Introduction

Traumatic brain injury (TBI) is defined as an acute injury to the head caused by blunt or penetrating trauma or by acceleration/deceleration forces, but not by degenerative, or congenital problems. The major principles involved in managing severe TBI are control of intracranial pressure (ICP) and ensuring adequate cerebral perfusion pressure (CPP). Medical treatments aimed at achieving ICP control include head elevation, intubation for normocarbic ventilation, sedation, hyperosmolar therapy mannitol or hypertonic saline, induced hypocapnia, hypothermia, and by barbiturate induced metabolic...
suppression.\textsuperscript{23,24} Surgical treatments involving ventricular cerebrospinal fluid drainage and decompressive craniectomy (DC) are also effective at achieving ICP control.\textsuperscript{25,26}

DC, which is performed worldwide to treat severe TBI, involves removing part of the skull to allow the brain to swell for ICP control. However, the efficacy of the procedure in terms of improving patient outcome remains controversial.\textsuperscript{23,24} Nevertheless, DC is still widely used as a last resort in patients with uncontrollable ICP. Several retrospective and prospective studies have suggested that DC effectively reduces ICP and improves prognosis in patients with refractory intracranial hypertension after TBI.\textsuperscript{5,10,12,22} However, indications for DC remain difficult to define for surgeons in emergency setting, as surgical techniques remain a controversial issue in the literature.\textsuperscript{6,15}

Classic technical recommendations for DC stress are that bone cutting should be performed in the frontotemporoparietal region to reach the base of the frontal bone and spare calvarium 20 mm from midline, to prevent injury to bridging veins and additional bleeding.\textsuperscript{28,29} Wagner et al.\textsuperscript{29} suggested that a diameter of greater than 12 cm is desirable, after observing that doubling of the diameter from 6 to 12 cm resulted in an increase in decompressive volume from 9 to 86 cc. However, no definitive standard surgical technique is available for DC and surgeons use various methods to control ICP on a case by case basis. Thus, in view of the above, we retrospectively investigated the relationship between superior sagittal sinus (SSS) to bone flap distance and clinical outcomes.

**Materials and Methods**

**Study population**

This retrospective study investigated 68 patients treated during a 24-month period from January 2016 to December 2017 at the trauma center of Pusan National University Hospital. These 68 patients were selected from 255 TBI patients that underwent DC with acute subdural hematoma removal by either of two surgeons. Patients over 16 years of age with mild to severe TBI, a high or mixed density lesion (<25 cc), and progressive deterioration of neurological status (a Glasgow Coma Scale [GCS] motor score decrease of 2 points or blunt papillary response) within 24 hours of injury were included. However, we excluded those with a serious extracranial comorbidity and an Abbreviated injury scale scores of >3, those taking antiplatelets or anticoagulants with a bleeding tendency (low platelet count <80,000, prolonged international normalized ratio >1.5, activated prothrombin time >60 sec), those with intense brain injuries, such as, multiple skull fractures, a bilateral lesion, or penetrating brain injury, with bilateral mydriasis of critically endangered status and a definite surgical contraindication, and those that received a unilateral large frontotemporoparietal craniectomy of anteroposterior (AP) with a maximum diameter of <12 cm.

**Surgical procedure**

Different DC methods have been applied for decompression of refractory intracranial hypertension in TBI patients. Types of DC were as follows: 1) subtemporal decompression; 2) circular decompression; 3) fronto or temporoparietal DC; 4) large frontotemporoparietal DC; 5) hemispheric craniectomy; and 6) bifrontal DC.\textsuperscript{7} In this study, all patients received unilateral large frontotemporoparietal craniectomy (Figure 1) of at least 12 cm AP maximum diameter in accordance with the classic technical recommendations. Simultaneously, all patients received stellate type duraplasty with artificial dura mater to maximize brain expansion after bone removal. Medical care was sustained and included rehabilitation after surgery.

**FIGURE 1.** In the operative field view (A) and illustration (B) showing unilateral frontotemporoparietal craniectomy: frontal area 2 cm in front of the coronal suture and close to the skin incision (a), parietal area just posterior to the parietal bone and close to the skin incision (b), temporal squama (c), key hole area hide the zygomatic arch of the frontal bone (d).
Definitions of variables

We measured the nearest SSS margin to bone flap distances using postoperative brain computed tomography (CT) images (Figure 2) rather than skull X-ray images for accuracy. Measuring the distance from sagittal suture to bone flap by skull X-ray may result in an overestimation of distance. Therefore, patients were divided into two groups based on SSS to bone flap distance using a 20 mm cut-off in accordance with classic technical recommendations for DC, group A ≥ 20 mm and group B < 20 mm. Estimated blood loss (EBL) and operation times were obtained from anesthesia records. Anesthesiologists determined EBL by blood soaked gauzes, suction bottles fluid volumes, and transfusion volumes. Times spent in the intensive care unit (ICU) were obtained by chart review, and clinical outcomes were rated using the extended Glasgow Outcome Scale (GOS-E, 8-point scale, ranging from death at 0 points to good recovery at 7–8 points) at 3 and 6 months.

Statistical analysis

Statistical analyses were supported by the Department of Biostatistics, Clinical Trial Center, Biomedical Research Institute, Pusan National University Hospital. To compare the characteristics of participants with respect to SSS to bone flap distance, continuous variables were analyzed using either the independent t-test and reported as means and standard deviations. Categorical variables were analyzed using Fisher’s exact test or χ² test and reported as percentages. All analyses was performed using SPSS version 22.0 (IBM Corp., Armonk, NY, USA), and p-values less than 0.05 were considered statistically significant.

Results

Relationship between patients and SSS to bone flap distance

Baseline characteristics of the 68 (60 men and 8 women, mean age of 54.57 years) study subjects and SSS to bone flap distances are summarized in Table 1. The sample size of each group was 38 in group A and 30 in group B. The male/female ratios were 18:1 and 4:1, and the means ages were 53.58 and 55.83 years, respectively. The mean SSS to bone flap distances in groups A and B were 28.13 ± 6.09 mm and 13.98 ± 3.29 mm, respectively. The TBI severity in both groups of patients, as determined using GCS scores, was classified as mild to severe, and no significant intergroup difference was evident.

Outcomes

Table 2 summarizes perioperative outcomes by SSS to bone flap distance. Mean EBL and operation times were

| Variables                     | Total (n=68) | Group A† (n=38) | Group B‡ (n=30) | p-value  |

significantly lower in group A (mean EBL 655.26 ± 208.85 mL in group A and 1803.33 ± 1083.25 mL in group B, and mean operation times 125.92 ± 29.78 min in group A and 144.83 ± 20.99 min in group B). Table 3 summarizes clinical outcomes by SSS to bone flap distance. The mean ICU stay was shorter for group A (16.67 ± 10.56 days vs. 19.45 ± 10.51 days), but not significantly. In addition, the mean GOS-E scores at 3 and 6 month follow-up visits (Figure 3) were not significantly different.

**Discussion**

DC is a neurosurgical technique in which a portion of the skull is removed to reduce ICP. The rationale for this procedure is based on the Monro-Kellie theory that expanding physical space to accommodate confined edematous brain tissue after brain injury will reduce ICP. Many surgical techniques to control ICP after TBI have been studied. DC involves making a standard trauma flap skin incision with the goal of exposing margins anteriorly to the superior border of the orbital roof while avoiding entry into the frontal sinus, posteriorly to at least 2 cm posterior to the external meatus, medially to a point 2 cm lateral to midline to maintain a SSS to bone flap distance of ≥ 20 mm, and inferiorly to the floor of the middle cranial fossa. The temporalis muscle is reflected anteriorly and can be resected if necessary. Burr holes are placed in the keyhole, the zygoma root and as preferred along the planned craniotomy route. A high-speed drill is used for the craniotomy. The lesser wing of the sphenoid is fractured and removed to the superior orbital fissure to provide sufficient decompression to prevent uncal herniation. The bone flap can be stored in abdominal subcutaneous fat or in situ using the hinge craniectomy method or it can be cryopreserved.

Many factors influence the postoperative outcomes of TBI patients. The most powerful independent prognostic variables identified to date are; age, GCS motor score, pupil response, and CT characteristics, including the Marshall CT classification and the presence of traumatic subarachnoid hemorrhage. Other important prognostic factors include PT, hypotension, hypoxia, the eye and verbal components of the GCS and glucose, platelet, and hemoglobin level. In the present study, we investigated the relationship between SSS to bone flap distance and clinical outcomes,
as well as EBL, operation times, ICU stay and GOS-E scores at 3 and 6 months postoperatively. We found that proximity between SSS and bone flap substantially increased EBL and prolonged operation times because of bridging veins compromise. Intraoperative bleeding obviously affects hemodynamic stability, extends operation anesthesia times, and increases the risk of wound infection, which indicates surgical intervention closer to the SSS to bone flap distance is associated with poorer clinical courses.\textsuperscript{2,13,14,20} To achieve better clinical outcomes in TBI, two requirements must be met. First, accurate, delicate illustrations of the surgical skin flap incision line and accurate patient positioning are needed, and due consideration should be given to the effects of gravity and skin retraction, which cause the incision line to be displaced toward the SSS. Second, anatomical SSS variations and the fracture line should be determined cautiously before surgery. In particular, a SSS that begins posterior to the foramen cecum in the frontal bone and courses backwards along the superior margin of falx cerebri, then widens near the internal occipital protuberance is referred to as the confluence of the sinuses. Surgeons should be aware that SSS variations sometimes occur during embryonic development.\textsuperscript{17} Many studies showed that a large craniectomy results in a significant decrease in ICP or the increase in CPP and GOS-E.\textsuperscript{2,30,32} Obviously, it is likely that decompressive effects depend on the volume gained by the craniectomy. However, we advise operators not to deviate from preoperative plans to create a larger bone flap and to strive to maintain a SSS to a bone flap distance of at least 20 mm intraoperatively. Because, if the AP diameter of bone flap is more than 12 cm, it is expected to be sufficient decompressed without closing to SSS. Also the possibility of complication will be increased as craniotomy in close proximity to SSS.

The current study has several limitations. First, it is inherently limited by its retrospective, single center design, and the relatively small number of patients included. Second, the method of EBLs calculation used depended on anesthesiologist experience and was somewhat subjective. Third, there was a lack of correlation between bone flap size and ICP/CPP, which are important factors of clinical prognosis in TBI. The study was also limited in not classifying acute brain injuries such as underlying cerebral contusions or diffuse axonal injury, which can significantly affect GOS-E. Nevertheless, the study has several strengths. 1) It is the first study to investigate relationships between SSS to bone flap distance during unilateral DC and clinical outcomes; 2) Since operations were performed by either of two neurosurgeons, operator-associated factors are unlikely to have affected outcomes; 3) It provides surgeons the opportunity to reflect on the non-uniformity of SSS to bone flap distances.

We suggest further larger-scale investigations be conducted with a multicenter, a randomized study design and extended follow-up that includes adjustment for potential confounders.

## Conclusion

The present study confirms that smaller SSS to bone flap distances increase operation times and EBL because bridging veins are compromised. Although no significant differences were observed between the GOS-E scores of the two study groups, ICU stays were slightly longer in the group with a SSS to bone flap distance of <20 mm. We recommend that in cases of TBI, preoperative radiological images be cautiously evaluated. Moreover, if decompression is indicated a minimum SSS to bone flap distance of 20 mm should be maintained for better outcomes.
