**Abstract**

Complete mitochondrial (mt) genomes and the gene rearrangements are increasingly used as molecular markers for investigating phylogenetic relationships. Contributing to the complete mt genomes of Gastropoda, especially Pulmonata, we determined the mt genome of the freshwater snail *Galba pervia*, which is an important intermediate host for *Fasciola* spp. in China. The complete mt genome of *G. pervia* is 13,768 bp in length. Its genome is circular, and consists of 37 genes, including 13 genes for proteins, 2 genes for rRNA, 22 genes for tRNA. The mt gene order of *G. pervia* showed novel arrangement (tRNA-His, tRNA-Gly and tRNA-Tyr change positions and directions) when compared with mt genomes of Pulmonata species sequenced to date, indicating divergence among different species within the Pulmonata. A total of 3655 amino acids were deduced to encode 13 protein genes. The most frequently used amino acid is Leu (15.05%), followed by Phe (11.24%), Ser (10.76%) and Ile (8.34%). Phylogenetic analyses using the concatenated amino acid sequences of the 13 protein-coding genes, with three different computational algorithms (maximum parsimony, maximum likelihood and Bayesian analysis), all revealed that the families Lymnaeidae and Planorbidae are closely related two snail families, consistent with previous classifications based on morphological and molecular studies. The complete mt genome sequence of *G. pervia* showed a novel gene arrangement and it represents the first sequenced high quality mt genome of the family Lymnaeidae. These novel mtDNA data provide additional genetic markers for studying the epidemiology, population genetics and phylogeographics of freshwater snails, as well as for understanding interplay between the intermediate snail hosts and the intra-mollusca stages of *Fasciola* spp.

**Introduction**

Many snails within the families Lymnaeidae and Planorbidae act as intermediate hosts of medically and veterinary important digenean trematodes that infect humans and domestic animals (especially sheep and cattle) [1,2]. *Galba pervia* (Pulmonata: Lymnaeidae) is widely distributed and is the dominant host snail for transmission of *Fasciola* spp. in China [3]. Fascioliasis caused by *Fasciola* spp. is a significant disease of livestock animals causing substantial economic impact [4–7]. More importantly, millions of humans have been infected by *Fasciola* spp. in a number of countries [8].

The metazoan mitochondrial (mt) genome, ranging in length from 14 to 18 kb, is typically circular and usually contains 36–37 genes, including 12–13 protein-coding genes, 2 ribosomal RNA (rRNA) genes and 22 transfer RNA (tRNA) genes [9]. In addition, mitochondrial genome usually contains at least one lengthy noncoding region which is essential regulatory element for the initiation of transcription and replication [9]. Mitochondrial DNA (mtDNA) has long been extensively used as genetic markers to resolve evolutionary relationships among animal species due to their maternal inheritance, higher mutation rates than nuclear genes, and relatively conserved genome structures compared to ribosomal DNA [10–15].
In coelomate animals, mt gene arrangements are usually relatively stable within each phylum [16]. However, Mollusca, the second largest animal phylum, exhibit high diversity in their mt genome structures. For example, the mt genomes of Mytilus edulis, Argopecten irradians and Chlamys ferrari contain supernumerary or lost tRNA genes [17,18]. The Gastropoda are the largest class of the Mollusca and their mt gene arrangements also exhibit high levels of variability [16]. There have been considerable controversies regarding the phylogenetic relationships of Gastropoda. Gastropoda were traditionally classified into three main subclasses based on their morphological characters: Prosobranchia, Opisthobranchia and Pulmonata. In modern taxonomies, Opisthobranchia and Pulmonata usually are clustered together in the clade Euthyneura [19,20]. When mt gene rearrangements occur, they may usually provide very powerful phylogenetic information for resolving phylogenetic relationships among taxa [21]. Compared to other metazoan animals, only 21 complete mt genome sequences of Pulmonata species have been sequenced and deposited in GenBank (Table 1) to date, and only a low quality mt genome has been determined for the family Lymnaeidae [22].

The objectives of the present study were to determine the complete mt sequence of the G. pervia, to compare the mt sequence with those of Radix balthica to infer further insights into the high variability of Gastropoda mitochondrial genomes, and to study phylogenetic relationships of Pulmonata using mt sequence dataset.

### Results and Discussion

#### Genome content and organization

The complete mt genome of G. pervia was 13,768 bp in length (Figure 1), and the mtDNA sequence was deposited in GenBank (accession number JN564796). The G. pervia mt genome contains 13 protein-coding genes (cox1-3, nad1-6, nad4L, atp6, atp8 and cyb), a small subunit ribosomal RNA gene (rns), a large subunit ribosomal RNA gene (rnl), and 22 transfer RNA genes, but without lengthy non-coding regions (Table 2). As found in other Gastropoda species, most of these genes are coded on the heavy strand (H-strand) except for atp6, atp8, nad3, cox3, 8 tRNA genes and rns. The details of gene locations were given in Table 2.

The complete mtDNA sequence of the complete mtDNA sequence of G. pervia are biased toward A and T, with T being the most favored nucleotide and G the least favored, in accordance with the mt genome of R. balthica and Biomphalaria glabrata and B. tenagophila [22,23]. The content of A+T is 72.67% for G. pervia (32.21% A, 40.46% T, 14.58% G and 12.75% C) (Table 3), 71.29% for R. balthica (31.68% A, 39.61% T, 15.39% G and 13.31% C), 75.78% for B. tenagophila (33.66% A, 42.12% T, 13.50% G and 10.72% C), respectively. Strand asymmetry (strand compositional bias) is usually reflected by skewness [24], which is calculated as (A%−T%)/(A%+T%) and (G%−C%)/(G%+C%), respectively. AT-skews and GC-skews of the whole mt genome were calculated for Pulmonata species to date (Table 3). This composition of full mtDNA sequence of G. pervia is strongly skewed away from A in favor of T (AT skew = −0.114), and GC skew = 0.067. The pattern of skew values of G. pervia is highly congruent with those observed in the mtDNA sequences of other pulmonate animals (Table 3). Previous studies suggested that GC skew is the best indicators of strand asymmetry [25]. Hence, all Pulmonata species

**Figure 1. The mitochondrial genome of Galba pervia.** Gene scaling is only approximate. All genes have standard nomenclature including the 22 tRNA genes, which are designated by the one-letter code for the corresponding amino acid, with numerals differentiating each of the two leucine- and serine-specifying tRNA (L1 and L2 for codon families CUN and UUR, respectively; S1 and S2 for codon families AGN and UCN, respectively). doi:10.1371/journal.pone.0042172.g001
in the present study show strand asymmetry (GC skew between 0.071 and 0.210) (Table 3). Interestingly, in all the mt genome sequences of Pulmonata species reported to date, only the GC skew of *Rhopalocaulis grandidieri* has negative value due to that the C content of *R. grandidieri* mt genome is relatively higher than its G content. In mammals, these asymmetrical and biased base composition of mt genomes may be due to the spontaneous deamination process of C and A in the H-strand during replication [26,27].

The gene arrangement differs among the mt genome sequences of 21 pulmonate animals, including that of *R. balthica* and *B. glabrata* and *B. tenagophila* (not shown). The gene arrangement in protein-coding genes seems to be stable in this group with a few exceptions. However, tRNA gene arrangement among these pulmonate animals is highly diversified, which provides further support for considerable variation in mt gene arrangement among pulmonate animals. Compared to the mt gene arrangement of *R. balthica*, the mt genome of *G. pervia* shows a novel gene arrangement (Figure 2). All rearranged genes are tRNA genes,

Overlapping of adjacent genes (protein-encoding genes overlapped) is common in many animal mt genomes, although the extent of overlaps varies [37–40]. The mt genes of G. pervia overlap a total of 526 bp in 21 locations which range from 1 to 158 bp, including overlapping between protein-encoding and tRNA genes (Table 2) which has also been found in Gastropoda mt genomes [41,42]. The G. pervia mt genes are separated by intergenic spacer sequences of a total of 179 bp in length, which are located in 13 regions and range from 1 to 42 bp in size (Table 2). The longest intergenic region (42 bp) is located between cox3 and tRNA-Ile genes.

Protein-coding genes and codon usage patterns

The boundaries between protein-coding genes in the mt genome of G. pervia were determined by aligning their sequences and by identifying translation initiation and termination codons with comparison to those of R. balitica and Biomphalaria spp. The predicted translation initiation and termination codons for the protein-coding genes of G. pervia mt genome were compared with those of R. balitica and Biomphalaria spp.. As shown in Table 2, the start codons of 13 protein-coding genes are ATN codon, which is typical of most metazoan mt genomes. The start codons inferred in the G. pervia mt genome were ATA and ATG, and all reading-frames of the G. pervia ended with TAG or TAA as termination codons, whereas no anomalous initiation codons and incomplete stop codons are used, although they frequently occur in protein-coding genes of most Gastropoda mtDNA genomes [29].

The pattern of codon usage in the mtDNA of G. pervia was also studied. Excluding the termination codons, a total of 3655 amino

in which 3 tRNA genes (tRNA-His, tRNA-Gly and tRNA-Tyr) changed their positions or directions (Figure 2). The tRNA-His arrangements represent translocation, tRNA-Gly arrangements represent shuffling, and tRNA-Tyr arrangements represent remote inversion translocations. Generally, tRNA gene rearrangements can be classified as translocations (across a protein-coding gene), local inversion (inverted but remaining in the position), remote inverted (translocated and inverted), and shuffling (on the same mt strand but in a different position) [28]. Within the Gastropoda, gene rearrangements have been particularly prevalent, and the mt gene rearrangement events in Gastropoda mt genomes have been discussed [29,30]. To date, four mechanisms have been proposed to explain mt gene rearrangement in metazoan: (i) the tandem duplication followed by random loss (TDRL) of supernumerary genes owning to selection favoring small genomes [31,32], (ii) illicit priming of replication by tRNA genes [33], (iii) tandem duplication followed by nonrandom loss of excess genes [34], and (iv) nonhomologous intergenome or intragenome recombination is presumed to be the most possible explanation for local inversion [35]. Considering all the data available so far, these mechanisms still do not explain mt gene rearrangement events in Gastropoda, because these compactly organized mt genomes of Gastropoda (with very few and short noncoding sequences) suggest strong selection against maintaining remnants of duplication events [36]. However, in G. pervia, a 6 bp and in R. balitica a 156 intergenic region were found in the location of tRNA-His, which might support TDRL as a mechanism acting in Pulmonata mt genome rearrangements.
Acids were Leu (15.05%), followed by Phe (11.24%), Ser (10.76%) (Table 4). Underlined genes are coded on the light strand.

**Figure 2. Comparison of the mitochondrial gene arrangement between Galba pervia and Radix balthica.** All genes have standard nomenclature including the 22 tRNA genes, which are designated by the one-letter code for the corresponding amino acid, with numerals differentiating each of the two leucine- and serine-specifying tRNA (L1 and L2 for codon families CUN and UUR, respectively; S1 and S2 for codon families AGN and UCN, respectively). Underlined genes are coded on the light strand.

doi:10.1371/journal.pone.0042172.g002

Transfer RNA and ribosomal RNA genes

The 22 tRNA genes in G. pervia mt genome vary in length from 55 to 75 nucleotides with differences in stem and loop sizes of dihydrouridine (D) and ypC loops. The 22 tRNA genes are located on both strands. Of these, 14 tRNA are encoded on the H-strand and 8 on the light strand (L-strand) (Table 2). The order and orientation of the gene arrangement pattern are identical to that of R. balthica, except for the positions and directions of the tRNA-His, tRNA-Gly and tRNA-Tyr genes. All of the 22 tRNA genes can be folded into normal cloverleaf structure, except for tRNA-Ser<sup>AGN</sup> that lacks DHU arm. Their putative secondary structures are similar to those of R. balthica or B. tenagophila (not shown), indicating their similar functions. In mt genomes of most Gastropoda animals, tRNA-Ser<sup>UCN</sup> generally lacks DHU arm [30,42,43], but it has a standard cloverleaf structure in mt genome of G. pervia. It is interesting that the secondary structures of mt tRNA genes are highly variable among Gastropoda animals. Previous studies suggested that the reduction of tRNA stem was caused by a strong pressure for mt genome minimization [44].

The rrn<sub>M</sub> and rrn<sub>L</sub> genes of G. pervia were identified by sequence comparison with those of R. balthica. The rrn<sub>M</sub> is located between tRNA-Val and tRNA-Met, and the rrn<sub>L</sub> is located between tRNA-Val and the tRNA-Leu<sup>UCN</sup>. The lengths of the rrn<sub>M</sub> and rrn<sub>L</sub> genes of G. pervia are 713 bp and 1009 bp, respectively. The lengths of the rrn<sub>M</sub> and rrn<sub>L</sub> genes of G. pervia are 713 bp and 969 bp, respectively. The A+T contents of the rrn<sub>M</sub> and rrn<sub>L</sub> of G. pervia are 72.09% and 74.93%, respectively. Sequence identities in the rrn<sub>M</sub> and rrn<sub>L</sub> genes between G. pervia and R. balthica are 83.45% and 81.97%, respectively.

**Phylogenetic analyses**

The phylogenetic relationships of 20 Pulmonata species based on concatenated amino acid sequence datasets, plus the mt DNA sequence of G. pervia obtained in the present study, using maximum parsimony (MP), maximum likelihood (ML) and Bayesian analyses (Bayes) analyses are shown in Figure 3. The amino acid sequences of R. balthica were not used due to its low quality mt genome. The topologies of the trees from the MP, ML and Bayes analyses were identical or similar. In the tree, two major clades were recovered within Pulmonata: clade I and clade II form monophyletic groups, respectively. Within the clade I, Siphonaria pectinata and S. gigas clustered together with high statistical support, indicating that S. pectinata is sister to S. gigas. Within the clade II, Placobranchidae+Volvatellidae and other families form monophyletic groups, respectively.

The results of the present study revealed that G. pervia and B. tenagophila are closely related with high statistical support, indicating that Lymnaeidae and Planorbidae are closely related families, consistent with previous classification based on their morphological features and molecular data [45,46]. Interestingly, MP and ML analyses revealed that families Amphibolidae and Pyramidellidae are not closely related (with very low bootstrap probability value), whereas Bayes analysis strongly supported that Amphibolidae and Pyramidellidae are closely related with high posterior probability value (Figure 3). Recent molecular phylogenetic studies revealed that the monophyly of Pulmonata was clearly rejected by the phylogenetic position of a representative of the Stysellommatophora (Onchidella celtica) which is more closely related to Pyramidula dolabrata than it was to any other Pulmonate [47]. This is probably due to the use of a small dataset. Thus, sampling of more taxa is needed to more accurately define phylogenetic positions of these families in further studies. In the present study, the phylogenetic status of the family Ellobiidae remains problematic, consistent with findings of recent molecular phylogenetic studies [48,49].

Here, we will not further discuss the phylogenetic relationships of these families (eg., Clausiliidae, Aplysiidae, Volvatellidae, Pleurobranchidae, Siphonariidae and Ellobiidae) since their phylogenetic relationships have been discussed in detail by a recent study using nearly 80 Pulmonata species based on analyses of 18S, 16S and COI sequences [50]. Some recent studies showed that analyses using whole mt genome sequences (amino acid sequences) yield more accurate results than that using singe or small sets of gene sequences [51,52]. Thus, more mt genomes of Pulmonata need to be sequenced and evolutionary relationships of Pulmonata should be reexamined.

In conclusion, the present study determined the mt genome sequence of G. pervia, which represents the first sequenced high quality mt genome of freshwater snails of the family Lymnaeidae. The G. pervia mt genome exhibits novel mt gene arrangement compared with other Pulmonata species. Phylogenetic analysis based on the mt amino acid sequence dataset revealed that Lymnaeidae and Planorbidae are closely related families, supporting previous classifications based on their morphology and molecular studies. These novel mtDNA data should be useful for further studying the population genetics and phylogeographics of this freshwater snail, which in turn would contribute to the effective control of Fasciola spp. transmitted by it.
Materials and Methods

Sample collection and DNA extraction

An adult freshwater snail representing *G. pervia* was collected from Guilin City, Guangxi Zhuang Nationality Autonomous Region, China. The specimen was washed in physiological saline, identified morphologically to species according to existing keys and descriptions [53], fixed in 70% (v/v) ethanol and stored at 22°C until use.

Total genomic DNA was extracted from its thoracic muscle tissue by treatment with sodium dodecyl sulphate/proteinase K (Merck), followed by purification using Wizard™ DNA Clean-Up System (Promega) and then eluted into 60 μl H₂O according to the manufacturer’s recommendations. The DNA sample was stored at 22°C until further use.

Amplification and sequencing of partial *cox1*, *nad1*, *cytB*, *cox3* and *rrnL*

Partial fragments of *mt cox1*, *nad1*, *cytB*, *cox3* and *rrnL* genes were amplified using 5 sets of primers (Table 5) designed according to mtDNA sequences of other Pulmonata deposited in GenBank. PCR reactions were carried out in a 25 μl reaction volume consisting of 16.75 μl sterile deionized water, 2.5 μl 1×PCR Buffer (Mg²⁺ free), 2.0 μl MgCl₂ (25 mM), 2.0 μl dNTPs (2.5 mM each), 0.25 μl each primer (50 pmol/μl), 0.25 μl ExTaq DNA polymerase (5 U/μl, Takara) and 1.0 μl DNA template (40 ng/μl) under the following conditions: after an initial denaturation at 94°C for 5 min, then 94°C for 1 min (denaturation), 50–55°C for 30 s (annealing), 72°C for 1 min (extension) for 35 cycles, followed by 72°C for 10 min (final extension). Each amplicon (5 μl) was examined by agarose gel electrophoresis to validate amplification efficiency. Then the *cox1*, *nad1*, *cytB*, *cox3* and *rrnL* amplicons were

Table 4. Codon usage of *Galba pervia* mitochondrial protein-coding genes.
sent to BGI-Shenzhen Company, China for sequencing from both directions.

Long-PCR amplification and sequencing

The obtained nucleotide sequences of partial \textit{cox}1, \textit{nad}1, \textit{cyt}b, \textit{cox}3 and \textit{rrn}L were used to design primer sets (Table 6) for long PCR amplification of the entire \textit{G. pervia} mt genome. Five overlapping long PCR fragments covering the entire mt genome of \textit{G. pervia} were obtained. The Long-PCR reaction volume amounted 50 \textmu l containing 27.5 \textmu l sterile deionized water, 5.0 \textmu l 10\texttimes LA PCR Buffer (Mg\textsuperscript{2+} free), 5.0 \textmu l MgCl\textsubscript{2} (25 mM), 8.0 \textmu l dNTPs (2.5 mM each), 0.5 \textmu l each primer (50 pmol/\textmu l), 0.5 \textmu l LA Taq DNA polymerase (5 U/\textmu l, Takara) and 3 \textmu l DNA template (40 ng/\textmu l). Long-PCR cycling conditions used were 92\textdegree C for 2 min (initial denaturation), then 92\textdegree C for 10 s (denaturation), 40\textdegree C for 30 s (annealing), and 60\textdegree C for 5 min (extension) for 5 cycles, followed by 92\textdegree C for 10 s, 40\textdegree C for 30 s, and 66\textdegree C for 5 min for 20 cycles and a final extension at 66\textdegree C for 10 min. All amplifications were done on a T-Gradient thermo-cycler (Biometra, Germany). The 5 long-PCR fragments were sequenced using a primer-walking strategy.

Gene annotation and sequence analysis

Sequences were assembled manually and aligned against the complete mt genome sequence of \textit{R. balthica} and \textit{B. tenagophila} using the computer program Clustal X 1.83 [54] to identify gene boundaries. The open-reading frames and codon usage profiles of protein-coding genes were analyzed by the Open Reading Frame Finder [http://www.ncbi.nlm.nih.gov/gorf/gorf.html] using the invertebrate mitochondrial code. Translation initiation and translation termination codons were identified based on comparison with the mt genome of \textit{R. balthica} and \textit{B. tenagophila}. The

Figure 3. Inferred phylogenetic relationship among Pulmonata species based on mitochondrial DNA sequences. The concatenated amino acid sequences of 13 protein-coding genes were analyzed utilizing maximum parsimony (MP), maximum likelihood (ML) and Bayesian analysis (Bayes), using \textit{Aplysia californica} and \textit{A. dactylomela} as outgroup. The numbers along branches indicate bootstrap probability (BP) and posterior probability (PP) resulting from different analyses in the order: MP/ML/Bayes. Alternative topologies were correspondingly shown on the downside of the tree. The coloured species indicated that the phylogenetic status of the family Ellobiidae remains problematic.

doi:10.1371/journal.pone.0042172.g003
Phylogenetic analyses

Phylogenetic relationship among the 20 Pulmonata species (Table 1), plus the mt DNA sequence of G. pereia obtained in the present study was reconstructed based on amino acid sequences of 15 protein-coding genes using the 2 Opisthobranchia species (Aplysia californica, GenBank accession number NC_005827 and A. dactylomela, NC_015088) as the outgroup. Each gene was translated into amino acid sequence using the invertebrate mitochondrial genetic code in MEGA 4 [56], and aligned based on its amino acid sequence using default settings, and ambiguously aligned regions were excluded using Gblocks online server (http://molevol.cmima.csic.es/castresana/Gblocks_server.htm) [57] using the options for a less stringent selection. The final amino acid sequences of the 13 protein-coding genes were then concatenated into single alignments for phylogenetic analyses. Three different inference methods, namely MP, ML, and Bayes, were used for phylogenetic analyses. MP analysis was performed using PAUP™ 4.0b10 [58], with indeps treated as missing character states. A total of 1,000 random addition searches using TBR were performed for each MP analysis. Bootstrap probability (BP) was calculated from 1,000 bootstrap replicates with 10 random additions per replicate in PAUP. ML analyses were performed using PhyML 3.0 [59], and the McArt+H+G+F model with its parameter for the concatenated dataset was determined for the ML analysis using ProtTest 10.2 based on the Akaike information criterion (AIC) [60]. BP value for ML trees was calculated using 1000 bootstrap replicates. Bayesian analyses were conducted with four independent Markov chains run for 1,000,000 metropolis-coupled MCMC generations, sampling a tree every 100 generations in MrBayes 3.1.1 [61]. The first 2,500 trees were omitted as burn-in and the remaining trees were used to calculate Bayesian posterior probabilities (PP). Phylogenograms were drawn using the Tree View program version 1.63 [62].
