Abstract
We develop a new protocol for sharing entanglement (one ebit) between two parties using the natural dynamics of helical multiferroic spin chains. We introduce a novel kicking scheme of the electric field for enhancing the teleportation fidelity in our protocol that works in the presence of an appropriate choice of parameters. We also investigate the effect of a common spin environment causing decoherence in the entanglement sharing channel. We compare the results to that of XXZ and XX models subject to a similar entanglement sharing protocol and find that the helical multiferroic chain with the kicking scheme provides a better singlet fraction. We show that the kicking scheme in conjunction with the optimized parameters enhances the fidelity of teleportation even in the presence of impurities and/or decoherence. The advantage of the kicking scheme shown in the impurity cases is an important result to be useful in a realizable setup of helical multiferroic spin chain.

Keywords Teleportation · Singlet fraction · Helical multiferroics

1 Introduction
The basic question of transmitting quantum information has been central to the development of various quantum communication protocols such as quantum teleportation...
[1] and direct state transfer [2]. A variety of systems have been studied as quantum channels which enable the transfer of qubits using the often-cited protocols [3–13]. Many types of spin chain systems have been found to be effective for both teleportation and direct transfer [14–19]. A related development has been in routing quantum information through network of spin chains [20–24] while studying the effect of phase of the spin chain, quench, and external field.

On the experimental side, with the remarkable progress in nanotechnology and material science during the last two decades, several quantum information protocols have become experimentally realizable in spin chain systems. For instance, solid-state-based one-dimensional and quasi-one-dimensional multiferroic spin chains (such as LiCu$_2$O$_2$) were experimentally realized. In the experimentally investigated system by Menzel et. al. [25], it has been shown (using spin-polarized scanning tunneling spectroscopy), that the effect of changing the spin direction at one site at the edge of the chain can be accessed on the other end of the chain. A key feature of the particular spin chain system studied here is that it possesses an intrinsic electric polarization associated with spin non-collinearity. This ferroelectric property of the quantum quasi-one-dimensional $S = 1/2$ magnet such as LiCu$_2$O$_2$ was experimentally verified [26], and allows us to act on the chain with an external electric field. In addition to LiCu$_2$O$_2$, there are a number of other helical multiferroics materials with intrinsic coupled magnetic and ferroelectric order parameters [26–33] which were also shown to be useful in quantum information processing [34,35], among various other applications.

The focus of this manuscript is on addressing the question that whether it is possible to achieve high quality teleportation using helical spin chains as an entanglement sharing channel? We have also studied that whether the magneto-electric coupling associated with helical multiferroics can be functionalized for improving the fidelity of quantum teleportation.

In a realistic setting, the entanglement sharing channel such as a spin chain may have embedded impurities and may also be susceptible to noise and other environmental effects. These factors are expected to affect the transfer of quantum information and therefore, would influence the fidelity of information transfer. Specifically, in quantum teleportation, noise may set in at any point of time which may lead to the conversion of a pure entangled state (to be shared initially) into a mixed state or inaccurate detection of the shared entangled state by sender and/or receiver [36]. In this regard, local environment has been seen to have effects that are sometimes counterintuitive such as an increase in the teleportation fidelity [37–42].

In this manuscript, we have proposed a generic protocol wherein the entanglement is generated and encoded in the middle of a spin chain and it becomes available at the ends through the intrinsic dynamics of the chain. The parties involved in teleportation have access to the ends of the chain and hence, the available entanglement is utilized by the sender and receiver for the teleportation task. Here we show that helical multiferroics can indeed be used to share the entanglement such that an appreciable fidelity is achieved. In general, we have considered systems with helical spin order and identified the system parameters required for high-fidelity teleportation. Moreover, using a Floquet map, we have studied the system dynamics numerically in the presence of kicked electric field which has been found to increase the teleportation fidelity if an
appropriate set of parameters is chosen. Additionally, we have considered the effect of impurities and uniform environment on the teleportation fidelity.

The paper is organized in the following manner: At first, we discuss the spin chain system with helical multiferroic Hamiltonian and its characteristics, particularly the various interaction terms. We also present the unique kicking scheme that we would use throughout the manuscript. Afterward, we discuss the quantum teleportation protocol highlighting the role of the entanglement as a resource and addressing the question of how does the quality of teleportation depend on this resource. The formula for teleportation fidelity—a measure that quantifies the quality of teleportation is derived for our specific protocol and also in the setting of an environment which causes decoherence. In the next section, we discuss the numerical results with kicked electric field to demonstrate that a higher fidelity can be achieved using this scheme. In this respect, we also study the cases with specific types of impurities as earmarked in [35] and a specific type of environment which causes decoherence in the system [24,43,44]. Moreover, we compare the results obtained to that of XX and XXZ models found in previous studies as well as when subject to our entanglement sharing protocol.

2 Models

We study a one-dimensional multiferroic chain (along the $x$-axis) of localized spins $S_i$ modeled by a $J_1$–$J_2$ Hamiltonian and also including the interaction energy of an external electric field $E$ coupled to the spin-driven electric polarization of the chain. The Hamiltonian of this chain is given by:

$$
\mathcal{H} = -J_1 \sum_i S_i S_{i+1} - J_2 \sum_i S_i S_{i+2} + E(t)g_{\text{ME}} \sum_i (S_i \times S_{i+1})^z.
$$

(1)

The first two terms stand for the Heisenberg-type exchange interactions of the spin $S_i$ with nearest ($S_{i+1}$) and next nearest neighbors ($S_{i+2}$) with different coupling constants, i.e., $J_1$ and $J_2$ respectively. Taking $J_1 > 0$, i.e., ferromagnetic nearest neighbor interaction and $J_2 < 0$, i.e., anti-ferromagnetic next nearest interaction leads to frustration and helical spin order. The third term is the coupling (with a magnetoelectric coupling constant $g_{\text{ME}}$) of an electric field $E$ applied along the $y$ direction to the spin-driven ferroelectric polarization. We note that the ferroelectric polarization of one-dimensional chiral multiferroic chains can be easily controlled and switched in an experiment [45].

As seen from Eq. 1, helical multiferroic systems possess two coupled order parameters: magnetization and ferroelectric polarization. The latter can be acted upon by an external field and hence, the spin dynamics can be steered by means of an electric field. The key element in this regard is the $z$ component of the vector chirality $(S_i \times S_{i+1})^z$. We study the following cases: (1) a static electric field ($E = E_0$), and (2) apart from $E_0$ we apply a train of kicks with a period $\tau$ and amplitude $E_1$ along $y$-direction. The underlying assumption in the second case is that the duration of one pulse in the train is much shorter than the intrinsic timescale of the system (set by $J_1$, $J_2$, $g_{\text{ME}}$ and is typically in the picosecond time range) and thus, our pulse train has a structure shown
in Fig. 1a. Such a train of electric filed can be achieved in effect by highly asymmetric single-cycle THz electric pulses having an appropriate profile providing for a sharp pulse for a short time and a static-dc electric field at later times [30,46]. Henceforth, all occurrences of time would be considered in the units of $1/J_1$.

Under the kicked field, the Hamiltonian can be split into static and dynamic parts as follows:

$$\mathcal{H} = \mathcal{H}_0 + \mathcal{H}_1(t),$$

$$\mathcal{H}_0 = -J_1 \sum_{i=1}^{N-1} S_i.S_{i+1} - J_2 \sum_{i=1}^{N-2} S_i.S_{i+2} + E_0 \sum_{i=1}^{N-1} (S_i \times S_{i+1})^z, \quad (2)$$

$$\mathcal{H}_1 = E_1 \sum_{n=1}^{n_{\text{max}}} \delta(t - n\tau) \sum_{i=1}^{N-1} (S_i \times S_{i+1})^z. \quad (3)$$

Here, $N$ is the number of sites in the chain considered, $n$ indexes the kicks, $n_{\text{max}}$ is the number of kicks, $E_0 = g M E\mathcal{E}_0$, and $E_1 = g M E\mathcal{E}_1$. The open boundary condition of the spin chain is apparent from the range of index $i$ for the different terms of the Hamiltonian. Starting at $t = 0$ from an initial state, say $|\psi(t = 0)\rangle$ the time evolution operators:

$$\hat{U}_0 = \exp \left( i J_1 \tau \sum_{i=1}^{N-1} S_i.S_{i+1} + i J_2 \tau \sum_{i=1}^{N-2} S_i.S_{i+2} - i E_0 \tau \sum_{i=1}^{N-1} (S_i \times S_{i+1})^z \right).$$
\[ \hat{U}_1 = \exp \left( -i E_1 \sum_{i=1}^{N-1} (S_i \times S_{i+1})^z \right), \]  
\[ (4) \]

 deliver the state just after the \( r^{th} \) kick (or at time \( t = r\tau \)) as

\[ |\psi(t = r\tau)\rangle = (\hat{U}_1 \hat{U}_0)^r |\psi(t = 0)\rangle. \]
\[ (5) \]

In comparison with the multiferroic Hamiltonian given in Eq. 1, the Hamiltonian of XXZ model has the following generic form:

\[ H = J_x \sum_{i=1}^{N-1} \left( \hat{S}_i^x \hat{S}_{i+1}^x + \hat{S}_i^y \hat{S}_{i+1}^y + 1 \right) + J_z \sum_{i=1}^{N-1} \hat{S}_i^z \hat{S}_{i+1}^z, \]
\[ (6) \]

where \( J_x \) and \( J_z \) are the nearest neighbor exchange interactions. The Hamiltonian in Eq. 6 reduces to that of the XX model when \( J_z = 0 \).

We subscribe to the impurity models discussed in Ref. [35] and borrow the effects of specific impurities considered therein as well as the terminology. Figure 1c demonstrates the effects of Type I and Type II impurities set amidst a spin chain. For both the types of impurities, an assumption is made—the nearest and next nearest neighbor interactions involving the impurity do not change. Also, the magnetoelectric coupling is assumed to remain the same. The effects of impurity are confined to 3 sites near the impurity as shown in Fig. 1c. The impurities cause elongation and contraction of various “bonds” resulting in corresponding changes in the interaction strengths \( J_1 \) and \( J_2 \). The term \( J_{22}/J_2 \) considered in all of the figures concerning the effect of impurities is indicative of the impurity strength and refers to a particular bond near the embedded impurity which can be ascertained from Fig. 1c. For the case of Type I impurity, increment in \( J_{22} \) also causes similar increment in \( J_{11} \) and decrement in \( J_{222} \). Similarly, in case of Type II, increment in \( J_{22} \) happens simultaneously with decrement in \( J_{111} \) and \( J_{222} \). We have assumed that the factor of increment of \( J_{22} \) in all the cases is the same as that of the factor of change in \( J_{11} \), \( J_{222} \) and \( J_{111} \).

### 3 Quantum teleportation fidelity

Quantum teleportation is a well-known protocol for transferring quantum information between two parties [1], which can be accomplished by using an entangled pair of qubits, a quantum channel and two bits of classical information sent via a classical channel. This teleportation scheme is generally referred to as standard teleportation scheme (STS). One of the key steps involved in quantum teleportation of a single qubit is the sharing of one qubit each of an entangled pair of qubits, preferably a Bell-pair, between the sender and the receiver. The quality of teleportation is quantified by the fidelity between the intended qubit and the qubit received. This fidelity is dependent on the singlet fraction which is defined in [47,48] as follows:

\[ f = \langle \Omega^{00} | \chi | \Omega^{00} \rangle, \]
\[ (7) \]
where $\chi$ denotes the state of the qubits carrying entanglement (here, the end qubits—$r_1, r_2$ in Fig. 1b) and $|\Omega^{00}\rangle = \frac{|00\rangle + |11\rangle}{\sqrt{2}}$ is a Bell pair. In principle, the maximum singlet fraction can be obtained by considering all the possible Bell pairs in the above equation rather than just $|\Omega^{00}\rangle$. The fidelity of teleportation, as discussed above, has been found to be related to singlet fraction in the following way [47,48]:

$$F = \frac{2f + 1}{3}. \quad (8)$$

In our protocol, we assume that initially, a Bell pair ($|\Omega^{00}\rangle$) is generated and encoded at the middle of the spin chain. This can be achieved, in principle by using local gates—particularly Hadamard and CNOT gates in succession on the middle qubits (shown in Fig. 2).

Through the natural dynamics of the spin chain, it is to be expected that significant entanglement will be available at the ends of the spin chain with the sender and receiver at a later time, which they could utilize in teleportation. This proposition is motivated by the prospect of a commercial arrangement wherein the “service provider” has a mechanism to provide entanglement (or ideally one ebit of entanglement) to each party, thus, controlling the quantum teleportation and hence, being able to commercialize its “service”. Various other systems such as XX spin chains and anti-ferromagnetic spin chains [9,19,49] have been shown to be effective for the task of availing entanglement preceding teleportation. However, the mechanisms used to generate and distribute entanglement in the aforementioned references are different than our case. For example, in [9] a dimerized chain is used which possesses ground states having singlet pairs on alternate pairs of sites. By changing a set of parameters, the ground state of the system is made to possess singlet pairs with a ‘global’ singlet between first and the last sites. Noisy quantum channels have also been studied in this regard and have been shown to be effective [36].

Let us consider the case with an even number of sites in a spin chain. We label the chain sites starting from the left as 1, 2, ..., $N/2$, $N/2 + 1, \ldots, N - 1, N$. We assume that the chain is initially prepared in all spin up state, i.e., $|00\ldots00\rangle$ and a Bell pair is generated and encoded at sites $N/2$ and $N/2 + 1$ (see Fig. 1). This initial state can be constructed by applying a Hadamard gate on the $N/2$ site followed by a CNOT gate with $N/2$ site as controlled site and $N/2 + 1$ site as target site (see Fig. 2). In experiment, this can be constructed by applying a strong constant magnetic field to align all spins in up direction, and followed by applying rf field $\pi$ pulse to rotate the target spin at $N/2 + 1$ site to generate a Bell state $|\Omega^{00}\rangle$ in the middle [50]. At $t > 0$, we switch off the strong constant magnetic field and let the spins evolve through their internal dynamics. The state of the system at $t = 0$ can be written as follows:

$$|\psi(t = 0)\rangle = |0\ldots0\rangle \otimes |\Omega^{00}\rangle \otimes |0\ldots0\rangle = \frac{|0\ldots0\rangle + |N/2, N/2 + 1\rangle}{\sqrt{2}}, \quad (9)$$

where $|N/2, N/2 + 1\rangle$ refers to spin flipped state from $|0\rangle$ to $|1\rangle$ at sites $N/2$ and $N/2 + 1$. Note that the Hamiltonian in Eq. 1 commutes with the total magnetization, i.e., $[M, H] = 0$. The total magnetization is given through the total $Z$ component.
Local gate operations with Hadamard and CNOT gates

*Fig. 2* The process of using local gates in the middle of the initialized spin chain to prepare a Bell pair which then propagates

of spins at all sites which is $M = \sum_{i=1}^{N} \hat{S}^z_i$. Therefore, the time evolution of such a system does not mix the different spin (magnetization) sectors. Hence, after time evolving $|\psi(t = 0)\rangle$ we obtain:

$$|\psi(t)\rangle = e^{-iHt/\hbar} |\psi(0)\rangle = \frac{G|0\rangle + G|N/2, N/2 + 1\rangle}{\sqrt{2}},$$  \hspace{1cm} (10)

where $G \equiv \exp\left(-iHt/\hbar\right)$ is the time evolution operator. Because of the commutation of $M$ with $H$, we know that

$$G|0\rangle \rightarrow e^{-iE^0t}|0\rangle, \hspace{1cm} G|N/2, N/2 + 1\rangle \rightarrow |j, j'\rangle,$$  \hspace{1cm} (11)

where $|j, j'\rangle$ refers to a general spin flipped state from $|0, 0\rangle$ at sites $j$ and $j'$ only, meaning a general state with 2 spins down and other spins up, and $E^0$ is the eigenenergy of the state $|0\rangle$ with respect to the Hamiltonian $H_0$ (Eq. 1). Therefore, the time evolved state can be expressed as:

$$|\psi(t)\rangle = \frac{e^{-iE^0t}|0\rangle}{\sqrt{2}} + \frac{1}{\sqrt{2}} \sum_{j} \sum_{j'} \langle j, j'|G|N/2, N/2 + 1\rangle |j, j'\rangle.$$  \hspace{1cm} (12)

It is noteworthy that the extra phase in the $|0\rangle$ state will be the same irrespective of the kicked or unkicked time evolution used, once the spin chain parameters are fixed.
Fig. 3 a Partial trace to obtain the density matrix of the edge qubits (ρ̂_{out}) results in the following possibilities: (A) type 1: Partial trace yields \( |11\rangle \) – a single possible case. (B) type 2: \( |10\rangle \) resulting from a partial trace. N-2 cases of such type are possible. (C) type 3: partial trace gives \( |01\rangle \). N-2 cases of such a type possible (D) type 4: \( |00\rangle \) obtained after partial trace. \( N-2 \) \( C_2 \) cases which adds up to \( N \) \( C_2 \) as expected. 

b S denotes the main system consisting of a helical spin chain that interacts with the environment \( \Xi \). Note that the number of spins in the environment is more than that in the main system. The coupling \( g_k \) determines the magnitude of interaction between the system and the environment. We Consider a uniform environment with the same coupling constant at various sites of the environment. The Hamiltonian of the main system is \( H_F \), that of the system interacting with environment is \( H_\Xi \) and of the complete system is \( H_{\text{total}} \).

The corresponding output density matrix, i.e., for the receiver qubits at both the ends is obtained by tracing over all other qubits and is given as follows:

\[
\rho_{\text{out}} = \text{Tr}_{2,3,\ldots,N-2,N-1}[\rho(t)] \\
= \frac{1}{2} |00\rangle\langle 00| + \frac{1}{2} \sum_{j,j'} \langle j,j' | G | N/2, N/2 + 1 \rangle^2 |00\rangle\langle 00| \\
+ \frac{1}{2} \sum_{j,j'} \langle j,j' | G | N/2, N/2 + 1 \rangle^2 |01\rangle\langle 01| \\
+ \frac{1}{2} \sum_{j,j'} \langle j,j' | G | N/2, N/2 + 1 \rangle^2 |10\rangle\langle 10| \\
+ \frac{1}{2} |\{1, N | G | N/2, N/2 + 1 \}^2 |11\rangle\langle 11| \\
+ \frac{1}{2} e^{-iE_0 t} \langle 1, N | G | N/2, N/2 + 1 \rangle^* |00\rangle\langle 11| \\
+ \frac{1}{2} e^{iE_0 t} \langle 1, N | G | N/2, N/2 + 1 \rangle |00\rangle\langle 11|,
\]

where type 2 refers to all possible spin chains with the first qubit definitely as \( |1\rangle \) and any one of other qubits except for the last as \( |1\rangle \) which has N-2 possibilities in total and would yield \( |10\rangle \) after partial tracing. Type 3 refers to all possible chains with the last qubit definitely \( |1\rangle \) and anyone of the other qubits except for the first as \( |1\rangle \) which has N-2 possibilities in total and yields \( |01\rangle \) after partial tracing. Type 4 refers to all possible spin chains with neither of first or last qubits (\( r_1 \) and \( r_2 \)) as \( |1\rangle \) but any two of other qubits as \( |1\rangle \) which has a total of \( N-2 \) \( C_2 \) possibilities yielding \( |00\rangle \) on partial tracing. Figure 3a gives a pictorial representation of all cases and indicates the number of possibilities.
Finally, for $|\psi_{in}\rangle = |\Omega^{00}\rangle$, the singlet fraction (f) is given as:

$$f = \langle \psi_{in}|\rho_{out}|\psi_{in}\rangle$$

$$= \frac{1}{4} + \frac{1}{4} \sum_{j,j'} |\langle j, j'|G|N/2, N/2 + 1\rangle|^2 + \frac{1}{4} |\langle 1, N|G|N/2, N/2 + 1\rangle|^2$$

$$+ \frac{1}{2} Re\left[ e^{iE_0 t} \langle 1, N|G|N/2, N/2 + 1\rangle \right].$$ (14)

4 Singlet fraction with uniform spin environment

We will now introduce a realistic setting where a uniform spin environment acts on the multiferroic spin chain system, thereby altering its dynamics. Here we are considering a uniform spin environment which is formed by a spin chain of length $P$ (having $P$ sites) [24,43,44].

We can consider the spin chain is placed on the substrate of a long one dimensional spin chain of $P$ spins. In this arrangement, it is easy to visualize the coupling of our chain with the quantum substrate (see Fig. 3b). Denoting the Hamiltonian of the main system by $H_F$, the part of Hamiltonian for the coupling between the environment and the main system is

$$H_{\Xi} = 2 \sum_{i=1}^{N} \hat{S}_i^z \otimes \sum_{k=1}^{P} g_k \hat{S}_k^z.$$ (15)

This whole system, including the main system and the environment is represented in Fig. 3b. The Hamiltonian of the complete system is given by

$$H_{total} = H_F + H_{\Xi}.$$ (16)

Here, we have assumed that the environment is not self-interacting. This model of the environment and the particular model of interaction with the main system has been studied before in the case of a general quantum information transfer channel [44]. The noise is based on a “central spin interaction” model introduced in [43]. Owing to its adoption in the analysis of other schemes concerning quantum information transfer protocols, and the fact that its effect in our entanglement sharing scheme can be analytically calculated is one of the reasons that we considered this particular model. Moreover, the physical basis of the environment model is rooted in the decoherence noise experienced by spin chains and/or many body physical platforms, viz. coupled quantum dots, under experimental conditions.

For the derivation of singlet fraction in a system where the middle two spins are substituted by a Bell pair and the system interacts with the environment as given by Eq. 15, we assume that the environment is initially in the state $|\psi_{\Xi}(0)\rangle = \sum_{m=0}^{2P-1} c_m |m\rangle$. Here, $|m\rangle$ represents the spin basis of an environment consisting of $P$ sites. Therefore, in this
case, the output density matrix is given as

$$\rho_{\text{out}} = \text{Tr}_{2,3,\ldots,N-2,N-1} \left[ \text{Tr}_\Xi (\rho(t)) \right],$$  \hspace{1cm} (17)

where $\rho(t)$ is the density matrix of the complete system at a general time $t$. It has been assumed that initially, the system and the environment are in a non-entangled state. So, following the steps in the previous derivation, we have, at time $t = 0$,

$$|\psi_{\text{total}}(0)\rangle = |\psi_S(0)\rangle \otimes |\psi_\Xi (0)\rangle = \left[ |0\rangle + |N/2, N/2 + 1\rangle \right] \otimes \sum_{m=0}^{2^p-1} c_m |m\rangle, \hspace{1cm} (18)$$

where $|\psi_{\text{total}}\rangle$ represents the state of the full system consisting of the main system (with its state represented by $|\psi_S\rangle$) and the environment (with its state represented by $|\psi_\Xi \rangle$). Therefore, at a later time $t$,

$$|\psi_{\text{total}}(t)\rangle = \frac{G|0\rangle}{\sqrt{2}} |\epsilon_0(t)\rangle + \sum_j \sum_{j'} \langle j,j'|G|N/2, N/2 + 1\rangle |j,j'\rangle |\epsilon_{j,j'}(t)\rangle, \hspace{1cm} (19)$$

where $G$ is the time evolution operator of the main system which has been previously indicated in Eq. 11. Also, $|\epsilon_0(t)\rangle$ and $|\epsilon_{j,j'}(t)\rangle$ are defined below.

$$|\epsilon_0(t)\rangle = \sum_{m=0}^{2^p-1} c_m e^{-iN t B_m} |m\rangle, \hspace{1cm} |\epsilon_{j,j'}(t)\rangle = \sum_{m=0}^{2^p-1} c_m e^{-i(N-2) t B_m} |m\rangle, \hspace{1cm} (20)$$

which have been calculated using the action of $H_\Sigma$ on $|\psi_\Xi (t)\rangle$. This depends specifically on the state of the environment. For the environment in an eigenstate $|m\rangle = |m_1, m_2, \ldots, m_P\rangle, \sum_{k=1}^P g_k \sigma_k^z |m\rangle$ gives $B_m$ as follows:

$$B_m = \sum_{k=1}^P \frac{1}{2} (-1)^{m_k} g_k. \hspace{1cm} (21)$$

The density matrix of the system obtained after tracing over the environment is as follows:

$$\text{Tr}_\Xi [\rho(t)] = \frac{1}{2} e^{-iE_0 t} |00\rangle \langle 00| + \frac{1}{2} \sum_j \sum_{j'} |\langle j,j'|G|N/2, N/2 + 1\rangle|^2 |j,j'\rangle \langle j,j'| \hspace{1cm}$$

$$+ \frac{1}{2} e^{-iE_0 t} \sum_j \sum_{j'} |\langle j,j'|G|N/2, N/2 + 1\rangle| |j,j'\rangle r^*(t) \hspace{1cm}$$

$$+ \frac{1}{2} e^{iE_0 t} \sum_j \sum_{j'} |\langle j,j'|G|N/2, N/2 + 1\rangle| |j,j'\rangle \langle 0|r(t), \hspace{1cm} (22)$$
where
\[ r(t) = \langle \epsilon_0(t) | \epsilon_j, j'(t) \rangle = \sum_{m=0}^{2^P-1} |c_m|^2 e^{-i(N-2)t} B_m e^{iNt} B_m = \sum_{m=0}^{2^P-1} |c_m|^2 e^{2it} B_m. \] (23)

Finally, the output density matrix is obtained below.

\[ \rho_{\text{out}} = \text{Tr}_{2,3,...,N-2,N-1} \left[ \text{Tr}_2 \mathbb{E} \left[ \rho(t) \right] \right] = \frac{1}{2} |00\rangle\langle 00| + \frac{1}{2} \sum_{j,j'} \langle (j, j') | G | N/2, N/2 + 1 \rangle^2 |00\rangle\langle 00| + \frac{1}{4} |01\rangle\langle 01| + \frac{1}{4} |10\rangle\langle 10| + \frac{1}{2} e^{-iE_0t} \langle 1, N | G | N/2, N/2 + 1 \rangle^* |00\rangle\langle 11| - \text{Re} \left[ e^{iE_0t} \langle 1, N | G | N/2, N/2 + 1 \rangle r(t) \right]. \] (24)

Therefore, we obtain the singlet fraction as follows:

\[ f = \langle \psi_{\text{in}} | \rho_{\text{out}} | \psi_{\text{in}} \rangle = \frac{1}{4} + \frac{1}{4} \sum_{j,j'} \langle (j, j') | G | N/2, N/2 + 1 \rangle^2 + \frac{1}{4} |\langle 1, N | G | N/2, N/2 + 1 \rangle|^2 + \frac{1}{2} \text{Re} \left[ e^{iE_0t} \langle 1, N | G | N/2, N/2 + 1 \rangle r(t) \right]. \] (25)

We shall consider a specific case wherein the environment is in an all spin up state, i.e., \(|0\ldots0\rangle\). We also assume that the coupling constant \(g_k\) is, in fact, the same for all environment sites referred by index \(k\). We can now evaluate \(r(t)\) with \(c_0 = 1\) and \(B_m = \frac{Bg}{2}\) where \(g\) is the uniform coupling constant considered. Therefore, \(r(t) = e^{Pitg}\) can be used in Eq. 25 to obtain the corresponding singlet fraction.

### 5 Numerical results for kicked and un kicked multiferroic chains

Using the protocol for sharing entanglement as outlined in the previous sections, we proceed to calculate the singlet fraction offered by the helical multiferroics and, therefore, classify them as whether they are suitable for the purpose of being used...
in teleportation. We also probe the gain in singlet fraction offered by the kicking scheme. As expected from Eq. 8, teleportation fidelity would follow the same trend as the singlet fraction.

We study the temporal characteristics of singlet fraction for a LiCu$_2$O$_2$ spin chain for which, $J_2/J_1 \approx -1$. This has been shown for kicked and un kicked chains in Fig. 4a with different kick intervals $\Delta \tau$. In Fig. 4b, we have shown the effect of environment on the temporal variation of singlet fraction for an un kicked chain. As expected from Eq. 25, the environment is seen to cause oscillations in the singlet fraction which increase in frequency as the coupling constant between the environment and the chain is increased. Counterintuitively, these oscillations due to the environment may also lead to higher singlet fraction than the case without the environment, especially in the case when the coupling $-g$ is high. As we note from Fig. 4a, the kicked electric field offers enhanced singlet fraction in certain instances. Next, we have analyzed the temporal behavior of singlet fraction in the presence of a kicked field and a uniform environment in Fig. 5. As before, certain instances show an increase in the singlet fraction. However, this may not be enough to mitigate the environmental effects at all the instances as seen from Fig. 5a–c which show this interplay for various values of the coupling $-g$. The high oscillatory behavior in the singlet fraction which is introduced by a strong coupling with the environment is evident from Fig. 5c.

Next, for the case of kicked chains, we have found the maximum singlet fraction ($f_{\text{max}}$) subject to varied number of kicks (i.e. the time of evolution) albeit bounded by the maximum time $t_{\text{max}} = 1000$ and for the un kicked chains subject to varied time of evolution (also bounded by the maximum time $t_{\text{max}} = 1000$). We have taken the difference between the maximum singlet fraction for kicked and un kicked cases, i.e., $\Delta f_{\text{max}} = f_{\text{max}}^{\text{kicked}} - f_{\text{max}}^{\text{un kicked}}$ and shown its variation with the time interval between the kicks ($\Delta \tau$) and the amplitude of kicked electric field ($E_1$) in Fig. 7. These parameters, along with the number of kicks required for $f_{\text{max}}$ are expected to be in our control through the duration, frequency and shape of applied electric field [46] and, hence, can be optimized to ensure high fidelity. Fig. 7 demonstrates that kicked electric field

![Fig. 4](image)

**Fig. 4** a Singlet fraction ($f$) vs time for the un kicked case is given by the blue plot and that with kicks is given by orange ($\tau = 0.05$) and green ($\tau = 0.1$) colored plots. There is a visible change in teleportation fidelity when we resort to the kicking scheme. For most of the time, $f$ is seen to decrease but we also see increased $f$ at a few instances of time. b Singlet fraction vs time for un kicked chains with varying degree of coupling with the environment ($g$). As the coupling constant is increased, the environment causes rapid oscillations in the singlet fraction as is evident from the graphs as well as Eq. 25. All cases have been considered with chain length, $N = 16$, environment chain length (in b only), $P = 20$, $E_0 = 0.01$, $E_1 = E_0/0.1 = 0.1$, $J_1 = 1$, $J_2 = -1$.
Quantum teleportation by utilizing helical spin chains…

Fig. 5  Singlet fraction vs time for kicked chains with varying degree of coupling with the environment in a–c compared with the unkicked case. There are few instances of increase in $f$ due to kicking, but such instances are mitigated by the rapid oscillations caused by the environment in the strong coupling regime i.e. high $g$. However, a higher singlet fraction can still be obtained at some instances as shown in all cases. All cases have been considered with chain length, $N = 16$, the number of environment sites $P = 20$, $E_0 = 0.01$, $E_1 = E_0/0.1 = 0.1$, $J_1 = 1$, $J_2 = -1$

Fig. 6  $f_{\text{max}}$ which indicates that the singlet fraction is maximized over the number of kicks as a function of $\tau$ and $E_1$. $E_0 = 0.01$, $J_1 = 1$, $J_2 = -1$ in all the cases. All values above 0.5 affirm the suitability of spin chain for entanglement sharing. For a $N = 10$ and b $N = 16$, the maximum value of singlet fraction 0.7552 and 0.6922, respectively, are achieved when maximized over $E_1$ and $\tau$

Fig. 7  Change in singlet fraction ($\Delta f_{\text{max}}$) obtained due to kicking for various chain lengths. The increase in singlet fraction is more significant for smaller chain (a) than longer chain (b). $E_0 = 0.01$, $J_1 = 1$, $J_2 = -1$ in all the cases
Fig. 8 Maximum singlet fraction $f_{\text{max}}$ obtained for kicked chains maximized over the number of kicks and also the kick interval vs. the strength of the kicking electric field $E_1$ for various chain lengths and for various strengths of coupling between chain and environment ($g$) for fixed $N = 16$, $P = 20$. The corresponding change in maximum singlet fraction $\Delta f_{\text{max}}$, for various chain lengths and for various strengths of coupling between chain and environment ($g$) for fixed $N = 16$, $P = 20$. In all the cases, $E_0 = 0.01$, $J_1 = 1$, $J_2 = -1$ can be used to increase the singlet fraction. We observe that for $N = 10$, $\Delta f_{\text{max}}$ increases more than that for $N = 16$, especially at higher values of $E_1$, which is apparent from the color bars of the plots (A) and (B). Also, higher values of $\Delta f_{\text{max}}$ are reached more often for $N = 10$ than $N = 16$, due to the smaller length of the chain. For $N = 16$, the maximum gain in singlet fraction due to kicking is $\sim 0.1$ which translates to a gain of $\sim 0.067$ in the teleportation fidelity. This is a $\sim 10\%$ increase for the fidelity in the range of $\sim 0.6$. 

Next, we introduce a new notation: $f_{\text{max}}^{\text{xxx}}$ for the maximum singlet fraction obtained after maximizing over the kick interval ($\tau$) as well. In this way, we ascertain the role of kicked electric field strength ($E_1$) on $f_{\text{max}}$ and $\Delta f_{\text{max}}$ in Fig. 8a, b respectively albeit without any effect of the environment, i.e., for $g = 0$, and for varied lengths of the chain. We note that even the presence of small $E_1$ leads to a sharp increase in $\Delta f_{\text{max}}$ maximized over $\tau$. This behavior is seen for all the chain lengths considered and is more for the shorter chain lengths. As seen from Fig. 8c, d, even for different couplings between the environment and the spin chain (specifically shown for $N = 16$), the electric field causes an increase in $\Delta f_{\text{max}}$ maximized over $\tau$ ($\equiv \Delta f_{\text{max}}^{\text{xxx}}$). This establishes that even in the presence of such an environment, the electric field can increase the singlet fraction and hence, the fidelity of teleportation. It is also noteworthy that the environment does not lead to a significant change in $\Delta f_{\text{max}}^{\text{xxx}}$ as illustrated in Fig. 8c, d which is intuitive because it leads to rapid oscillations (as seen from Fig. 4) in the singlet fraction which more or less envelope trend without the environment. This translates into minimal increase/decrease when other parameters are optimized.

It is important to note here that we have only considered small lengths of spin chains due to exact diagonalization constraints. For such small chain lengths, in Fig. 8a, we see that $f_{\text{max}}$ decreases with the chain length which indicates that the entanglement
6 Comparison with XX and XXZ models

For the sake of completeness, we now compare the previous studies with our own, specifically the teleportation fidelities obtained in various other cases like [9–11,19]. In [9], a dimerized frustrated model has been considered which exhibits a near perfect transfer using a perfect singlet pair at the ends with end to end concurrence = 1. Evidently, this has been achieved while optimizing the system parameters. In [11], again perfect transfer has been shown to be possible by optimizing various parameters in a class of XX models. In [10], the system considered is antiferromagnetic Heisenberg chain with different couplings at the ends which has been shown to exhibit good teleportation fidelity at different finite temperatures. On a comparative scale, though our system fares a little poorer than the aforementioned instances, our model with some connections to a real material has an advantage of being susceptible to an external electric field, which we have shown to be useful for enhancing the teleportation fidelity.

In any case, it is instructive to study and compare various models for entanglement sharing using our protocol—meaning by introducing a Bell pair at the middle of spin chain and expecting the system dynamics to avail appreciable entanglement at the receiver sites (i.e., the ends of the spin chain).

Figure 9 shows that the XXZ model with $N = 10$ exhibits a singlet fraction (maximized over time of evolution which is bounded by $t_{\text{max}} = 1000$) $f_{\text{max}}$ vs $J_z/J_x$ in a class of XXZ models. The maximum singlet fraction obtained in the case of helical multiferroics after optimizing over the number of kicks, $\tau$ and $E_1 \in (0, 5]$ and bounded by $t_{\text{max}} = 1000$–$f_{\text{maxxx}}$ has also been shown. All cases have been considered with chain length $N = 10$. XXZ model has been considered for $J_x = 1$ in all cases. Helical multiferroics have been considered with $E_0 = 0.01$, $J_1 = 1$, $J_2 = -1$ in all the cases sharing scheme may not be very effective for larger $N$ as the singlet fraction would hover about 0.5.

Figure 9 Singlet fraction (optimized over time of evolution bounded by $t_{\text{max}} = 1000$) $f_{\text{max}}$ vs $J_z/J_x$ in a class of XXZ models. The maximum singlet fraction obtained in the case of helical multiferroics after optimizing over the number of kicks, $\tau$ and $E_1 \in (0, 5]$ and bounded by $t_{\text{max}} = 1000$–$f_{\text{maxxx}}$ has also been shown. All cases have been considered with chain length $N = 10$. XXZ model has been considered for $J_x = 1$ in all cases. Helical multiferroics have been considered with $E_0 = 0.01$, $J_1 = 1$, $J_2 = -1$ in all the cases.
and also the kicked electric field \( E_1 \in (0, 5] \) of the same length \( N = 10 \) to that of XX, XXZ model, we find that if we select an optimum value of the kicked electric field \( E_1 \), \( \text{LiCu}_2\text{O}_2 \) fares slightly better than both XX and XXZ chains, driven by an increase in the singlet fraction due to kicking.

### 7 Effect of impurities

We now move on to ascertain the effect of the introduction of a specific impurities (defined as Type I in Fig. 1c) on the singlet fraction. We resort to \( \text{LiCu}_2\text{O}_2 \) as the base system with \( J_2/J_1 = -1 \) and change the values of exchange interaction strength \( J_{22}/J_2 \) which is representative of the increasing impurity strength in our case. As per the model considered, starting from \( J_{11}/J_1 = J_{22}/J_2 = J_{222}/J_2 = 1 \), these exchange interaction strengths are tweaked in line with increment in the compression and hence, with the increasing strength of impurity. There are two impurities which are placed in both arms of the spin chain if taken from the middle of the chain at the sites 4 and 13. We first resort to Type I impurities and see the effect of their introduction in Fig. 10a where the maximum singlet fraction \( f_{\text{maxxx}} \) is shown (maximized over number of kicks, time interval between the kicks \( \tau \), bounded by \( t_{\text{max}} = 1000 \)) and the kick strength \( E_1 \in (0, 5] \). In the unkicked case, the optimization is just over the time of evolution which is also bounded by \( t_{\text{max}} = 1000 \). Clearly, the effect of the introduction of impurities can be seen as the impurity strength (represented by \( J_{22}/J_2 \)) is increased. The increase in strength of impurity leads to a considerable fall in the singlet fraction. However, the effect is much suppressed by the introduction of the kicking scheme. Even the chains characterized by high impurity strength which exhibited decreased singlet fraction now assume much higher values and the effect of impurity is largely mitigated at all impurity strengths. For the case of Type I impurities, highest singlet fraction is obtained for \( J_{22}/J_2 = 1.4 \) which is \( f_{\text{maxxx}} = 0.6953 \). The corresponding teleportation fidelity is \( f_{\text{maxxx}} = 0.7969 \). The other associated impurity parameters...
for this particular spin chain offering the highest singlet fraction are $J_{11}/J_2 = 1.4$ and $J_{222}/J_2 = 0.7143$ ($\equiv 1/1.4$).

Similarly, we have also considered a case with two Type II impurities (Fig. 1c) embedded within the arms if taken from the middle of the spin chain at the sites 4 and 13. The base system remains the same, i.e., $LiCu_2O_2$ and an increasing value of $J_{22}/J_2$ indicates a higher strength of impurity. As before, the other bond parameters relevant to the introduction of impurity i.e. $J_{111}$ and $J_{222}$ also change in proportion to the change in $J_{22}$. In Fig. 10b, we have considered the maximum singlet fraction obtainable without the kicks and compared it with the kicked case. As before, in the kicked case, we have considered the maximum singlet fraction ($f_{\text{maxxx}}$) obtained by varied electric field strength $E_1 \in (0, 5]$, number of kicks (bounded by $t_{\text{max}} = 1000$), and time interval between the kicks ($\tau$). In the un kicked case, as before, the optimization is over the time of evolution which is also bounded by $t_{\text{max}} = 1000$. From Fig. 10b, we see that the introduction of such impurities does not lead to considerable change in the singlet fraction as the impurity strength is increased which is in sharp contrast to the introduction of Type I impurities (apparent from Fig. 10a). However, the kicking scheme still leads to the mitigation of the impurity affects and also an appreciable increase in the singlet fraction and, hence, the teleportation fidelity. The highest singlet fraction of $f_{\text{maxxx}} = 0.6812$ is obtained for $J_{22}/J_2 = 1.9$ for the kicked case. This translates to a teleportation fidelity of $f_{\text{maxxx}} = 0.7875$. The other parameters associated with this impurity embedded system are $J_{111}/J_2 = 0.5263$ ($\equiv 1/1.9$) and $J_{222}/J_2 = 0.5263$ ($\equiv 1/1.9$).

8 Conclusions

The teleportation of quantum information is preceded by the distribution of entanglement between the parties involved. Teleportation fidelity quantifies the amount of shared entanglement available between the two distant parties. In this manuscript, we explored the usage of an experimentally realizable helical multiferroic chain as an entanglement sharing channel. First, we calculated an expression for teleportation fidelity assuming a protocol where a Bell state ($|\Omega^{(0)}\rangle$) is prepared and introduced at the center of a spin chain and entanglement at the end of chains is expected to be utilized in quantum teleportation. We have discovered the effectiveness of helical spin chains to be utilized in quantum teleportation by analyzing the teleportation fidelity. By resorting to a novel kicking scheme proposed in the manuscript, higher singlet fraction and teleportation fidelity may be obtained as shown in Figs. 8, 6. Most of the cases that we have studied already exhibited singlet fraction over 0.5 which translates to a teleportation fidelity of over 0.66. However, with kicking, we have seen significant improvement over these values. This effect can be seen from Fig. 7 where the maximum singlet fraction subject to optimal number of kicks and time interval has been plotted against the magnitude of kicked electric field ($E_1$). There is noticeable but irregular increase in the maximum singlet fraction obtainable.

We have also studied the effect of a common spin environment to the multiferroic spin chain. This common spin environment (non self-interacting) is realized by placing the spin chain on the substrate of a longer one-dimensional spin system with noninter-
acting spins. The uniform environment setting has been considered for derivation of the singlet fraction. Specifically, we have also probed strong and weak cases of coupling of the environment with the main system by changing the coupling constant $g$, though keeping it uniform at all the sites of the chain for simplicity. Surprisingly, our studies have shown that such a common spin environment can increase or decrease the maximal fidelity obtainable using a particular spin chain. This effect can be attributed to the oscillations caused by such an environment (Figs. 4b, 5). This phenomenon is totally governed by Eq. 25 though with added flexibility in the range of optimum kick interval $\tau$ and/or number of kicks. The interplay of all these factors may lead to a subtle increase/decrease in maximum teleportation fidelities which is hard to predict. Moreover, the previous works in this direction have also indicated counterintuitive trends [37,38,40,42]. While using the kicking scheme, the optimal number of kicks and the kicking interval would ensure higher teleportation fidelity.

We compared the usefulness of various simpler spin chain models subject to our entanglement sharing protocol and do conclude that the results testify the usefulness of the helical, XX and XXZ spin chains for use in quantum teleportation as entanglement sharing channels using the protocol introduced in this manuscript. Moreover, the kicking scheme enables us to achieve higher fidelity than unkicked helical chains as well as XX and XXZ chains.

Finally we discussed the effects of the impurities and the novel kicking scheme. Though the introduction of a single impurity of either type has almost negligible effect on teleportation fidelity, the introduction of two such impurities (especially Type I) placed in both arms from the middle of spin chain has considerable effect notably when the impurity strengths are high. The kicking scheme mitigates the effect of the introduction of the impurities and prepares the otherwise unsuitable chains to be relevant for use in teleportation.
