Changes in coupled carbon–nitrogen dynamics in a tundra ecosystem predate post-1950 regional warming

N. John Anderson1✉, Daniel R. Engstrom2, Peter R. Leavitt3,4, Sarah M. Flood1 & Adam J. Heathcote2

Arctic ecosystems are changing in response to recent rapid warming, but the synergistic effects of other environmental drivers, such as moisture and atmospheric nitrogen (N) deposition, are difficult to discern due to limited monitoring records. Here we use geochemical analyses of 210Pb-dated lake-sediment cores from the North Slope of Alaska to show that changes in landscape nutrient dynamics started over 130 years ago. Lake carbon burial doubled between 1880 and the late-1990s, while current rates (~10 g C m\(^{-2}\) yr\(^{-1}\)) represent about half the CO\(_2\) emission rate for tundra lakes. Lake C burial reflects increased aquatic production, stimulated initially by nutrients from terrestrial ecosystems due to late-19th century moisture-driven changes in soil microbial processes and, more recently, by atmospheric reactive N deposition. These results highlight the integrated response of Arctic carbon cycling to global environmental stressors and the degree to which C–N linkages were altered prior to post-1950 regional warming.
Terrestrial carbon stores in the Arctic are substantial\(^1\) and are mainly held in permafrost\(^2\); as such they represent a potential significant feedback into the climate system as soils warm\(^3,4\). However, as many key processes (e.g., photosynthesis, soil microbial respiration) in arctic ecosystems are often nitrogen (N) limited\(^5\), future alterations to organic carbon (C) pools may be linked to changes in N fluxes\(^6,7\), including fixation, cycling, and transfer among adjacent ecosystems\(^8\). Recent warming at high latitudes has resulted in deepening of the seasonal active layer and permafrost thawing with an associated increase in mineralisation of organic matter and release of CO\(_2\) and CH\(_4\) to the atmosphere\(^9\). Such warming also alters soil microbial processes, which releasing nutrients (especially N\(^10\)) that stimulate both terrestrial\(^11\) and aquatic productivity\(^11\), with potential important consequences for regional rates of C storage.

Future impacts of changing temperature and precipitation on nutrient cycling and ecosystem function are difficult to assess because of the inherent limitations of short-term experimental approaches and the paucity of decadal-scale monitoring records, particularly at high latitudes. Similarly, few studies have evaluated how the coupling between C and N cycles may have shifted in response to past climatic variability\(^12\). As lakes are a key component of arctic landscapes and are often net heterotrophic (net ecosystem respiration > primary production)\(^13,14\), they may be critical sites to quantify centennial-scale responses of C and N biogeochemistry to climate change. For example, atmospheric warming is expected to increase CO\(_2\) efflux from lakes\(^15\); however, associated changes in terrestrial C storage and N cycling as well as altered hydrological pathways\(^16\) may also alter lateral transfer of terrestrial organic carbon as particulate (POC) and dissolved (DOC) to streams and lakes\(^17\), where it may be either stored in sediments\(^14\) or released to the atmosphere following bacterial respiration or photochemical mineralisation\(^18,19\). The degree to which these processes offset each other are poorly constrained\(^17,20\) in part because of complex changes in mobilisation and interaction of C and N as permafrost thaw\(^21\).

The landscapes of the North Slope of Alaska are now undergoing pronounced permafrost thaw (deepening of the active layer), altered seasonality, and declining snow cover\(^22,23\). While atmospheric temperatures have increased terrestrial productivity, warming soils have enhanced soil microbial activity and respiration thereby elevating CO\(_2\) and CH\(_4\) release\(^4\). At the same time soil N dynamics\(^24\), shrub expansion (greening)\(^25\), thermokarst, and soil erosion are all changing in complex manners\(^22\). These terrestrial processes have cascading effects on lakes and wetlands\(^14\), which are important landscape components for both C processing and storage\(^18,26,27\).

Here, we use whole-basin organic C burial rates and stable isotope analyses of C and N (\(\delta^{13}C\), \(\delta^{15}N\)) in \(2^{10}\)Pb-dated sediment cores (see Supplementary Fig. 1) to quantify how historic climate variation has altered coupled C and N cycles in five lakes located near the Toolik Lake Long-Term Ecological Research (LTER) Field Station in the Kuparuk River Basin, Alaska, USA\(^28\) (Table 1). Data from these sediment records (see Supplementary Data #1) provide an integrated record of lake and catchment nutrient dynamics over the last ~200 years, and show that a combination of changing moisture availability, climate warming, and reactive N deposition over the past 130 years has increased aquatic production and aquatic C burial regionally. Importantly, changes to lake and catchment nutrient cycling were initiated in the late-nineteenth century by a post-Little Ice Age climatic rebound\(^29\) well before the rapid and more widely recognised post-1950s warming.

### Results and discussion

**Aquatic and sediment carbon dynamics.** Sediment records from the five study lakes show that mean regional C burial rates slowly increased from ~4 g C m\(^{-2}\) yr\(^{-1}\) in the nineteenth century, more than doubling by the 1990s (Fig. 1c). Both rates and trends over time are markedly similar across all sites (Supplementary Fig. 2). The background burial rates (~4 g C m\(^{-2}\) yr\(^{-1}\)) characterise the natural C sequestration rate for lakes situated in moist, acidic tussock tundra, while present-day rates (~10–12 g C m\(^{-2}\) yr\(^{-1}\)) represent nearly 50% of total C emissions from freshwater lakes in this region (~24 g C m\(^{-2}\) yr\(^{-1}\))\(^18\). Most importantly, burial rates increased substantially during a period of 100 years.

There is also clear sedimentary evidence that the increased C burial rates arose mainly from enhanced in-lake production, driven by changes in lake catchment nutrient cycling and increased N influx. Present-day C/N ratios across all sites are <15 and \(\delta^{13}C\) values are around ~30%, both of which are essentially algal signatures\(^30\) and substantially lower than corresponding values for tussock peat or catchment runoff (Fig. 2a). In addition, the temporal trends in the sediment \(\delta^{13}C\) data are broadly similar (Fig. 1c and Supplementary Fig. 2b) and suggest that aquatic primary producers used CO\(_2\) respired from terrestrially fixed C rather than atmospheric CO\(_2\). This process is recognised as being important today\(^19\), but the \(\delta^{13}C\) profiles suggest that C dynamics started to change from ~1880 (Breakpoint~1877; see “Methods” and Supplementary Fig. 3 for summary of breakpoint analyses). Algal communities—as summarised by PCA axis-1 scores of fossil diatom assemblages (Fig. 1d and Supplementary Figs. 2e and 4)—also began to shift in the late 1800s, followed by even more marked changes in the late-1960s (Breakpoint 1968). These trends are matched by

*Ratio of catchment to lake surface area.

*Attenuation coefficient of visible light; data from Tseng et al.\(^71\)
As the study lakes are shallow (mean depths = 2.7–4.9 m) and relatively clear (light attenuation, $K_a = 0.33–0.75 \text{ m}^{-1}$) (Table 1), autotrophic production is dominated by benthic algae$^{31,32}$. This conclusion is supported by related studies of nearby lakes, where benthic diatoms together with *Nitella* and mosses contributed substantially to whole-lake metabolism$^{33}$. Whole-lake (pelagic + benthic) production estimates in these lakes ranged from 4 to 20 g C m$^{-2}$ yr$^{-1}$ (ref. 18).

Given that the organic sediment in our study lakes is predominantly autochthonous in origin (see ref. 34 for a discussion of the effect of benthic algae on isotopic signatures; see also Fig. 2a), the observed increases in C burial strongly imply greater aquatic production, which in turn requires increased nutrient input. Lakes in the Kuparuk Basin are generally N-limited$^{35}$, and nitrogen plays a central role in both terrestrial and aquatic productivity, as well as controlling community structure in this region$^{36}$.

When interpreting sediment-core profiles, it is important, however, to recognise that their recent organic matter content is influenced to varying degrees by post-depositional diagenesis. Sediment C/N ratios initially reflect differential mineralisation rates, but as shown by Galman et al.$^{37}$ C/N profiles stabilise very quickly, within 10 years or so. Therefore, the emphasis here has been placed on longer-term changes. Bulk sedimentation rates have also increased (see ref. 38), which tends to counter diagenetic effects due to more rapid burial of organic matter. Furthermore, using a multi-proxy approach serves to emphasise the ecological signal as opposed to diagenetic noise. Similarly, the range of morphometries and water chemistry of the 5 lakes compared to the coherence of the geochemical response suggests that diagenesis is not the main process driving the sediment records. We therefore contend that the change in carbon burial in our study lakes is linked closely to changes in N dynamics in catchment soils, as well as inputs of reactive atmospheric N (Nr).

**Nitrogen biogeochemistry.** The change in sediment N-isotopic signatures ($\delta^{15}N$) also began in the late-nineteenth century (Breakpoint = 1847–1878; Supplementary Fig. 3), which is temporally consistent with increased N loading to area lakes as reflected in the increased C accumulation rates, $\delta^{13}C$, and lake productivity indicators (Fig. 1c, d and Supplementary Fig. 2). As $\delta^{15}N$ of bulk organic matter records complex changes in N fluxes from multiple sources as well as changes in N cycling, the direction and magnitude of the $\delta^{15}N$ trends vary considerably among our five lakes (Supplementary Fig. 2d). Specifically, two records show enrichment with $^{15}N$ (Perfect, Forgetful), one (Efficient) changes little, while two (Surprise, Relaxing) exhibit declining $\delta^{15}N$ (Fig. 1e). Although the latter pattern is consistent with an influx of isotopically depleted N from the atmosphere$^{39}$, alternate patterns in these and other regional lakes$^{40,41}$ demonstrate that N cycling is unlikely to be driven purely by atmospherically-derived N. The $\delta^{15}N$ trends are unrelated in any significant way (Pearson’s $r = -0.48$ to 0.57 with all $p$-values $> 0.32$) to physiochemical characteristics of the study lakes (Table 1), indicating importance of the differences in catchment N sources and in-lake N fractionation processes. Consistent with this interpretation, we note that baseline ($\sim 1800$) $\delta^{15}N$ values vary from sources characteristic of recently fixed N$_2$ ($\sim 0 \%$) to those in which terrestrial N is subject to intense recycling ($\sim 4 \%$)$^{42}$.

That said, we note a striking pattern in the study lakes between the relative increase in sediment N content and the change in $\delta^{15}N$ between the nineteenth century (1800–1880) and the last two decades represented in the cores (1980–2000). The lake cores with the largest increase in sediment N (ΔN) (Perfect, Forgetful) show a positive shift in $\delta^{15}N$, while the lakes with the smallest increase in ΔN (Relaxing, Surprise) exhibit a negative shift in

Fig. 1 Drivers of ecosystem change and environmental response in five lakes on the Alaskan North Slope. Environmental drivers: a Modelled temperature anomalies for the Arctic (blue filled circles)$^{29}$ and measured mean annual temperature at Barrow (open brown circles)$^{39}$. b Changes in nitrogen stocks in terrestrial ecosystem and soils at the Toolik LTER modelled by McKane et al.$^{47}$ (solid lines); and changes in nitrate concentrations measured in a Greenland ice core$^{70}$ (green filled circles). Limnological response: c Mean lake-wide carbon burial in the five study lakes integrated by decade (grey fill); and $z$-scores for carbon: nitrogen ratios (open squares) and carbon isotopic composition (filled black circles) in master cores from the five study lakes. Fitted trend lines and 95% confidence intervals (shading) from a general additive model (GAM). d $z$-scores for biogenic silica (BSi) (open circles) and axis-1 scores from a PCA ordination of fossil diatom assemblages (green filled circles) for cores from two of the study lakes. Fitted lines and confidence intervals from GAMs. e $z$-scores for nitrogen isotopes in cores with increasing (Perfect, Forgetful; blue symbols) and decreasing (Surprise, Relaxing; red symbols) trends. GAM trend lines and confidence intervals as in Panels c and d. For the environmental response variables in the sediment-core records, two time-lines of major ecological change (vertical lines), the first beginning around 1880 (carbon burial and stable isotopes) and the second -1970 (diatoms and biogenic Si) are based on breakpoint analysis (see “Methods” and Supplementary information).
However, is not well constrained at decadal timescales, such that marked increases in regional air temperature since 1974 have occurred in association with increased thermokarst erosion. Greening (shrub expansion), thawing permafrost and (Fig. 1c, e) well before anthropogenic warming of the atmospheric atmosphere through denitrification. Typically, much of the N released from thawing soils is lost to the atmosphere through denitrification and terrestrial uptake is not able to utilise the atmospheric N deposition and in situ fixation thereby increasing aquatic productivity. The latter change is recorded in the lake-sediment record.

Synthesis: coupled terrestrial-aquatic biogeochemistry. There is now unambiguous evidence for widespread environmental change in the Arctic, especially from studies on the North Slope of Alaska. Greening (shrub expansion), thawing permafrost and increased thermokarst erosion have occurred in association with marked increases in regional air temperature since 1974. The temporal disruption of C-N coupling within tundra landscapes, however, is not well constrained at decadal timescales, such that longer-term evaluation requires a combination of ecosystem models and palaeoecological methods.

Here, we have identified two main periods of change in regional biogeochemistry and C cycling (Fig. 1b, c): the first starting in the mid- to late-nineteenth century as indicated by rising C burial and declining \( \delta^{13}C \) values (breakpoint ~1877; Supplementary Fig. 3), and a second beginning in the mid-twentieth century marked by accelerating C and BSi burial and changing algal composition (breakpoints for BSi 1926 and 1978, diatom turnover 1968). These temporal trends in sediment geochemistry are strikingly similar to those predicted by the results of ecosystem modelling that showed terrestrial N mineralisation and loss in the Kuparuk Basin increasing after ~1860 due to decreased soil moisture (Fig. 1b; see “Methods”). Typically, much of the N released from thawing soils is lost to the atmosphere through denitrification, although some is also exported to streams and lakes where it can increase aquatic productivity.

Both terrestrial and aquatic ecosystems in the Kuparuk Basin are highly sensitive to environmental forcing, and our palaeoecological results suggest that biogeochemical cycling of C and N first began to change in the late-nineteenth century (Fig. 1c, e) well before anthropogenic warming of the atmospheric was substantial. Although a reversal of the circum-Arctic cooling associated with the Little Ice Age (LIA), which spanned the period approximately 1300 to 1850 AD, is well documented, most regional warming occurred after ~1950 due to a combination of human influence and a change in the Pacific Decadal Oscillation in the mid-1970s. Further, the agreement between the two independent ecological hindcasts—modelled ecosystem N balance and sediment geochemical records—suggest that coupled aquatic-terrestrial C-N dynamics in the Kuparuk Basin began to change in the late-nineteenth century driven by post-LIA changes in ecosystem and soil N processes (Fig. 1b) due to warming and altered soil moisture (see discussion in McKane et al. [47]). The sediment-core results thus highlight both the protracted nature of ecosystem response to global-change forcing at high latitudes and the importance of a holistic approach to terrestrial-aquatic linkages during the Anthropocene, especially of altered N cycling.

Methods

Study sites. Study sites are located on the North Slope of the Brooks Range in Alaska, USA, in the vicinity of the Toolik Lake LTER Field Station. The local vegetation is dominated by tussock tundra, and there is continuous permafrost. The study lakes are small (<10 ha) and relatively shallow, with maximum depths of ~13 m. Lake waters are slightly alkaline (pH ~8) and moderately dilute with conductivity ranging from 50 to 200 µS cm⁻¹. DOC ranges from 2.7 to 4.3 ppm. There are no distinct inflow streams, and catchment/lake area ratios are small (1.2 to 4.5). The present-day lake ice-free period in this area is ~3.5 months, and monitoring data at nearby Toolik lake show no trend in either ice-off or ice-on over the last 20 years (https://toolik.alaska.edu/).

McKane et al. [47] suggested that N mineralisation in tundra soils of the North Slope of Alaska is strongly dependent on moisture content. They provide a detailed discussion of the role soil moisture and other factors influence the model results. Much of the nitrogen released from thawing soils is lost from the terrestrial ecosystems through denitrification, and terrestrial uptake is not able to utilise the expanding nutrient pool, such that some portion is transferred laterally (associated with increased hydrological flux) to streams and lakes where it complements atmospheric N deposition and in situ fixation thereby increasing aquatic productivity. The latter change is recorded in the lake-sediment record.

Field and laboratory methods. Details of core retrieval and core processing can be found in Fitzgerald et al. [38]. Briefly, three piston cores from each lake were fully dated using \(^{210}Pb\) and analysed for organic content using standard loss-on-ignition methods. \(^{210}Pb\) chronologies were determined for the last 150–200 years using the constant rate of supply (c.r.s.) model and extrapolated if needed to ca. 1800. \(^{210}Pb\) dating accuracy declines substantially in sediments older than 150 years, but because of very low sedimentation rates and near-constant supported \(^{210}Pb\), we were able to calculate dates for most cores back to ca. 1800. The uncertainty for these dates is, of course, quite large, as shown in age-depth profiles in the Supplementary Fig. 1.
The dry mass sediment accumulation rate (DMAR, g cm\(^{-2}\) yr\(^{-1}\)) was multiplied by the proportional biogenic silica (BSi) and organic matter (OM) content to derive BSi and OM accumulation rates. A correction of 0.46954 was applied to the latter to derive the organic carbon accumulation rate (CAR; g C m\(^{-2}\) yr\(^{-1}\)).

Samples of tussock peat (moSS) and runoff water were collected from a 1-ha experimental sub-catchment of Toolik Lake in 2016 and analysed for C and N isotopes.

Whole-basin C fluxes. Carbon burial rates derived from single cores are not representative of whole-basin rates due to the problem of sediment focussing
40. As multiple cores from each study lake were dated (see above and ref. 38), the cores could be integrated into a whole-basin rate and a focusing correction factor determined for each core. The focusing-corrected CAR were then integrated into decadal intervals and averaged for each lake. Reported modern organic CAR values exclude the most recent decade (1990–2000), which may be biased high by incomplete mineralisation
57.

Palaeoecological proxies. A single, centrally-located core from each of the lakes was analysed for C and N isotopes, represented here in standard delta notation (\(\delta^{13}C\) and \(\delta^{15}N\)) relative to standard sources. Two additional proxies, biogenic silica (BSi) and fossil diatoms, were analysed on the central core for two of the lakes with good diatom preservation (Efficient and Perfect). Diatoms were poorly preserved in sediments of the other three lakes and so were not analysed. Biogenic silica content was determined using a timed-course alkali extraction method
58,59. Diatoms were identified and enumerated following standard methods
60, and community composition summarised as the first axis score in a PCA ordination.

Stable isotopes were determined at the Institute of Environmental Change and Society, University of Regina, using a ThermoQuest, (F–MAT) Delta Plus XL mass spectrometer coupled to a Carlo Erba elemental analyser and following
Savage et al.
81. \(\delta^{13}C\) values were not corrected for the Suess effect because the in-lake CO\(_2\) is mainly derived from recycled terrestrial carbon. The results of the Marine Biological Laboratory General Ecosystem Model (MBL–GEM) was used as an independent estimate of changing nitrogen dynamics in catchment soils and vegetation
82.

Statistical analyses. Palaeoecological data from each lake-sediment-core were transformed to z-scores for the purpose of inter-lake comparison, and the main changes in each proxy were undertaken on the mean z-scores of all lakes for a given variable (Supplementary Fig. 3). The rationale for this approach was that it allows identification of departures from regional trends in the geochemical data through time across all or groups of lakes, while removing lake-specific variability. However, Supplementary Fig. 5a-c show breakpoints estimated on each core individually (untransformed) for those proxies that were z-transformed for the main breakpoint analysis (\(\delta^{13}C\), \(\delta^{15}N\), and BSI).

Major trends in palaeoecological proxies were characterised by fitting generalised additive models (GAMs)
50,52,58,59 with a thin plate regression spline
63. This method allows for non-linear modelling of trends with a formal assessment of uncertainty based on 95% confidence intervals
64. To assess major areas of change in the geochemical and biological sediment records, breakpoint analyses were conducted to detect structural deviations from a simple linear regression model
65. GAMs were modelled using the statistical Software
62,66,67.

Acknowledgements

We are grateful to Bill Fitzgerald (University of Connecticut), Carl Lamborg (University of California, Santa Cruz), Chun-Mao Tseng (Taiwan National University) for help with the core collection and Will Daniels (Brown University) for the water and peat isotope sampling. Jill Coleman Wasik and Erin Mortenson undertook the BSi and 210Pb dating analyses at the SCWRS.

Author contributions

J.A. and D.R.E. conceived and designed the study. N.J.A., D.R.E., and A.J.H. processed the core collection and Will Daniels (Brown University) for the water and peat isotope sampling. Jill Coleman Wasik and Erin Mortenson undertook the BSi and 210Pb dating analyses at the SCWRS.
