Kaposi’s sarcoma-associated herpesvirus (KSHV or HHV-8) has been associated with several neoplasias, including childhood endemic Kaposi’s sarcoma (KS). It is possible that strain genotypes could contribute to the differences in regional presentation (mainly sub-Saharan Africa), childhood infection, lack of male sex bias, distinct disseminated forms and rapid fatality observed for childhood endemic KS. Early studies, at the advent of the HIV/AIDS epidemic, identified only the K1-A5 genotype in childhood KS biopsies as well as blood of a few HIV positive and negative febrile infants in Zambia, a highly endemic region. This current enlarged study analyses blood infections of 200 hospitalized infants (6–34 months age) with symptoms of fever as well as upper respiratory tract infection, diarrhoea, rash or rhinitis. KSHV and HIV viraemia and were prevalent in this group, 22% and 39%, respectively. Multiple markers at both variable ends of the genome (K1, K12, and K14.1/K15) were examined, showing diverse previously adult-linked genotypes (K1 A2, A5, B, C3, D, with K12 B1 and B2 plus K14.1/K15 P or M) detected in both HIV positive and negative infants, demonstrating little restriction on KSHV genotypes for infant/childhood transmission in a childhood endemic KS endemic region. This supports the interpretation that the acquisition of childhood KSHV infections and subsequent development of KS are due to additional co-factors. J. Med. Virol. 79:1555–1561, 2007.

KEY WORDS: Kaposi’s sarcoma associated herpesvirus; HHV-8; childhood endemic KS; HIV/AIDS; virus genotype

INTRODUCTION

World-wide seroepidemiological analyses of Kaposi’s sarcoma associated herpesvirus (KSHV) have associated this virus with KS. Analyses of tissue biopsies by polymerase chain reaction (PCR) have identified KSHV in KS: including HIV/AIDS associated, classic (Mediterranean) and endemic (African). However, little is known about childhood endemic KS, childhood endemic KS (Sub-Saharan African regions). Childhood endemic KS can be rapid and aggressive, often presenting as lymphadenopathy, having disseminated forms. Childhood endemic KS has expanded since the HIV/AIDS epidemic and extends to half of childhood cancers in some African countries, while practically absent in Europe or USA [Sarmati, 2004]. Is this a different strain or one now spread by HIV/AIDS as an emergent childhood disease? What are the implications for vaccine development for control? Here this is examined via analyses of genotypes in blood-borne infant infections in Zambia, a childhood endemic KS endemic region.

The highest childhood KSHV seroprevalence are in several African countries including Nigeria (20%), Uganda (21%), Zambia (47%), Egypt (44%), Tanzania (58%), and Cameroon (32%); increasing with age, for example, in adults the seroprevalence is higher in Tanzania (89%) and Cameroon (62%), as reviewed
ends of the genome. Both HIV positive and negative using multiple markers for sites of variation from both regions, a further study was undertaken analyzing in infant infections in childhood endemic KS endemic in order to test whether there are restricted genotypes identified in this population [Kasolo et al., 1998]. In

dominating in Eastern and Central Africa [Poole et al., 1999; Zong et al., 1999; Kakoola et al., 2001]. In contrast, in childhood endemic KS the K1-A5 genotype was demonstrated [Cook et al., 1999; Meng et al., 1998]. K1-A5 genotypes in

PCR

DNA was extracted from 200 μl whole blood (Qiagen, Crawley, UK) and resuspended in 50 μl nuclelease-free H2O (Sigma, Gillingham, UK). PCR was carried in 20 μl reactions using 1 μl DNA with PCR master mix (Promega, Southampton, UK) and pfu polymerase with plus primers for human prolarctin gene, KSHV K12 (646 bp, LGH2076/2075 and 407 bp, nested T07IF/IR), K14.1/K15 (P,362 bp, and M,450 bpLGH2079, LGH2033, and LGH2506), HIV (BUP/UP/nested BU3) or HCMV (gN, gB1, and gB2, 150 bp) as described [Kasolo et al., 1998; Nanteza et al., 1998; Poole et al., 1999; Mattick et al., 2004; Whitby et al., 2004; Mattes et al., 2005]; plus K1vri designed to detect all genotypes: K1vri1 5’TGTCGAGCTGCTGCGGTTTGG 3’; K1vri2 5’ACACAGGGTTTGAGACGGGTGTTG 3’; K42 5’TGGATCAGTTGCTGACGAGCTGT 3’. A strict three lab policy for PCR (DNA-free lab reagent addition, DNA lab for DNA addition, PCR lab for amplifications) was used against contamination and none detected; water negative controls for every 5–10 reactions were negative. KSHV sequences collected had unique signatures.

Nucleotide Sequencing and Analyses

The amplified PCR products were purified (Qiagen MinElute), followed by nucleotide sequencing using BigDye v3.1 (ABI) and ABI 3730 analyzer as described [Mattick et al., 2004]. Sequence analyses used Genbank comparisons using Blast and multiple alignments with ClustalW [Chenna et al., 2003]. Phylogenetic trees were constructed using Phylip programs, with Blosum62 distance matrix, a topological tree algorithm and 100 bootstrap analyses [Brodksky et al., 1992; Felsenstein, 2004]. Sequence submitted to EBI/Genbank.
RESULTS

Detection of KSHV

DNA was extracted from peripheral whole blood samples from the cohort of 200 febrile infants, hospitalized in Lusaka, Zambia. These were then analyzed by PCR and sequencing using primers specific for KSHV as well as human DNA control (Prolactin). All KSHV sequences collected had unique signatures and there was no evidence for PCR contamination. Moreover, many sequences subsequently derived had not been previously identified in the laboratory. One hundred and forty-one samples were included in the analyses which showed consistent results, and a positive human prolactin gene control.

PCR detection of HIV and KSHV was also compared with human cytomegalovirus (HCMV), another herpesvirus related to morbidity and mortality in these HIV positive children. The results showed HIV, KSHV, and HCMV detected in 39%, 22%, and 11% infants, respectively (Table I). KSHV and HCMV coinfections were rare (3/14 HCMV positive). Although co-infections with HIV were more frequently identified with KSHV than with HCMV (65% vs. 47%) supporting the expansion of this infection with HIV/AIDS consistent with studies in adults.

Clinical Features KSHV Infected Infants

The PCR reaction (1/50 of 0.2 ml blood with sensitivity of 10–100 copies) detected at least 2,500 copies/ml blood, consistent with KSHV viremia. Given the ages of the patients (6–34 months), these are most likely primary infections, with possible maternal or sibling transmission through non-sexual routes as suggested previously for this population and neighboring regions [He et al., 1998; Mbulaiteye et al., 2003, 2006a; Dedicoat et al., 2004]. Fever was the inclusion criteria and other

### TABLE I. KSHV Genotypes in Hospitalized Febrile Infants (6–34 months) in Zambia

| Patient | HIV | HCMV | KSHV | K1 | K12 | K14.1/15 | Age | Symptoms               |
|---------|-----|------|------|----|-----|----------|-----|------------------------|

*Patients positive for KSHV or HCMV are shown URTI, upper respiratory tract infection [Fever with Rhinitis or Pharyngitis or tonsillitis].

Diverse Genotypes African Infant KSHV Infections

J. Med. Virol. DOI 10.1002/jmv
hospital diagnosed causes of fever were excluded (malaria or bacterial infections). Amongst the 31 infants who were PCR positive for KSHV, upper respiratory tract infections were the most common symptom 45% (14/31), followed by diarrhea 19% (6/31), rash 3% (1/31) and rhinitis 3% (1/31) (Table I).

**Nucleotide Sequencing and Genotype Analyses**

Many samples were at the limit of detection by PCR, which restricted subsequent multiple analyses by nucleotide sequencing. The PCR positive K1 loci was first examined by sequencing. The results showed the K1 A5 genotype, previously identified in infected children and in childhood KS in this region, but also unexpected diversity. The K1 A5 genotype was common 23% (5/22), now linked here with K12 B1 or B2 and K14.1 P genotypes, consistent with previous results for a distinct strain in this region (Table I and Fig. 1), and presenting with respiratory symptoms (4/5). However, also shown were K1-B (4/22), (prevalent in African adult KS) as well as K1-A2, A3, and C3, previously common in adult Mediterranean/Asian/Europe KS (C3, 7/22). There were HIV positive and negative examples of all. The Zambian infant blood KSHV sequences clustered with representative of K1 A, B, C, or D genotypes from adult KS biopsy samples (Fig. 2).

At the loci from the right hand of the genome K12 and K14.1/K15 genotypes were identified, using primers to amplify regions as characterized previously [Poole et al., 1999]. Previous studies showed divergence of nucleotide sequences of K12 at selected positions, mostly intergenic non-coding, and some used as representative genotypes (Fig. 3). There were 21 Zambian infant K12 genotypes identified and these clustered with K12 B1 and B2 genotypes, similar to sequences identified in adult KS biopsies in other parts of Africa as shown [Poole et al., 1999; Kakoola et al., 2001] (Fig. 3). The PCR based assay for the K14.1/15 distinguishes by size the P or M genotypes. The dominance of the K14.1/15 P genotype (17/18) is in agreement with previous studies showing predominance in Eastern African regions also in adult KS biopsies (Table I) [Lacoste et al., 2000]. For all sites analyzed some samples could not be detected by the primers used, suggesting further diversity.

One K1 sequence overlapped all of the genotypes, ABCD (K111), either a local progenitor virus or effects of recombination (Figs. 1 and 2). This was distinct from previous progenitor strains (K1-43Berr closest, 18% divergence) [Lacoste et al., 2000; Whitby et al., 2004]. However, the K12 B1 genotype from this sample was similar to other B1 sequences from the region.

**DISCUSSION**

In earlier studies, of a childhood endemic KS region, Zambia, analyses of blood infection in five infants showed only K1-A5 genotypes and this correlated with the genotype identified in different infant and childhood KS samples [Kasolo et al., 1998]. Here the origin of the
KSHV strains infecting infants is analyzed in a larger study of blood infections in 200 hospitalized febrile infants. KSHV sequences were identified in 31 individuals. Given the young age (6–34 months) of the patients, and the relative levels detected, these appeared to be primary or early infections of which little is known. In addition to fever, many had symptoms of upper respiratory tract infections or diarrhoea, but no evidence yet for KS. Multiple loci were used to genotype the virus. The results showed diverse adult-like genotypes identified in both HIV positive or negative infants. These included the following K1/K12/K14.1/15 genotypes: K1-A5, A2, A3, B, C3 or A/B/C/D; K12-B1 or B2; K14.1/15 P or M. It is also possible that given rapid increases in HIV/AIDS in Zambia, the genotype pool of KSHV may have expanded, leading to emergence of diverse childhood infections. Recently, blood DNA from five older children (>5 years age) in Uganda also showed 3 K1-A5 and 2 K1-B [Mbulaiteye et al., 2006a]. This is consistent with results shown here, although here further loci have been analyzed, with more diversity identified in the Zambian region in a larger group of younger children and infants. Thus, in a childhood KS endemic region, childhood KSHV infection can occur with diverse genotypes.

Fig. 2. Phylogenetic tree of K1 sequences from childhood KSHV blood infections in comparison to reference genotypes from Figure 1 shows extensive diversity. Scale and branch lengths indicate relative genetic distance. In the bootstrap analyses the multiple alignment was resampled generating 100 trees. Bootstrap values achieved are expressed in percentages and placed at the nodes.

Fig. 3. Nucleotide changes in the K12 region shows B genotypes identified in African regions. Reference genotypes are shown (A, AC, M, B1, and B2), including Ugandan reference sequences from adult KS biopsy materials, compared to the Zambian infant patients blood genotypes showing B1 and B2. The K12 segment is in the reverse complement orientation (coding) from the genomic sequence. The positions of nucleotide variation and reference sequences are as shown previously with position 1 as in [Poole et al., 1999; Kakoola et al., 2001] or 118,065 in the BC1 genomic sequence, or position 51 in Poole et al. [1999], (positions 30, and 64 is 115 in Poole et al. [1999]). K12 ORF, Kaposin A, ends at position 147 as in Poole et al. [1999] and Kakoola et al. [2001] or 117,919 in the BC1 genome [Russo et al., 1996]. The PCR product was from 118, 116–117, 469. Hyphens and dots indicate identical or deleted residues.

J. Med. Virol. DOI 10.1002/jmv
Despite the diversity of genotypes identified in the infant blood KSHV infections, is there any evidence for distinct strains for childhood transmission? The K1A5 genotype is prevalent in KS biopsy samples from patients in regions of Africa where there is childhood endemic KS [Kasolo et al., 1998; Lacoste et al., 2000; Kakoola et al., 2001]. Furthermore, the P genotype of K14.1/15 is also linked to this region [Lacoste et al., 2000], where only one M genotype was identified. Moreover, only the K12 B genotype (both B1 and B2) was identified in these infant infections, and these genotypes are dominant in adult KS identified in other African regions [Poole et al., 1999; Lacoste et al., 2000; Kakoola et al., 2001]. Most of the K12 variation is in the 3' non-coding intergenic region. However, the encoded Kaposin A is a tumorigenic transforming gene interacting with cytohesin-1 integrin regulator, and two coding changes were identified (Fig. 4) [Muralidhar et al., 1998; Kliche et al., 2001]. One shown in some B1 genotypes, C64G gives rise to Leu34 to Val, though conservative, it disrupts an LXXLL motif (to LXXVL), reported required for cellular transformation [Tomkowicz et al., 2005]. The other substitution is divergent, G112C, giving Ala50 to Pro in all B genotypes compared to both reference M and P type genomes (BC1 and GK18, respectively) [Russo et al., 1996; Rezaee et al., 2006]. Thus several genotype markers may link with childhood endemic KS endemic regions. However, the observation of multiple K1 genotypes and past evidence for linked genome diversity [Poole et al., 1999], suggests multiple KSHV strains can be transmitted to infants.

Since the data shown here indicates there does not appear to be any strain restriction for infant infection in a region endemic for childhood KS, this implicates other cofactors for childhood KSHV transmission and KS development. Seroepidemiological studies on KSHV transmission, identify factors including genetic predisposition, low socioeconomic status, immunosuppression from HIV/AIDS or other influences, plus surface water exposure, possibly linking to hygiene [DeSantis et al., 2002; Mbulaiteye et al., 2003, 2005; Plancoulaine et al., 2003; Klasskala et al., 2005]. In this regard, evidence for mother to child or close siblings transmission in African KS endemic populations has been demonstrated [He et al., 1998; Mbulaiteye et al., 2003, 2006a; Dedicoat et al., 2004] with virus detected in saliva and urine [Beyari et al., 2004; Brayfield et al., 2004; Mbulaiteye et al., 2004]. Factors for development of adult KS require KSHV seropositivity, and include linkage to higher socioeconomic status, water exposure, HIV/AIDS immunosuppression, or immunogenetic regulation [Ziegler et al., 1997, 2003; Sitasi and Newton, 2001; Gaya et al., 2004]. However, not all African countries with high childhood KSHV seroprevalence have high childhood endemic KS, thus additional factors affect childhood endemic KS development. Whether these African childhood infections with diverse KSHV genotypes as shown here, have differences in subsequent KSHV transmission or KS development, remains to be determined and has important implications for vaccine design.
