(Dated: July 6, 2010)

The transmission phase through a quantum dot with few electrons shows a complex, non-universal behavior. Here we combine configuration-interaction calculations —treating rigorously Coulomb interaction— and the Friedel sum rule to provide a rationale for the experimental findings. The phase evolution for more than two electrons is found to strongly depend on dot’s shape and electron density, whereas from one to two the phase never lapses. In the Coulomb (Kondo) regime the phase shifts are significant fractions of $\pi$ ($\pi/2$) for the second and subsequent charge addition if the dot is strongly correlated. These results are explained by the proper inclusion in the theory of Coulomb interaction, spin, and orbital degrees of freedom.

I. INTRODUCTION

Recent experiments by the Weizmann group have stirred much attention to the phase that electrons acquire when they traverse a quantum dot (QD) embedded in the arm of a Aharonov-Bohm interferometer. These fascinating measurements call for a deeper understanding of electron transport through a strongly interacting object. If many electrons — say $N > 10$ — populate a QD, the transmission phase $\Theta$ of the tunneling electron displays a much studied universal behavior: first $\Theta$ increases by $\pi$ through the conductance peak and then it lapses in the Coulomb valley. Here we focus on the relatively less studied few-electron regime, where the phase evolution depends on $N$. In the samples studied in Ref. the phase remains constant in the $N = 1$ valley, independently from QD tunings, whereas it lapses in the Coulomb blocked devices of Ref. For $N > 2$ the phase is not reproducible and shows both increments and lapses, likely due to QD shape and exchange effects.

In spite of several explanations of the few-electron scenario a clear picture is still missing. Many works introduce major simplifications, like spinless electrons, or other ad hoc assumptions. Even the interpretation of the simplest $N = 1 \rightarrow N = 2$ transition is controversial, being variably attributed to the occupation of either the same or a different orbital from that of the first electron, to the role of excited doorway channels to electron crystallization.

In this paper we compute $\Theta$ by fully including exchange and correlation effects. The theory is based on the application of the Friedel sum rule (FSR) as generalized in Ref. to a multiorbital interacting QD—an exact zero-temperature result, $T = 0$. Since the FSR holds for non degenerate ground states (GSs) only, it may be applied to either singlet Kondo GSs at zero field, $B = 0$, or non-degenerate GSs in the Coulomb blockade regime ($B \geq 0$ for singlets and $B > 0$ for doublets and higher-spin states).

It is worth recalling that, in the conductance valleys with odd $N$ at $T = 0$ and $B = 0$, the QD is always in the Kondo regime. In order to reach the Coulomb blockade regime by keeping $T = 0$, one needs to apply the field to the Aharonov-Bohm ring to destroy dot-lead Kondo correlations, hence removing QD spin degeneracy. This condition is reached when $\Gamma \ll \mu_B B$, with $\mu_B$ being the Bohr magneton and $\Gamma$ the QD level width. In the experiments the temperature is very low ($T \sim 30$ mK) and the field is relatively weak ($B \sim 10$ mT). Therefore, in order to compare measurements with the theoretical predictions reported in this paper, tiny widths $\Gamma$ are required, which are actually smaller than the values presently reported.

As anticipated above, the theory relies on the application of the FSR. The key idea is that the phase variation $\Delta \Theta$ for the addition of one electron to the QD is given by integrating the QD spectral density $N(\omega)$ between two consecutive conductance valleys (with $\Delta N = 1$). This is evaluated exactly for an isolated QD via full configuration interaction (CI) calculations with $N \leq 5$.

The simulations agree with the Coulomb-blockade results of Ref. (i) The phase evolution for $2 \leq N \leq 5$ strongly depends on the dot’s shape and density. (ii) $\Theta$ never lapses in the $N = 1$ valley, independently from dot parameters. Additionally, (iii) in the Coulomb (Kondo) regime the increment $\Delta \Theta$ through the conductance peak is significantly smaller than $\pi$ ($\pi/2$) as a consequence of strong Coulomb correlation.

The theory fails to reproduce the Coulomb blockade results of Ref. The reason of this discrepancy is presently unclear, but it is likely related to the significant departure from the condition ruling the range of applicability of the theory, i.e., $\Gamma \ll \mu_B B$ at $T = 0$. In order to treat the Coulomb blockade regime even at $B = 0$, one could compute the thermal Green function of the fully correlated system at $T > T_K$, with $T_K$ being the Kondo temperature. We leave for future work this alternative route, which would immediately provide the transmission phase $\Theta$ without invoking the FSR.

The structure of this paper is as follows. In Sec. we...
set the theoretical model and illustrate the usage of the FSR to compute the transmission phase variation \( \Delta \Theta \) between consecutive conductance valleys. After briefly recalling the full CI method in Sec. III, we address in Sec. IV the evolution of the phase in the absence of \( \Theta \). We then include all many-body correlations by connecting the phase shift \( \theta_{X,\sigma} \) per channel \((X, \sigma)\) \((X = e, o\) labels the parity) to the exact spectral density \( N_{X,\sigma}(\omega) \) accumulated at the QD via the FSR \( \text{cf. Eq. (20)} \) of Ref. 15:

\[
1 \frac{d \theta_{X,\sigma}(\omega)}{d \omega} = \pi N_{X,\sigma}(\omega).
\]

Here \( N_{X,\sigma}(\omega) \) is the density displaced at the QD by the electron in the scattering state \((X, \sigma)\) tunneling at the energy \( \hbar \omega \) fixed by the chemical potential \( \mu = \hbar \omega \). We mimic the action of the plunger gate in the linear response regime by varying the value of \( \mu \) with respect to the QD energy levels.

In practice, to use the FSR we integrate it over the energy window between two consecutive Coulomb valleys with \( N + 1 \) electrons in the QD, respectively.\textsuperscript{22} Whereas this procedure provides the information on the total phase variation only, \( \Delta \theta_{X,\sigma} = \pi \Delta N_{X,\sigma} = \pi \hbar \int d\omega N_{X,\sigma}(\omega) \), it allows to compute \( \Delta N_{X,\sigma} \) from the interacting Hamiltonian of the isolated dot, \( H_{\text{QD}} \).

This key result is based on the conservation of the total number of scattering plus QD states both in the presence and absence of the QD in the arm of the interferometer.\textsuperscript{19}

(c) Transmission phase \( \Theta \) and phase shifts \( \theta_{e,o} \) vs \( N \) for the filling sequence plotted in (b).

---

**II. TRANSMISSION PHASE FROM THE FRIEDEL SUM RULE**

We model the experimental setup of Ref. 1 as in Fig. 1(a). Electrons flow along \( x \) from source (S) to drain (D), tunneling through a QD of elliptical shape. The ellipse is the generic low-energy form for a two-dimensional shallow, gate-defined potential,\textsuperscript{1-3} since the lowest-order non-vanishing terms of its series expansion are quadratic. The scattering matrix \( S \) is diagonal in the spin index \( \sigma \) in both Kondo and Coulomb blockade regimes. In fact, in the Kondo regime \((B = 0)\), no elastic spin-flip occurs.\textsuperscript{16,17} On the other hand, in the Coulomb blockade regime only one \( \sigma \) channel is active at time for a given energy since \( B \) removes spin degeneracy.

Additionally, we assume\textsuperscript{16} mirror reflection symmetry in the \( yz \) plane placed in the QD center, at \( x = 0 \) [Fig. 1(a)], hence the stationary scattering states \( \psi_{e,o}(x) \), eigenstates of \( S_{\sigma} \), are either even \( (e) \) or odd \( (o) \) with respect to \( x \rightarrow -x \) reflection: for \( |x| > R \),

\[
\psi_{e,o}(x) = e^{-ik|x|} + e^{2i\theta_{e,o}\pm ik|x|}
\]

and

\[
\psi_{o,e}(x) = \text{sgn}(x) \left[ e^{-ik|x|} + e^{2i\theta_{e,o}\pm ik|x|} \right].
\]

Here the even and odd outgoing waves are phase shifted by \( \theta_{e,o} \) and \( \theta_{o,e} \), respectively, \( k \) is the wave vector, \( R \) is the QD nominal longitudinal axis. The left and right travelling states \( \psi_{\pm,k,\sigma}(x) \) are superpositions of even and odd states:

\[
\psi_{\pm,k,\sigma}(x) = \frac{1}{2} \left[ \psi_{e,o}(x) \mp \psi_{o,e}(x) \right].
\]

Inside the QD, \( |x| < R \), electrons experience two-body Coulomb interactions in addition to the confinement potential \( \text{cf. Eq. (3)} \).

We first generalize the results of Ref. 20 for spinless, non-interacting electrons by including spins. The transmission amplitude \( t_{\sigma} \) for travelling states \( \psi_{\pm,k,\sigma}(x) \) is:

\[
t_{\sigma} = |t_{\sigma}| i e^{i\Theta} = i e^{i(\theta_{e,o}+\theta_{o,e})} \sin(\theta_{e,o} - \theta_{o,e}). \tag{1}
\]

Each time \( \sin(\theta_{e,o} - \theta_{o,e}) \) appearing in Eq. (1) changes sign, due to a variation of either \( \theta_{e,o} \) or \( \theta_{o,e} \) as a new electron tunnels into the QD, then a lapse of \( \pi \) occurs for the transmission phase \( \Theta \). Since this happens when \( t_{\sigma} = 0 \) \( \text{cf. Eq. (1)} \), the lapse is located in the conductance valley.\textsuperscript{20,21}
The CI evaluation of $\Delta \theta_{X,\sigma}$ relies on the formula
\[
\Delta N_{X,\sigma} = \frac{\Delta \theta_{X,\sigma}}{\pi} = \sum_{\alpha X} \left| \langle \Psi_{0}^{N+1} | c_{\alpha X,\sigma}^{\dagger} \Psi_{0}^{N} \rangle \right|^2,
\] (3)
where $|\Psi_{0}^{N}\rangle$ is the exact interacting GS of the isolated QD with $N$ electrons of energy $E_{N}^{0}$, $H_{QD} |\Psi_{0}^{N}\rangle = E_{N}^{0} |\Psi_{0}^{N}\rangle$, and $c_{\alpha X,\sigma}^{\dagger}$ creates an electron with spin $\sigma$ in the orbital of given parity $X$ and further specified by the set of quantum numbers $\alpha X$. Equation (3) follows from Eq. (21) of Ref. [14], which was inferred by connecting the phase shift to the delay time spent by the electron wave packet in the QD. This delay is obtained by integrating the wave function square modulus over both time and space. By orthogonality of QD orbitals, only terms diagonal in $\alpha X$ indices survive in the formula (3).

We eventually link the transmission phase variation $\Delta \theta$ to $\Delta \theta_{X,\sigma}$ through Eq. (1). In the Coulomb blockade regime only one scattering channel $(X,\sigma)$ is active at time between two consecutive valleys with respectively $N$ and $N+1$ electrons. The active channel is univocally determined by the total spins and parities of $|\Psi_{0}^{N}\rangle$ and $|\Psi_{0}^{N+1}\rangle$, as obtained by CI. On the other hand, in the Kondo regime time-reversal invariance (recall that $B = 0$) implies that $\Delta N_{X}\uparrow = \Delta N_{X}\downarrow$ evaluated as half the Coulomb blockade value given by Eq. (6). In this way we regain at once the result (2.16) that $\Delta \theta = \pi/2$ for the addition of the first electron. In fact, the term on the right hand side of Eq. (3) is trivially one when $N = 0$.

### III. THE FULL CONFIGURATION INTERACTION METHOD

The interacting Hamiltonian of the isolated QD is
\[
H_{QD} = \sum_{i=1}^{N} H_{SP}(i) + \frac{1}{2} \sum_{i \neq j} \kappa |r_i - r_j|, \quad \text{(4)}
\]
where the single particle (SP) term is
\[
H_{SP}(i) = \frac{p_{i}^{2}}{2m^{*}} + \frac{1}{2} m^{*} (\omega_{0x}^{2} x_{i}^{2} + \omega_{0y}^{2} y_{i}^{2}) + \frac{1}{2} g^{*} \sigma_{i} \mu_{B} B. \quad \text{(5)}
\]
Here $\sigma_{i} = \pm 1$, $\kappa$ is the dielectric constant, $m^{*}$ is the electron effective mass, $g^{*}$ is the gyromagnetic factor, and the QD confinement frequencies in the $x$ and $y$ directions, $\omega_{0x}$ and $\omega_{0y}$, have characteristic lengths $a = [h/(m^{*}\omega_{0x})]^{1/2}$ and $b = [h/(m^{*}\omega_{0y})]^{1/2}$, respectively (the ratio $a/b$ is related to the ellipse eccentricity). In Eq. (4) the weak $B$ does not affect orbital degrees of freedom.

To wholly include in our theory Coulomb correlation, we solve numerically the few-body problem of Eq. (4) by means of the full CI method (also known as exact diagonalization, for details see Ref. [15]). The CI few-body GS $|\Psi_{0}^{N}\rangle$ is essentially a linear combination of the Slater determinants $|\Phi_{i}^{N}\rangle$,
\[
|\Psi_{0}^{N}\rangle = \sum_{i} c_{i} |\Phi_{i}^{N}\rangle, \quad \text{(6)}
\]
with the unknown $c_{i}$s being the output of the calculation. Here the determinants $|\Phi_{i}^{N}\rangle$ are obtained by filling in all possible ways with $N$ electrons the $N_{SP}$ lowest-energy SP orbitals (two-fold spin degenerate at $B = 0$), eigenstates of the SP Hamiltonian (5). In the Fock space of these Slater determinants $H_{QD}$ is a large sparse matrix, that we exactly diagonalize by means of the parallel code DonRodrigo [23] eventually obtaining the coefficients $c_{i}$ of Eq. (6).

The diagonalization proceeds in each Hilbert space sector labeled by $N$, the total spin, and the total parity of the few-body wave function. After we have obtained the GSs $|\Psi_{0}^{N}\rangle$ and $|\Psi_{0}^{N+1}\rangle$, we evaluate $\Delta N_{X,\sigma}$ via Eq. (3), and eventually infer $\Delta \Theta$ as explained in Sec. IV.

In the CI calculations reported in Sec. V we used $N_{SP} = 36$ and diagonalized matrices of maximum linear size $2.25 \times 10^{6}$. The relative error for the energy was less than $10^{-4}$ for $a/b = 1$.

### IV. THE SPINFUL NON-INTERACTING CASE

To illustrate the effect of the inclusion of the spin degree of freedom in the calculation of the transmission phase $\Theta$ let us consider for the time being only the SP Hamiltonian, $H_{SP}$, and neglect Coulomb interaction. The GS is a Slater determinant with the lowest $N$ spin-orbitals filled. $|\Psi_{0}^{N}\rangle = \prod_{i=1}^{N} c_{\alpha_{i},\sigma_{i}} |0\rangle$ ($|0\rangle$ is the vacuum). The Aufbau filling sequence for $1 \leq N \leq 6$ is depicted in Fig. (1b) for $a/b < 1$. The first two electrons occupy the $s$ orbital with opposite spin, then the 3rd and 4th electrons fill in the $p_{y}$ orbital, which is shifted in energy from the $p_{x}$ orbital by $\Delta = h\omega_{0y}(1-a^{2}/b^{2})$. Note that the first electron entering a new SP level is always $\uparrow$, due to the effect of $B$. The evaluation of the phase shift $\Delta \theta_{X,\sigma}$ at each electron addition is straightforward, since in Eq. (3) only one addendum gives a non-zero contribution to $\Delta \theta_{X,\sigma}/\pi$—exactly one—as a new spin-orbital $(\alpha X,\sigma)$ is occupied; the other ones vanish due to the orthogonality of the states. Therefore in Fig. (1b) one has $\Delta N_{X,\sigma} = 1$ for the sequence $(X,\sigma) = (e,\uparrow), (e,\downarrow), (e,\uparrow), (e,\downarrow), (e,\uparrow), (e,\downarrow)$ of six consecutive electron additions, with the $p_{y}$ ($p_{x}$) orbital even (odd) under $x \rightarrow -x$.

The evolution of $\Theta$ for the filling sequence of Fig. (1b) is shown in Fig. (1c). Both increments and lapses of $\Theta$ are derived through Eq. (1) (lapse locations in the conductance valleys with fixed $N$ are arbitrary). A remarkable feature of Fig. (1c) is that $\Theta$ increases by $\pi$ in both transitions $N = 0 \rightarrow N = 1$ and $N = 1 \rightarrow N = 2$, since the first two electrons occupy the same $s$ orbital with opposite spin. This is fundamentally different from the spinless case [29] where a total increase of $\Theta$ by $2\pi$ between $N = 0$ and $N = 2$ occurs only if the two electrons occupy orbitals of different parities.

Two lapses of $\pi$ occur for $\Theta$ in the blockaded regions with $N = 2$ and $N = 3$ [Fig. (1c)] as the phases $\theta_{\uparrow\uparrow}$ and $\theta_{\downarrow\downarrow}$ increase more than $\pi$, respectively. The whole pattern of $\Theta$ in Fig. (1c) up to five electrons coincides
we parameterize the electron density
the previous section. Ref. 1, if one excludes the possibility of a phase lapse.

\[ \sim \]
the case for \( \Delta \Theta \)

For \( N = 1 \)

\[ \Delta \Theta = \pi \]

Then \( \Theta \) remains constant in the \( N = 1 \) valley, independently from the values of either \( r_s \) or \( a/b \) [cf. Fig. 2]. The second electron addition is analyzed in Fig. 2, plotting in the \( (r_s, a/b) \) space the contour map of \( \Delta \Theta \) for \( N = 1 \rightarrow N = 2 \). Here we vary the anisotropy ratio \( a/b \) by keeping the ellipse area \( \pi ab \) fixed, so the density remains constant. The contour lines of Fig. 2 provide the value of \( \Delta \Theta \) in the Coulomb blockade regime, whereas its Kondo counterpart may be simply obtained by dividing \( \Delta \Theta \) by two (cf. also Fig. 3). As \( r_s \) increases, \( \Delta \Theta \) monotonously decreases, since correlation effects become stronger at lower density, as the Coulomb term in \( H_{QD} \) [Eq. (4)] overcomes the SP term. A similar trend occurs by increasing \( a/b \), since a stronger anisotropy effectively lowers the dimensionality of the system, again enforcing correlation effects. Note that by overlapping the experimental value \( \Delta \Theta \sim \pi/4 \) with the plot of Fig. 2 we find \( r_s \approx 4 \) for \( a/b = 1 \). This value corresponds to \( \hbar \omega_0 = 1.2 \) meV for GaAs, which is comparable to the experimental estimate of 0.5 meV.

From the analysis of CI data of Fig. 2 we find that the orbital purities of both the first and second electrons are always even, independently from \( r_s \) and \( a/b \). This prediction agrees with the Wigner-Mattis theorem: the two-electron GS is always a singlet and the orbital part of its wave function is nodeless. This result conflicts with other explanations, and it is expected to hold even in the presence of disorder and/or more complicated potentials.

In Fig. 3 we follow the evolution of \( \Theta \) up to five electrons for a significant range of QD anisotropies. At the experimental density \( (\hbar \omega_0 = 0.5 \) meV \) a slight variation of \( a/b \) is sufficient to alter the phase behavior for \( N > 2 \). Indeed, the relative differences between the values of \( a/b \) for the 3rd, 4th, and 5th panels are as small as \( 5\% \). Therefore, \( \Theta \) is sensitive to fluctuations of the experimental QD parameters, as reported in Ref. 1.

The occurrence of alternative scenarios in Fig. 3 is another signature of correlation. In fact, several excited states lie very close in energy to the GS, as it is the case in the crossover to electron crystallization. Hence a small deformation of the QD shape easily induces a crossing between states of different symmetry. We here highlight only the most relevant features of a rich zoology, focusing on Coulomb blockade results (solid lines in Fig. 3). In a circular QD at such low density (4th panel of Fig. 3) the three-electron GS is a spin quadruplet as an effect of correlation. Because the two-electron GS is a singlet, the transition \( N = 2 \rightarrow N = 3 \) is spin blockaded, i.e., \( \Delta \Theta = 0 \) without any lapse as \( \Delta N_{x_0} = 0 \). A slight deformation of the QD (3rd and 5th panels) changes the \( N = 3 \) GS into a doublet, lifting the spin blockade (\( \Delta \Theta \neq 0 \) between \( N = 2 \) and \( N = 3 \)).

V. THE ROLE OF COULOMB INTERACTION

When correlation effects exceed the mean-field level, are relevant, we expect that \( \Delta N_{x_\sigma} < 1 \), as suggested in Ref. 15. Since the CI ground states \( \Phi^N_0 \) are superpositions of the Slater determinants \( \{ \Phi^N_i \} \) [cf. Eq. (5)], after expansion on this basis many cross terms give no contribution to Eq. (3): the stronger the correlation, the larger the number of Slater determinants, the smaller \( \Delta N_{x_\sigma} \). This seems to be the case in Ref. 11 for \( \Delta \Theta \sim 3\pi/4 \) in the \( N = 1 \rightarrow N = 2 \) transition of Fig. 4b and \( \Delta \Theta \sim 3\pi/4 \) for \( N = 6 \rightarrow N = 7 \) in Fig. 5. This could even be the case for \( \Delta \Theta \sim 0 \) for \( N = 3 \rightarrow N = 4 \) in Fig. 4a of Ref. 11 if one excludes the possibility of a phase lapse. Such interpretation is alternative to the one suggested in the previous section.

To assess the impact of correlation in the CI results, we parameterize the electron density \( n \) of the circular dot \( (\omega_0 = \omega_{0x} = \omega_{0y}) \) via the dimensionless radius \( r_s \) of the circle whose area is equal to the area per electron, \( r_s = 1/(a_B^* (\pi n)^{1/2}) \), where \( a_B^* \) is the effective Bohr radius and \( n \) is estimated as in Ref. 25. We next focus on the evolution of \( \Theta \) as a function of both \( r_s \) and ellipse anisotropy ratio \( a/b \). The first electron addition in the Coulomb (Kondo) regime always gives \( \Delta \Theta = \pi \) \( (\Delta \Theta = \pi/2) \). Then \( \Theta \) remains constant in the \( N = 1 \) valley, independently from the values of either \( r_s \) or \( a/b \) [cf. Fig. 2]. The second electron addition is analyzed in Fig. 2, plotting in the \( (r_s, a/b) \) space the contour map of \( \Delta \Theta \) for \( N = 1 \rightarrow N = 2 \). Here we vary the anisotropy ratio \( a/b \) by keeping the ellipse area \( \pi ab \) fixed, so the density remains constant. The contour lines of Fig. 2 provide the value of \( \Delta \Theta \) in the Coulomb blockade regime, whereas its Kondo counterpart may be simply obtained by dividing \( \Delta \Theta \) by two (cf. also Fig. 3). As \( r_s \) increases, \( \Delta \Theta \) monotonously decreases, since correlation effects become stronger at lower density, as the Coulomb term in \( H_{QD} \) [Eq. (4)] overcomes the SP term. A similar trend occurs by increasing \( a/b \), since a stronger anisotropy effectively lowers the dimensionality of the system, again enforcing correlation effects. Note that by overlapping the experimental value \( \Delta \Theta \sim \pi/4 \) with the plot of Fig. 2 we find \( r_s \approx 4 \) for \( a/b = 1 \). This value corresponds to \( \hbar \omega_0 = 1.2 \) meV for GaAs, which is comparable to the experimental estimate of 0.5 meV.

From the analysis of CI data of Fig. 2 we find that the orbital purities of both the first and second electrons are always even, independently from \( r_s \) and \( a/b \). This prediction agrees with the Wigner-Mattis theorem: the two-electron GS is always a singlet and the orbital part of its wave function is nodeless. This result conflicts with other explanations, and it is expected to hold even in the presence of disorder and/or more complicated potentials.

In Fig. 3 we follow the evolution of \( \Theta \) up to five electrons for a significant range of QD anisotropies. At the experimental density \( (\hbar \omega_0 = 0.5 \) meV \) a slight variation of \( a/b \) is sufficient to alter the phase behavior for \( N > 2 \). Indeed, the relative differences between the values of \( a/b \) for the 3rd, 4th, and 5th panels are as small as \( 5\% \). Therefore, \( \Theta \) is sensitive to fluctuations of the experimental QD parameters, as reported in Ref. 1.

The occurrence of alternative scenarios in Fig. 3 is another signature of correlation. In fact, several excited states lie very close in energy to the GS, as it is the case in the crossover to electron crystallization. Hence a small deformation of the QD shape easily induces a crossing between states of different symmetry. We here highlight only the most relevant features of a rich zoology, focusing on Coulomb blockade results (solid lines in Fig. 3). In a circular QD at such low density (4th panel of Fig. 3) the three-electron GS is a spin quadruplet as an effect of correlation. Because the two-electron GS is a singlet, the transition \( N = 2 \rightarrow N = 3 \) is spin blockaded, i.e., \( \Delta \Theta = 0 \) without any lapse as \( \Delta N_{x_0} = 0 \). A slight deformation of the QD (3rd and 5th panels) changes the \( N = 3 \) GS into a doublet, lifting the spin blockade (\( \Delta \Theta \neq 0 \) between \( N = 2 \) and \( N = 3 \)).
Transmission phase

\[ \Theta \text{ vs } N \] for different dot anisotropies \( a/b \). Solid (dashed) lines refer to the Coulomb blockade (Kondo) regime. We used GaAs parameters and \( \hbar \omega_0 = 0.5 \text{ meV} \). From top to bottom: \( a/b = (1.5)^{-1}, (1.15)^{-1}, (1.05)^{-1}, 1, 1.05, 1.15, 1.5 \).

FIG. 3: \( \Theta \) vs \( N \) for different dot anisotropies \( a/b \). Solid (dashed) lines refer to the Coulomb blockade (Kondo) regime. We used GaAs parameters and \( \hbar \omega_0 = 0.5 \text{ meV} \). From top to bottom: \( a/b = (1.5)^{-1}, (1.15)^{-1}, (1.05)^{-1}, 1, 1.05, 1.15, 1.5 \).

VI. CONCLUSION

In conclusion, we highlighted the role of exchange and correlation in the transmission phase of a few-electron quantum dot. Our findings are relevant for transport experiments through strongly interacting nano objects, including molecules and carbon-based nanostructures.

at the Hartree-Fock level, which may decrease $\Delta N_{X\sigma}$ from its unit value. On the other hand, our CI results for $\Delta N_{X\sigma}$ are exact, including both the mean-field relaxation as well as the effect of correlations beyond mean-field. The latter are dominant at large values of $r_s$.
