS$_2$O$_7$, the second harmonic generation (SHG) response of Sr$_2$ZnS$_2$O$_S$ is enhanced by two orders of magnitude. In addition, Sr$_2$ZnS$_2$O$_S$ can exhibit a large band-gap and high laser damage threshold. These advantages make Sr$_2$ZnS$_2$O$_S$ a promising IR NLO crystal. Our research will provide insights into the rational design of new IR NLO crystals.

Introduction

Mid-infrared (MIR) sources covering 3 to 5 $\mu$m and 8 to 12 $\mu$m are of great interest in industrial and civil applications such as molecular spectroscopy, remote sensing, free-space communication, and environmental monitoring.$^{1–5}$ However, it is difficult for solid-state lasers to directly radiate MIR coherent light. Nevertheless, relying on frequency conversion techniques of nonlinear optical (NLO) crystals, such as optical parametric oscillators (OPOs) and optical parametric amplifiers (OPAs), is an effective way for solid-state lasers to generate MIR radiation. In these processes, the performances of NLO crystals determine the conversion efficiency of IR coherent light. So, they play a strategically important role in the development of IR lasers. In the past three decades, although a series of high-performance NLO crystals have been discovered and widely commercialized in the ultraviolet and visible regions, including $\beta$-BaB$_2$O$_4$ (BBO),$^6$ LiB$_3$O$_5$ (LBO),$^7$ CsLiB$_6$O$_{10}$ (CLBO),$^8$ KH$_2$PO$_4$ (KDP)$^9$ and KTiOPO$_4$ (KTP),$^{10}$ NLO crystals available in the infrared (IR) region are still seldom, and they are mainly some chalcopyrite-type chalcogenides, such as AgGaS$_2$ ($Q = S$, Se)$^{11,12}$ and ZnGeP$_2$. $^{13}$ Although these crystals feature very large second harmonic generation (SHG) coefficients, the low laser damage thresholds (LDTs) of AgGaS$_2$ ($Q = S$, Se) and harmful two-photon absorption (TPA) of ZnGeP$_2$ limit their wide applications,$^{14}$ particularly under high-power conditions. So, exploring new IR NLO crystals with high LDTs and large band gaps is still a current research interest.$^{15–18}$

For the design of new IR NLO crystals, metal chalcogenides, oxides and halides are the three most important materials. Regarding chalcogenides, they generally exhibit large SHG responses and wide IR transparency,$^{1,29}$ while low LDTs and undesired TPA caused by their small band-gaps as well as the difficulty in crystal growth are the main problems restricting their wide applications, just as observed in typical AgGaS$_2$ ($Q = S$, Se) and ZnGeP$_2$. $^{21}$ Compared to chalcogenides, metal oxides can exhibit larger band-gaps and thus higher LDTs as well as easier crystal growth.$^{22}$ But the poor IR transparency and relatively weak SHG responses make their application limited within 5 $\mu$m.$^{23}$ Therefore, it is clear that chalcogenides can exhibit larger SHG response and better IR transmission, while metal oxides have advantages in band-gaps and LDTs. Therefore, combining two types of anions may be an expectant strategy for designing high-performance IR NLO crystals with balanced properties. Up to now, although some oxychalcogenide IR NLO crystals, e.g. SrZn$_2$O$_S$ ($E_g = 3.86$ eV, 0.06$ \times$ AgGaS$_2$),$^{24}$ Sr$_3$Ga$_4$O$_{14}$S$_{14}$ ($E_g = 3.90$ eV, 0.8$ \times$ AgGaS$_2$),$^{25}$ SrGeOSe$_S$ ($E_g = 3.16$ eV, 1.3$ \times$ AgGaS$_2$),$^{26}$ BaGeOSe$_2$ ($E_g = 3.20$ eV, 1.1$ \times$ AgGaS$_2$),$^{27}$ and Sr$_6$Cd$_3$Sb$_6$O$_7$S$_{10}$ ($E_g = 1.89$ eV, 4.0$ \times$ AgGaS$_2$),$^{28}$ have been reported, these compounds are still less investigated than their maternal oxides or chalcogenides. In particular, how to optimize the structure of oxychalcogenides to use the advantages of oxides and chalcogenides to the maximum through a rational structure design is still indistinct.
In this research, we choose the melilite-type Sr$_2$ZnSi$_2$O$_7$ as a structural template to design a new oxychalcogenide through rational chemical substitution. Sr$_2$ZnSi$_2$O$_7$ crystallizes in the noncentrosymmetric (NCS) space group $P4_2/m$. Its structure features a pentagon-like layer, which endows its structure with better flexibility and designability. But remarkably, the SHG response of Sr$_2$ZnSi$_2$O$_7$ is only $35.0 \times \chi^2$SiO$_2$, almost two orders of magnitude smaller than that of AgGaS$_2$. And owing to the absorption of the metal–oxygen bonds, it also has poor IR transmission. In our study, we used Sn atoms to substitute Si in melilite-type Sr$_2$ZnSi$_2$O$_7$, first, because Sn atoms are heavier and more polarizable than Si atoms, which is helpful for the material to exhibit a wider IR transmission and larger SHG response. Moreover, with the help of the unique pentagonal layer configurations, we expect to use heavier and more polarizable S atoms to selectively substitute the terminal O atoms in the pentagonal layers as well as the bridging O atoms in relatively light Zn–O–Sn bonds, whereas retaining the O atoms in Sn–O–Sn bonds, which have the heaviest equivalent mass for metal–oxygen bonds in the structure and have the smallest effect on IR transmission of the materials. Meanwhile, the hetero-anionic [SnOS$_3$] tetrahedra may exhibit large polarization, which will favor the material to generate a large SHG response. By doing these, we have successfully synthesized the first hetero-anionic thiostannate, Sr$_2$ZnSn$_2$OS$_6$. It exhibits not only a wide IR transmission, but also a large SHG response, $\sim 0.7 \times$ AgGaS$_2$, which is two orders of magnitude larger than that of maternal Sr$_2$ZnSi$_2$O$_7$. These results indicate that Sr$_2$ZnSn$_2$OS$_6$ is a promising IR NLO crystal. Herein, we will report its synthesis, structure, and NLO properties.

Results and discussion

The polycrystalline sample of Sr$_2$ZnSn$_2$OS$_6$ was obtained by a solid-state reaction in a sealed silica tube (for more details see the ESI†). The purity of the sample was confirmed by powder X-ray diffraction (PXRD). In order to investigate the thermal behavior of Sr$_2$ZnSn$_2$OS$_6$, we carried out a series solid state reactions with different calcination temperatures and performed their powder XRD from 500 to 800 °C (Fig. S1†). It is clear that Sr$_2$ZnSn$_2$OS$_6$ is thermally stable until 750 °C. After 750 °C, Sr$_2$ZnSn$_2$OS$_6$ decomposes into SrS, SnS and ZnS (Fig. S1†). The millimeter-size crystal of Sr$_2$ZnSn$_2$OS$_6$ was grown by the solution method with SrS as the flux (Fig. S2†), and the specific crystal photograph is shown in Fig. S3.† The structure was determined by single crystal XRD and the crystallographic data are given in Table S1.†

Sr$_2$ZnSn$_2$OS$_6$ crystallizes in the NCS tetragonal space group $P4_2/m$. In the asymmetric unit of Sr$_2$ZnSn$_2$OS$_6$, there are one unique Sr, one Zn, one Sn, one O and two S atom(s). Among them, the Sn atom is coordinated by one O atom and three S atoms forming the typical ZnS$_4$ tetrahedron with identical Zn–S distances, $d$(Zn–S) = 2.333(16)Å (Fig. 1a). In the pentagon ring, the SnO$_3$ tetrahedron connects with a ZnS$_4$ tetrahedron by sharing the S atoms, and the two SnO$_3$ tetrahedra are connected by sharing the O atoms. These pentagons further form two-dimensional (2D) [ZnSn$_2$OS$_6$]$_x$ layers (Fig. 1b), which are separated by Sr$^{2+}$ cations to form the structure of Sr$_2$ZnSn$_2$OS$_6$ (Fig. 1d). Regarding the Sr$^{2+}$ cations, they are located in an eight-coordinated SrOS$_7$ bicapped trigonal prism with the $d$(Sr–O) = 2.786(5)Å and $d$(Sr–S) = 3.113(2)–3.150(17)Å, respectively (Table S2†). These bond distances are comparable to those of other reported compounds.† Bond valence calculations show that the bond valence sums (BVSs) for each atom are 2.12, 2.00, 4.04, and 1.73 for Sr$^{2+}$, Zn$^{2+}$, Sn$^{4+}$, and O$^{2-}$, respectively. The

BVSs of $S^{2-}$ anions are in the range of 2.08–2.14 (Table S3†). All the BVSs are consistent with the expected valences.

Structurally, Sr₂ZnSn₂O₆ can be seen as a homologue of Sr₂ZnSi₂O₆ (Fig. 1e–h). Compared with Sr₂ZnSi₂O₆, Sr₂ZnSn₂O₆ exhibits the following structural features: (i) the Si⁴⁺ cations in Sr₂ZnSi₂O₆ were substituted by the heavier Sn⁴⁺ cations, which are the heaviest cations but have similar coordination to Si⁴⁺ in group IV; (ii) all the terminal O atoms in the Zn–O or Sn–O bonds, and all the bridging O atoms in the Zn–O–Sn bonds are substituted by the heavier S atoms, while the O atoms in the Sn–O–Sn bonds are retained (Fig. 1e and f). The above substitution will be favorable for Sr₂ZnSn₂O₆, Sr₂ZnSn₂O₆, and Sr₂ZnSn₂O₆ to exhibit wide IR transmission. Generally, the IR absorption of materials mainly originates from the vibration of the groups. Thus, in Sr₂ZnSn₂O₆, the large equivalent mass of SnO₃ and ZnS₄ groups will be favorable for widening the IR transmission of materials. In Sr₂ZnSi₂O₆, the Si–O bonds have the lightest equivalent mass, so they have the greatest effect on IR transmission. Using the heavier Sn⁴⁺ cations to substitute Si⁴⁺ can reduce the effect. As shown in Fig. S4,† the peaks at 1123, 963, 894, and 832 cm⁻¹ correspond to the asymmetric and symmetric stretching vibrations of Si–O bonds. The peak at 587 cm⁻¹ can be assigned to the bending vibrations of Si–O bonds in Sr₂ZnSi₂O₆. Furthermore, a micron sized crystal was used to measure the IR transmission spectrum of Sr₂ZnSn₂O₆. Similar measurements have also been found in the previous research. It is clear that there is no obvious absorption in the range from 1800 to 800 cm⁻¹, corresponding to 5.5 to 12.5 μm (Fig. 2a). The absorption peak at 800 cm⁻¹ can be assigned to the stretching vibration of the Sn–O–Sn bond. In addition, except for the Si⁴⁺ cations, the terminal O atoms and bridging O atoms in those bonds with low equivalent mass (e.g. the O in the Zn–O–Sn bonds) are also more prone to vibrate than the bridging O atoms in the heavy Sn–O–Sn bonds. Therefore, substituting them with the relatively heavy S atoms would also be helpful to further widen the IR transmission region of the material. The rational substitution from Sr₂ZnSi₂O₆ to Sr₂ZnSn₂O₆ can be attributed to the minimum distortion of pentagonal rings. In Sr₂ZnSi₂O₆, the pentagonal ring is composed of four long Si–O–Zn bonds and one short Si–O–Si bond (Fig. 1g). From Sr₂ZnSi₂O₆ to Sr₂ZnSn₂O₆, substituting O atoms with S atoms in Sn–O–Zn bonds and retaining O atoms in the Sn–O–Sn bonds can best retain a similar pentagonal-ring-configuration, i.e. also including four long Sn–S–Zn bonds and one short Sn–O–Sn bond (Fig. 1h).

Furthermore, Raman spectroscopy of Sr₂ZnSn₂O₆ is shown in Fig. 2b. In the Raman spectra, the absorption peaks at 400, 368, and 346 cm⁻¹ can be attributed to the characteristic absorption of Sn–S modes, the peaks around 272 cm⁻¹ should be from the Zn–S bonds and the absorption peaks below 200 cm⁻¹ (including 141 and 82 cm⁻¹) are mainly attributed to Sr–S vibrations.\textsuperscript{19,41}

The UV-vis-NIR diffuse reflectance spectrum in the range of 200–2300 nm was also measured by using a Shimadzu SolidSpec-3700DUV spectrophotometer (Fig. 2c). It was transformed into an $F(R)$ versus $h\nu$ curve based on the Kubelka–Munk function.\textsuperscript{42} Extrapolating the linear part of the rising curve to zero, an experimental band gap of 3.52 eV can be obtained. The band gap of Sr₂ZnSn₂O₆ is much larger than those in commercial AgGaS₂ (2.56 eV)\textsuperscript{11} and AgGaSe₂ (1.83 eV).\textsuperscript{12} Since the large bandgap will reduce the proportion of two photon or multiphoton absorption, the large band-gap is generally helpful for producing a large LDT.\textsuperscript{43} So, the LDT of Sr₂ZnSn₂O₆ was also measured by using a Q-switched pulse laser (1064 nm, 10 ns, 10 Hz) with a powder AgGaS₂ sample as the reference. It indicates that Sr₂ZnSn₂O₆ has a good laser damage resistance, and the measured LDT (131 MW cm⁻²) is about 10 times that of AgGaS₂ (12 MW cm⁻²).\textsuperscript{44}

Sr₂ZnSn₂O₆ crystallizes in the NCS space group $P4_21/m$. Its SHG response was measured based on the Kurtz–Perry method by using a laser with a wavelength of 2.09 μm and with powder AgGaS₂ as the reference.\textsuperscript{45} The sample of AgGaS₂ was purchased in commercial quantities.

![Fig. 2](image-url) (a) IR transmission spectrum from single crystals, (b) Raman spectrum, and (c) UV-vis-NIR diffuse reflectance spectrum of Sr₂ZnSn₂O₆.

![Fig. 3](image-url) (a) SHG intensity versus particle size for Sr₂ZnSn₂O₆ and AgGaS₂. (b) Comparison of SHG intensities for Sr₂ZnSn₂O₆ and AgGaS₂ at the particle sizes of 150–180 μm.
from Sichuan Ninth Research Institute (Fig. S5†) and the powder AgGaS₂ sample was obtained by grinding the AgGaS₂ crystal. As shown in Fig. 3a, the SHG intensities of Sr₂ZnSn₂OS₆ increase with its particle size. So, Sr₂ZnSn₂OS₆ can achieve type-I phase-matching. The SHG response with the particle size in the range of 150–180 μm is approximately 0.7 × AgGaS₂ (Fig. 3b), indicating that Sr₂ZnSn₂OS₆ exhibits moderate SHG response. Apart from the large SHG response, a suitable birefringence is also necessary for the application of NLO crystals. Hence, we measured the birefringence of Sr₂ZnSn₂OS₆ by using a cross-polarizing microscope. The orientation of such a utilized crystal was determined as [100] by using the “Index Crystal Faces” program in Bruker SMART APEX III. The observed color of Sr₂ZnSn₂OS₆ in cross-polarized light is second-order yellow. The thickness of the crystal used for the measurement is 8 μm (Fig. S6†). According to the Michel-Levy chart, the retardation (R value) is 920 nm. Thus, the birefringence of Sr₂ZnSn₂OS₆ in the visible region is 0.12, which is large enough for ensuring the phase matching of Sr₂ZnSn₂OS₆.

The above measurements indicate that Sr₂ZnSn₂OS₆ not only exhibits well-balanced NLO properties, including a wide transmission region, large band-gap, and high LDT as well as moderate birefringence and SHG response (Fig. 4a), but also presents the first Sn-containing oxychalcogenide IR NLO with [SnOS₃] hetero-anionic tetrahedra (Fig. 4b). In order to better understand the origin of these excellent NLO properties, especially the moderate SHG response and birefringence, we further calculated the electronic structure of Sr₂ZnSn₂OS₆ through the first-principles calculation.

As shown in Fig. 5a, Sr₂ZnSn₂OS₆ is a direct-gap compound and the calculated band gap is 2.71 eV, which is smaller than the experimental value (3.52 eV). The smaller calculated band gap can be attributed to the limitation of the density functional theory (DFT) method. The density of states (DOS) and partial densities of states (PDOS) of Sr₂ZnSn₂OS₆ are shown in Fig. 5b. The top of the valence band (VB) is predominately composed of O 2p and S 3p states, mixed with small amounts of Sn 5p, while the bottom of the conductive band (CB) mainly originates from O 2p, S 3p, and Sn 5s,5p states. As we know, the optical properties of a material are mainly affected by the electronic transitions between the energy levels close to the forbidden band. So, the SHG response and birefringence will be mainly determined by [SnOS₃] and [ZnS₄] tetrahedra (Fig. S7†). Particularly for [SnOS₃] tetrahedra, owing to the part substitution of O and S, the dipole moment of the SnOS₃ tetrahedron is obviously larger than that of ZnS₄ (Table S5†). It indicates that SnOS₃ tetrahedra...
have the main contribution to the SHG response and birefringence of Sr$_2$ZnSn$_2$OS$_6$. Meanwhile, the dipole moments of ZnO$_4$ and SiO$_4$ in Sr$_2$ZnSi$_2$O$_7$ are also calculated (Fig. S8†). By comparing the dipole moments of SiO$_4$ (6.29 D) and SnOS$_3$ (6.77 D), it can be found that the mixed-anion SnOS$_3$ units can exhibit larger polarity in the structure. These results indicate that the rational substitutions of S for O and Sn for Si have contributed the enhancement of the NLO response in Sr$_2$ZnSn$_2$OS$_6$.

Based on the calculated electronic structure, the NLO coefficient and birefringence of Sr$_2$ZnSn$_2$OS$_6$ can also be calculated. Sr$_2$ZnSn$_2$OS$_6$ belongs to the point group of 42m. It only has one non-zero independent SHG tensor, $d_{44}$ under the restriction of Kleinman symmetry. The calculation shows $d_{44} = 4.48$ pm V$^{-1}$, which is comparable with the experimental results. Moreover, the refractive indices and birefringence ($\Delta n$) were also calculated. The calculated birefringence is shown in Fig. 5c, and the birefringence $\Delta n = 0.14$ at 2090 nm. These calculated results are also essentially consistent with the experimental ones.

Conclusions

In summary, based on the rational partial substitution of S$^{2-}$ for O$^{2-}$ anions in Sr$_2$ZnSi$_2$O$_7$, the first Sn-containing oxychalcogenide IR NLO crystal Sr$_2$ZnSn$_2$OS$_6$ has been successfully designed and synthesized. It can exhibit excellent NLO properties, including a wide IR transmission region, large band gap (3.52 eV), and high LDT (10×AGS) as well as a suitable SHG response (0.7×AGS) and birefringence (0.14@2090nm), which are comparable with other excellent oxychalcogenides (Table 1). These results show that Sr$_2$ZnSn$_2$OS$_6$ would be a promising IR NLO crystal. The excellent NLO properties of Sr$_2$ZnSn$_2$OS$_6$ can be attributed to the rational substitution of S$^{2-}$ for O$^{2-}$, i.e. the terminal O atoms and the bridging O atoms in the light Zn–O–Sn bonds, which would lead to an insufficient IR transparency window, have been substituted by the heavier S, while the bridging O atoms in the heavy Sn–O–Sn bonds, which have a weak effect on the IR transparent region, are retained for constructing the distorted SnOS$_3$ groups to produce a moderate SHG response. These findings will be helpful to provide some new insights for the design of oxychalcogenide IR NLO crystals.
