Labeled Random Finite Sets and the Bayes Multi-Target Tracking Filter

Ba-Ngu Vo*, Ba-Tuong Vo†, Dinh Phung‡

Abstract—We present an efficient numerical implementation of the δ-Generalized Labeled Multi-Bernoulli multi-target tracking filter. Each iteration of this filter involves an update operation and a prediction operation, both of which result in weighted sums of multi-target exponentials with intractably large number of terms. To truncate these sums, the ranked assignment and K-th shortest path algorithms are used in the update and prediction, respectively, to determine the most significant terms without exhaustively computing all of the terms. In addition, using tools derived from the same framework, such as probability hypothesis density filtering, we present inexpensive look-ahead strategies to reduce the number of computations. Characterization of the $L_1$-error in the multi-target density arising from the truncation is presented.

Index Terms—Random finite set, marked point process, conjugate prior, Bayesian estimation, target tracking.

I. INTRODUCTION

Multi-target filtering involves the on-line estimation of an unknown and time-varying number of targets and their individual states from a sequence of observations [1]–[3]. While the term multi-target filtering is often used interchangeably with multi-target tracking, there is a subtle difference. In multi-target tracking, we are also interested in the trajectories of the targets. This work is concerned with a Bayesian multi-target filtering solution that also provides estimates of target trajectories, hence the name multi-target tracking filter.

The key challenges in multi-target filtering/tracking include detection uncertainty, clutter, and data association uncertainty. To date, three major approaches to multi-target tracking have emerged as the main solution paradigms. These are, Multiple Hypotheses Tracking (MHT) [4], [2]. Joint Probabilistic Data Association (JPDA) [1], and Random Finite Set (RFS) [5].

The random finite set (RFS) approach provides an elegant Bayesian formulation of the multi-target filtering/tracking problem in which the collection of target states, referred to as the multi-target state, is treated as a finite set [3], [5]. The rationale behind this representation traces back to a fundamental consideration in estimation theory–estimation error [6]. This mathematical framework subsequently became a very popular

multi-target estimation method with applications in sonar [7], computer vision [6], [9], [10], [11], field robotics [12], [13], [14], [15], [16] traffic monitoring [17], [18], [19], cell biology [20], [10], [21], sensor network and distributed estimation [22], [23], [24], [25] etc.

The centerpiece of the RFS approach is the Bayes multi-target filter [3], which recursively propagates the posterior density of the multi-target state forward in time. This filter is also a (multi-target) tracker when target identities or labels are incorporated into individual target states. Due to the numerical complexity of Bayes multi-target filter, the Probability Hypothesis Density (PHD) [5], Cardinalized PHD (CPHD) [26], and multi-Bernoulli filters [27], [6] have been developed as approximations. These filters, in principle, are not multi-target trackers because they rest on the premise that targets are indistinguishable.

In [28], [29], the notion of labeled RFSs is introduced to address target trajectories and their uniqueness. The key results include conjugate priors that are closed under the Chapman-Kolmogorov equation, and an analytic solution to the Bayes multi-target tracking filter known as the δ-generalized labeled multi-Bernoulli (δ-GLMB) filter. Although a simulation result was presented to verify the solution, specific implementation details were not given.

As a sequel to [29], the aim of this paper is to complement its theoretical contributions with practical algorithms that will facilitate the development of applications in signal processing and related fields. In particular, we present an efficient and highly parallelizable implementation of the δ-GLMB filter. Each iteration of the δ(GLMB filter involves multi-target posterior and prediction densities that are weighted sums of multi-target exponentials. While these sums are expressible in closed forms, the number of terms grow super-exponentially in time. Furthermore, it is not tractable to exhaustively compute all the terms of the multi-target densities first and then truncate by discarding those deemed insignificant.

The key innovation is the truncation of the multi-target densities without exhaustively computing all their components. The multi-target posterior and prediction densities are truncated using the ranked assignment and K-shortest paths algorithms, respectively. RFS techniques such as PHD filtering are used as inexpensive look-ahead strategies to drastically reduce the number of calls to the ranked assignment algorithm. Moreover, we establish that truncation by discarding δ-GLMB components with small weights minimizes the $L_1$ error in the multi-target density. To the best of our knowledge, this is the first result regarding the effect of truncation on the multi-target probability law.

The paper is organized as follows. Background on labeled RFS and the $\delta$-GLMB filter is provided in section II. Section III establishes the $L_1$-distance between a $\delta$-GLMB density and its truncated version. Sections IV and V present efficient implementations $\delta$-GLMB filter update and prediction respectively. Section VII details the multi-target state estimation, and discusses look-ahead strategies to reduce the computational load. Numerical results are presented in Section VII and concluding remarks are given in Section VIII.

II. BACKGROUND

This section summarizes the labeled RFS formulation of the multi-target tracking problem and the $\delta$-GLMB filter proposed in [29]. Labeled RFS is summarized in subsection II-A, followed by Bayes multi-target filtering basics in subsections II-B, II-C and II-D. The $\delta$-GLMB multi-target density and recursion are summarized in subsections II-E and II-F.

Throughout the paper, we use the standard inner product notation $(f, g) \triangleq \int f(x)g(x)dx$, and the following multi-object exponential notation $h^X \triangleq \prod_{x \in X} h(x)$, where $h$ is a real-valued function, with $h^\emptyset = 1$ by convention. We denote a generalization of the Kroneker delta that takes arbitrary arguments such as sets, vectors, etc, by

$$\delta_Y(X) \triangleq \begin{cases} 1, & \text{if } X = Y \\ 0, & \text{otherwise} \end{cases},$$

and the inclusion function, a generalization of the indicator function, by

$$1_Y(X) \triangleq \begin{cases} 1, & \text{if } X \subseteq Y \\ 0, & \text{otherwise} \end{cases}.$$  

We also write $1_Y(x)$ in place of $1_Y\{x\}$ when $X = \{x\}$.

A. Labeled RFS

An RFS is simply a finite-set-valued random variable [30], [31]. In this paper we use the FISST notion of integration/density to characterize RFSs [3], [5]. Treatments of RFS in the context of multi-target filtering can be found in [3], [32].

To incorporate target identity, each state $x \in X$ is augmented with a unique label $\ell \in L = \{\alpha_i : i \in \mathbb{N}\}$, where $\mathbb{N}$ denotes the set of positive integers and the $\alpha_i$’s are distinct.

**Definition 1** A labeled RFS with state space $X$ and (discrete) label space $L$ is an RFS on $X \times L$ such that each realization has distinct labels.

Let $\mathcal{L} : X \times L \rightarrow \mathcal{L}$ be the projection $\mathcal{L}(x, \ell) = \ell$, then a finite subset set $\mathcal{X}$ of $X \times L$ has distinct labels if and only if $X$ and its labels $\mathcal{L}(X) = \{\mathcal{L}(x) : x \in X\}$ have the same cardinality, i.e. $\delta_{|\mathcal{L}(X)|}(|\mathcal{L}(X)|) = 1$. The function $\Delta(X) \triangleq \delta_{|\mathcal{L}(X)|}(|\mathcal{L}(X)|)$ is called the distinct label indicator.

The unlabeled version of a labeled RFS is obtained by simply discarding the labels. Consequently, the cardinality distribution (the distribution of the number of objects) of a labeled RFS the same as its unlabeled version.

For the rest of the paper, single-object states are represented by lowercase letters, e.g. $x$, $X$ while multi-object states are represented by uppercase letters, e.g. $X$, $\pi$, symbols for labeled states and their distributions are bolded to distinguish them from unlabeled ones, e.g. $x$, $X$, $\pi$, etc, spaces are represented by blackboard bold e.g. $\mathbb{X}$, $\mathbb{Z}$, $\mathbb{L}$, $\mathbb{N}$, etc, and the class of finite subsets of a space $X$ is denoted by $\mathcal{F}(X)$. The integral of a function $f : X \times L \rightarrow \mathbb{R}$ is given by

$$\int f(x)dx = \sum_{\ell \in L} \int f((x, \ell))dx.$$

B. Bayesian Multi-target Filtering

To incorporate target tracks in the Bayes multi-target filtering framework, targets are identified by an ordered pair of integers $\ell = (k, i)$, where $k$ is the time of birth, and $i \in \mathbb{N}$ is a unique index to distinguish objects born at the same time. The label space for objects born at time $k$ denoted as $L_k$, is then $\{k\} \times \mathbb{N}$. An object born at time $k$, has state $x \in X \times L_k$.

The label space for targets at time $k$ (including those born prior to $k$), denoted as $L_{0:k}$, is constructed recursively by $L_{0:k} = L_{0:k-1} \cup L_k$. A multi-object state $X$ at time $k$, is a finite subset of $X \times L_{0:k}$. Note that $L_{0:k-1}$ and $L_k$ are disjoint.

Suppose that at time $k$, there are $N(k)$ target states $x_{k,1}, \ldots, x_{k,N(k)}$, each taking values in the (labeled) state space $X \times L_k$, and $M(k)$ measurements $z_{k,1}, \ldots, z_{k,M(k)}$ each taking values in an observation space $Z$. In the random finite set formulation the set of targets and observations, at time $k$, [3], [5] are treated as the multi-target state and multi-target observation, respectively

$$X_k = \{x_{k,1}, \ldots, x_{k,N(k)}\},$$

$$Z_k = \{z_{k,1}, \ldots, z_{k,M(k)}\}.$$

Let $\pi_k(\cdot | Z_k)$ denote the multi-target posterior density at time $k$, and $\pi_{k+1|k}$ denote the multi-target prediction density to time $k + 1$ (formally $\pi_k$ and $\pi_{k+1|k}$ should be written respectively as $\pi_k(\cdot | Z_0, \ldots, Z_{k-1}, Z_k)$, and $\pi_{k+1|k}(\cdot | Z_0, \ldots, Z_k)$, but for simplicity we omit the dependence on past measurements). Then, the multi-target Bayes recursion propagates $\pi_k$ in time [3], [5] according to the following update and prediction

$$\pi_k(X_k | Z_k) = \frac{g_k(Z_k | X_k) \pi_{k-1}(X_k)}{\int g_k(Z_k | X_k) \pi_{k-1}(X_k)dx},$$

$$\pi_{k+1|k}(X_{k+1}) = \int f_{k+1|k}(X_{k+1} | X_k) \pi_k(X_k | Z_k)dx_k,$$

where $g_k(\cdot)$ is the multi-target likelihood function at time $k$, $f_{k+1|k}(\cdot)$ is the multi-target transition density to time $k + 1$, and the integral is a set integral defined for any function $f : \mathcal{F}(X \times L) \rightarrow \mathbb{R}$ by

$$\int f(X)dx = \sum_{i=0}^{\infty} \int f((x_1, ..., x_i))dx_1, ..., dx_i.$$
C. Measurement likelihood function

For a given multi-target state \( X \), at time \( k \), each state \((x, \ell) \in X\) is either detected with probability \( p_D(x, \ell) \) and generates a point \( z \) with likelihood \( g(z|x, \ell) \), or missed with probability \( 1 - p_D(x, \ell) \). The multi-object observation \( Z = \{z_1, ..., z|Z|\} \) is the superposition of the detected points and Poisson clutter with intensity function \( \kappa \).

**Definition 2** An association map (for the current time) is a function \( \Theta : L_k \rightarrow \{0, 1, ..., |Z|\} \) such that \( \Theta(i) = \Theta(i') > 0 \) implies \( i = i' \). The set \( \Theta \) of all such association maps is called the association map space. The subset of \( \Theta \) with domain \( I \) is denoted by \( \Theta(I) \).

An association map describes which tracks generated which measurements, i.e. track \( \ell \) generates measurement \( z_{\Theta(\ell)} \in Z \), with undetected tracks assigned to 0. The condition \( \Theta(i) = \Theta(i') > 0 \) implies \( i = i' \), means that a track can generate at most one measurement at any point in time.

Assuming that, conditional on \( X \), detections are independent, and that clutter is independent of the detections, the function \( g \) in (5) covers both labeled Poisson and labeled multi-Bernoulli.

Equation (3) is equivalent to the likelihood function given by (54) in [29], and is more convenient for implementation.

D. Multi-target transition kernel

Given the current multi-target state \( X \), each state \((x, \ell) \in X\) either continues to exist at the next time step with probability \( p_s(x, \ell) \) and evolves to a new state \((x_+, \ell_+)\) with probability density \( f(x_+, x, \ell) \delta_\ell(\ell_+) \), or dies with probability \( 1 - p_s(x, \ell) \). The set of new targets born at the next time step is distributed according to

\[
f_B(Y) = \Delta(Y)w_B(L(Y))|p_B|^Y
\]

The birth density \( f_B \) is defined on \( X \times B \) and \( f_B(Y) = 0 \) if \( Y \) contains any element \( y \) with \( L(Y) \notin B \). The birth model \( f_B \) covers both labeled Poisson and labeled multi-Bernoulli.

The multi-target state at the next time \( X_+ \) is the superposition of surviving targets and new born targets. Assuming that targets evolve independently of each other and that births are independent of surviving targets, it was shown in [29] that the multi-target transition kernel is given by

\[
f(X_+ | X) = f_S(X_+ \cap (X \times L))f_B(X_+ - (X \times L))
\]

where \( f_S(W|X) = \Delta(W)\Delta(X)1_L(X)(\mathcal{L}(W))|\Phi(W;\cdot)|^X \) and \( \Phi(W; x, \ell) = \begin{cases} p_S(x, \ell)f(x_+, x, \ell), & \text{if } (x_+, \ell) \in W \\ 1 - p_S(x, \ell), & \text{if } \ell \notin \mathcal{L}(W) \end{cases} \)

E. Delta-Generalized Labeled Multi-Bernoulli

The \( \delta \)-generalized labeled multi-Bernoulli filter is a solution to the Bayes multi-target filter based on the family of generalized labeled multi-Bernoulli (GLMB) distributions

\[
\pi(X) = \Delta(X) \sum_{\xi \in \Xi} \omega(\xi, \delta_\xi(L(X)))|p(\xi)|^X
\]

where \( \Xi \) is a discrete space, each \( p(\xi, \cdot) \) is a probability density, and each \( w(\xi, \delta_\xi) \) is non-negative with \( \sum_{\xi \in \Xi} w(\xi, \delta_\xi) = 1 \). While this family is closed under the Bayes recursion [29], it is not clear how numerical implementation can be accomplished. Fortunately, using the identity \( w(\xi, \delta_\xi) = \sum_{\xi, J \in F(\Xi)} \omega(\xi, \delta_\xi(L(X))) \delta_\xi(J) \), and an alternative form of the GLMB, known as \( \delta \)-GLMB

\[
\pi(X) = \Delta(X) \sum_{(I, \xi) \in F(\Xi) \times \Xi} \omega(\xi, \delta_\xi(L(X)))|p(\xi)|^X
\]

where \( \omega(\xi, \delta_\xi) = w(\xi, \delta_\xi) \), provides a representation that facilitates numerical implementation.

In the \( \delta \)-GLMB initial multi-target prior

\[
\pi_0(X) = \Delta(X) \sum_{I \in F(\Xi_0)} \omega_0(\xi, \delta_\xi(L(X)))|p_0|^X
\]

each \( I \in F(\Xi_0) \) represents a set of tracks labels born at time 0, \( \omega_0(I) \) represents the weight of the hypothesis that \( I \) is the set of track labels at time 0, and \( p_0(\cdot, \ell) \) is the probability density of the kinematic state of track \( \ell \in I \). For example, suppose that there are 2 possibilities:

1. 0.3 chance of 1 target with label \((0, 2)\), and density \( p_0((0, (0, 2)) = N(\cdot; m_2, P_2) \)
2. 0.7 chance of 2 targets with labels \((0, 1)\), \((0, 2)\) and respective densities \( p_0((0, 1)) = N(\cdot; 0, P_1) \), \( p_0((0, 2)) = N(\cdot; m_2, P_2) \),

Then the \( \delta \)-GLMB representation is

\[
\pi_0(X) = 0.3\delta_0(0, 2)(L(X))|p_0|^X + 0.7\delta_0(0, 1, 0, 2)(L(X))|p_0|^X
\]

Note that the initial prior \( \pi_0 \) is a \( \delta \)-GLMB with \( \Xi = \emptyset \). For \( \delta \)-GLMB posterior and prediction densities that are conditioned on measurements up to time \( k \), the discrete space \( \Xi \) is the space of association map histories \( \Theta_{0:k} \equiv \Theta_0 \times ... \times \Theta_k \), where \( \Theta_t \) denotes the association map space at time \( t \). In particular, as shown in [29], for each \( k \geq 0 \) the posterior and prediction densities are \( \delta \)-GLMB densities:

\[
\pi_k|Z_k(X) = \Delta(X) \sum_{(I, \xi) \in F(\Xi_{0:k}) \times \Theta_{0:k}} \omega_k(\xi, \delta_\xi(L(X)))|p_k(\xi)|^X
\]

\[
\pi_{k+1}|d(X) = \Delta(X) \sum_{(I, \xi) \in F(\Xi_{0:k+1}) \times \Theta_{0:k}} \omega_{k+1}(\xi, \delta_\xi(L(X)))|p_{k+1}(\xi)|^X
\]

Each \( I \in F(\Xi_{0:k}) \) represents a set of track labels at time \( k \), and each \( \xi = (\theta_0, ..., \theta_k) \in \Theta_{0:k} \) represents a history of association maps up to time \( k \), which also contains the history of target labels encapsulating both births and deaths. The pair \( (I, \xi) \in F(\Xi_{0:k}) \times \Theta_{0:k} \) is called a hypothesis, and its associated weight \( \omega_k(\xi) \) can be interpreted as the probability of the hypothesis. Similarly the pair \( (I, \xi) \in F(\Xi_{0:k+1}) \times \Theta_{0:k} \) is called a prediction hypothesis, with probability \( \omega_{k+1}(\xi) \).
The densities $p_k^{(i)}(\cdot, \ell)$ and $p_{k+1|k}^{(i)}(\cdot, \ell)$ are the posterior and prediction densities of the kinematic state of track $\ell$ for association map history $\xi$.

**F. Delta Generalized Labeled Multi-Bernoulli Recursion**

The $\delta$-GLMB filter recursively propagates a $\delta$-GLMB posterior density forward in time via the Bayes update and prediction equations (2) and (1). Closed form solutions to the update and prediction of the $\delta$-GLMB filter are given by the following results [29].

**Proposition 3** If the current multi-target prediction density is a $\delta$-GLMB of the form (9), then the multi-target posterior is a $\delta$-GLMB given by

$$
\pi(X|Z) = \Delta(X) \sum_{(I, \xi) \in \mathcal{F}(L) \times \Xi} \sum_{\omega \in \Theta(I)} \omega^{(I, \xi)}(Z) \delta_I(\mathcal{L}(X)) \left[p^{(\xi)}(\cdot|Z)\right]^X
$$

where $\Theta(I)$ denotes the subset of current association maps with domain $I$,

$$
\omega^{(I, \xi)}(Z) \propto \omega^{(I, \xi)}[\eta_Z^{(\xi)}]^I,
$$

$$
\eta_Z^{(\xi)}(\ell) = \left<p^{(\xi)}(\cdot, \ell), \psi_Z(\cdot, \ell; \theta)\right>,
$$

$$
p^{(\xi)}(x, \ell|Z) = \left[p^{(\xi)}(x, \ell|Z)\right] = \left[p^{(\xi)}(x|Z)\right] \eta_Z^{(\xi)}(\ell).
$$

**Proposition 4** If the current multi-target posterior is a $\delta$-GLMB of the form (9), then the multi-target prediction to the next time is a $\delta$-GLMB given by

$$
\pi_+(X_i) = \Delta(X_i) \sum_{(I, \xi) \in \mathcal{F}(L) \times \Xi} \omega^{(I, \xi)} \delta_I(\mathcal{L}(X_i)) \left[p^{(\xi)}_+(\cdot|Z)\right]^{X_+}
$$

where

$$
\omega^{(I, \xi)} = \omega^{(I, \xi)}(I_+ \cap \Xi) w_B(I_+ \cap \Xi)
$$

$$
\omega^{(\xi)}(L) = [\eta^{(\xi)}_S]^I \sum_{I \subseteq L} [1 - \eta^{(\xi)}_S]^{I-L} \omega^{(I, \xi)}
$$

$$
\eta^{(\xi)}_S(\ell) = \left<p_S(\cdot; \ell), \psi_S(\cdot; \ell)\right>,
$$

$$
p^{(\xi)}_+(x, \ell) = 1_{\mathbb{L}_+}(x) p^{(\xi)}(x, \ell) + 1_{\mathbb{L}}(x) p_E(x, \ell)
$$

$$
p^{(\xi)}_S(x, \ell) = \frac{p_S(\cdot; \ell)}{\eta^{(\xi)}_S(\ell)}
$$

Note from Propositions 3 and 4 that the actual value of the association history $\xi$ is not used in the calculations, it is used merely as an indexing variable. On the other hand, the value of the label set $I$ is used in the calculations.

**III. CHARACTERIZING TRUNCATION ERROR**

A $\delta$-GLMB is completely characterized by the set of parameters $\{(\omega^{(I, \xi)}, p^{(\xi)}): (I, \xi) \in \mathcal{F}(L) \times \Xi\}$. For implementation it is convenient to consider the set of $\delta$-GLMB parameters as an enumeration of all hypotheses (with positive weight) together with their associated weights and track densities $\{(\omega^{(h)}, p^{(h)}): (I^{(h)}, \xi^{(h)}) \in \mathcal{H}\}$, as shown in Figure 1, where $\omega^{(h)}$ and $p^{(h)}$ are the weight and associated track densities of the kinematic state of track $\ell$ for association map history $\xi$.

![Fig. 1](image-url)
Now note that \( \|\mathbf{f}_\mathbf{t} - \mathbf{f}_\mathbf{r}\|_1 = \|\mathbf{f}_\mathbf{t}\|_1 - \|\mathbf{f}_\mathbf{r}\|_1 \), moreover,

\[
\left\| \frac{\mathbf{f}_\mathbf{t}}{\|\mathbf{f}_\mathbf{t}\|_1} - \frac{\mathbf{f}_\mathbf{r}}{\|\mathbf{f}_\mathbf{r}\|_1} \right\|_1 \leq \int \left( \sum_{(i, \xi) \in \mathbb{T}} \left( \frac{\omega(i, \xi)}{\|\mathbf{f}_\mathbf{t}\|_1} - \frac{\omega(i, \xi)}{\|\mathbf{f}_\mathbf{r}\|_1} \right) \right) \delta_I(\mathbf{L}(\mathbf{X})) \left[ p(\xi) \right] \mathbf{X} \delta \mathbf{X} + \int \left( \sum_{(i, \xi) \in \mathbb{H} - \mathbb{T}} \left( \frac{\omega(i, \xi)}{\|\mathbf{f}_\mathbf{t}\|_1} + \sum_{(i, \xi) \in \mathbb{H} - \mathbb{T}} \frac{\omega(i, \xi)}{\|\mathbf{f}_\mathbf{t}\|_1} \right) \right) \delta_I(\mathbf{L}(\mathbf{X})) \left[ p(\xi) \right] \mathbf{X} \delta \mathbf{X} = 1 - \frac{\|\mathbf{f}_\mathbf{r}\|_1}{\|\mathbf{f}_\mathbf{t}\|_1} + \frac{\|\mathbf{f}_\mathbf{t}\|_1 - \|\mathbf{f}_\mathbf{r}\|_1}{\|\mathbf{f}_\mathbf{t}\|_1} = 2 \frac{\|\mathbf{f}_\mathbf{t}\|_1 - \|\mathbf{f}_\mathbf{r}\|_1}{\|\mathbf{f}_\mathbf{t}\|_1}.
\]

It follows from the above result that the intuitive strategy of keeping \( \delta \)-GLMB components with high weights and discarding those with the smallest weights minimizes the \( L_1 \) error in the truncated multi-target density.

In the \( \delta \)-GLMB recursion, it is not tractable to exhaustively compute all the components first and then discard those with small weights. The trick is to perform the truncation without having to propagate all the components.

### IV. Delta-GLMB Update

This section presents a tractable implementation of the \( \delta \)-GLMB update by truncating the multi-target posterior without computing all the hypotheses and their weights, via the ranked assignment algorithm. Subsection [IV-A] summarizes the ranked assignment problem in the context of truncating the \( \delta \)-GLMB posterior. Subsection [IV-B] details the computation of the updated \( \delta \)-GLMB parameters and subsection [IV-C] presents the \( \delta \)-GLMB update algorithm.

#### A. Ranked Assignment Problem

Note from the \( \delta \)-GLMB weight update (14) that each hypothesis \( (I, \xi) \) with weight \( \omega(I, \xi) \) generates a new set of hypotheses \( (I, (\xi, \theta)) \), \( \theta \in \Theta(I) \), with weights \( \omega(I, (\xi, \theta))(Z) \propto \omega(I, \xi) \beta(I, \xi|\theta)(Z) \). For a given hypothesis \( (I, \xi) \), if we can generate the association maps \( \theta \in \Theta(I) \) in decreasing order of \( \beta(I, \xi|\theta) \), then the highest weighted components can be selected without exhaustively computing all the new hypotheses and their weights. This can be accomplished by solving the following ranked assignment problem.

Enumerating \( Z = \{z_1, ..., z_{|Z|}\} \), \( I = \{\ell_1, ..., \ell_{|I|}\} \), each association map \( \theta \in \Theta(I) \) can be represented by an \( |I| \times |Z| \) assignment matrix \( S \) consisting of 0 or 1 entries with every row and column summing to either 1 or 0. For \( i \in \{1, ..., |I|\}, j \in \{1, ..., |Z|\} \), \( S_{ij} = 1 \) if and only if the \( j \)th measurement is assigned to track \( \ell_i \), i.e. \( \theta(\ell_i) = j \). An all-zero row \( i \) means that track \( \ell_i \) is misdetected while an all-zero column \( j \) means that measurement \( z_j \) is a false alarm. Conversion from \( S \) to \( \theta \) is given by \( \theta(\ell_i) = \sum_{j=1}^{|Z|} j \delta_1(S_{ij}) \).

The cost matrix of an optimal assignment problem is the \( |I| \times |Z| \) matrix:

\[
C_Z^{(I, \xi)} = \begin{bmatrix} C_{I,1} & \cdots & C_{I,|Z|} \\ \vdots & \ddots & \vdots \\ C_{|I|,1} & \cdots & C_{|I|,|Z|} \end{bmatrix}
\]

where for \( i \in \{1, ..., |I|\}, j \in \{1, ..., |Z|\} \)

\[
C_{i,j} = -\ln \left( \frac{\beta(I, \xi)(\ell_i) p_D(\ell_i, \ell_j) \beta(z_j|\ell_j)}{\beta(I, \xi)(\ell_i) (1 - p_D(\ell_i, \ell_j)) \beta(z_j|\ell_j)} \right)
\]

is the cost of assigning the \( j \)th measurement to track \( \ell_i \) (the numerical computation of \( C_{i,j} \) is further detailed in Subsection [IV-B]).

The cost of an assignment (matrix) \( S \) is the combined costs of every measurement to target assignments, which can be succinctly written as the Frobenius inner product

\[
\operatorname{tr}(S^T C_Z^{(I, \xi)}) = \sum_{i=1}^{|I|} \sum_{j=1}^{|Z|} C_{i,j} S_{i,j}.
\]

Substituting (14) into equation (15), it follows that the cost of \( S \) (and the corresponding association map \( \theta \)) is related to the posterior hypothesis weight

\[
\omega(I, \xi, \theta)(Z) \propto \omega(I, \xi) \beta(I, \xi|\theta)(Z) \]

by

\[
[D] = \exp \left( -\operatorname{tr}(S^T C_Z^{(I, \xi)}) \sum_{i=1}^{|I|} \prod_{\ell \in I} \left( p(\xi(\ell), \ell, 1 - p_D(\cdot, \ell)) \right) \right).
\]

The optimal assignment problem seeks an assignment matrix \( S^* \) (and corresponding association map \( \theta^* \)) that minimizes the cost \( \operatorname{tr}(S^T C_Z^{(I, \xi)}) \). The ranked assignment problem seeks an enumeration of the least cost assignment matrices in non-decreasing order [34]. Consequently, solving the ranked optimal assignment problem with cost matrix \( C_Z^{(I, \xi)} \) generates, starting from \( \theta^* \), an enumeration of association maps \( \theta \) in order of non-increasing \( \left[ \beta(I, \xi|\theta) \right] \) and weights \( \omega(I, \xi, \theta)(Z) \propto \omega(I, \xi) \beta(I, \xi|\theta) \).

Remark: The standard ranked assignment formulation involves square cost and assignment matrices with rows and columns of the assignment matrix summing to 1. By introducing dummy variables, the above ranked optimal assignment problem can be reformulated with square matrices, but these variables and duplicate solutions need to be removed to obtain the final solutions.

The optimal assignment problem, a well-known combinatorial problem, introduced by Kuhn [33], who also proposed the Hungarian algorithm to solve it in polynomial time. Munkres further observed that it is strongly polynomial [35]. The ranked assignment problem is a generalization to enumerate the \( T \) least cost assignments, which was first solved by Murty [34]. Murty’s algorithm needs an effective bipartite assignment algorithm such as Munkres [35] or Jonker-Volgenant [36]. In the context of multi-target tracking, ranked assignment algorithms with \( O(T|Z|^3) \) complexity have been proposed for MHT in [37], [38], [39]. More efficient algorithms with \( O(T|Z|^3) \) complexity have been proposed in [40], [41], [42], with the latter showing better efficiency for large \( |Z| \).
B. Computing update parameters

We now detail the computation of the cost matrix $C_Z^{(I, \xi)}$ in (23) for the ranked assignment problem and the parameters $\eta_Z^{(\xi, \theta)}(\ell), p^{(\xi, \theta)}(\cdot, \ell|Z)$ of the updated $\delta$-GLMB components.

1) Gaussian mixture: For a linear Gaussian multi-target model, $p_D(x, \ell) = p_D, g(z|x, \ell) = N(z; Hx, R)$, where $N(\cdot; m, P)$ denotes a Gaussian density with mean $m$ and covariance $P$, $H$ is the observation matrix, and $R$ is the observation noise covariance. Suppose that each single target density $p^{(\xi)}(\cdot, \ell)$ is a Gaussian mixture of the form

$$j^{(\xi)}(\ell) \sum_{i=1}^m w_i^{(\xi)}(\ell) N(x; m_i^{(\xi)}(\ell), P_i^{(\xi)}(\ell)). \quad (25)$$

Then

$$C_{i,j} = -\ln \left( \frac{p_D \sum_{k=1}^{j^{(\xi)}} w_k^{(\xi)}(\ell) q_k^{(\xi)}(z_j; \ell)}{(1 - p_D) \kappa(z_j)} \right) \quad (26)$$

Moreover, for the updated association history $(\xi, \theta)$,

$$\eta_Z^{(\xi, \theta)}(\ell) = \sum_{i=1}^{j^{(\xi)}} w_i^{(\xi)}(\ell) \quad (27)$$

$$p^{(\xi, \theta)}(x, \ell|Z) = \sum_{i=1}^{j^{(\xi)}} \eta_Z^{(\xi, \theta)}(\ell) N(x; m_i^{(\xi)}(\ell), P_i^{(\xi, \theta)}(\ell)) \quad (28)$$

where

$$w_i^{(\xi)}(\ell) = w_i^{(\xi)}(\ell) \left( \frac{p_D \kappa(\ell \mid z_i)}{(1 - p_D) \kappa(z_i)} \right) \quad (29)$$

$$q_i^{(\xi)}(z; \ell) = N(z; Hm_i^{(\xi)}(\ell), H P^{(\xi)}(\ell) H^T + R) \quad (30)$$

$$m_i^{(\xi)}(\ell) = m_i^{(\xi)}(\ell) + K_i^{(\xi, \theta)}(\ell) (z_\ell - H m_i^{(\xi)}(\ell)) \quad (31)$$

$$P_i^{(\xi, \theta)}(\ell) = |1 - K_i^{(\xi, \theta)}(\ell) H| P_i^{(\xi)}(\ell), \quad (32)$$

and $p^{(\xi, \theta)}(\cdot, \ell|Z)$ is represented by the following set of weighted samples

$$\left\{ \left( \psi_Z(x_n^{(\xi)}(\ell), \ell; \theta) w_n^{(\xi)}(\ell), x_n^{(\xi)}(\ell) \right) \right\}_{n=1}^{j^{(\xi)}} \quad (33)$$

C. Posterior Density Truncation

Given the $\delta$-GLMB prediction density $\pi$ with enumerated parameter set $\{I(\xi), \xi(h), \omega(h), p(h)\}$, the $\delta$-GLMB posterior (13) can be written as

$$\pi(X|Z) = \sum_{h=1}^H \pi(h) X|Z) \quad (34)$$

where

$$\pi(h) X|Z) = \Delta(X) \sum_{j=1}^n \omega^{(\xi(h), \omega(h), \ell)}/p(h) \right)^X \quad (35)$$

Each $\delta$-GLMB prediction component (indexed by $h$) generates a set of $[\Theta(I(\xi))]$ components for the $\delta$-GLMB posterior.

Fig. 2. $\delta$-GLMB update. Component $h$ of the prior generates a (large) set of posterior components. The ranked assignment algorithm determines the $T(h)$ components with highest weights $\omega(h, 1) \geq \omega(h, 2) \geq \ldots \geq \omega(h, T(h))$.

A simple and highly parallelizable strategy for truncating the posterior $\delta$-GLMB (32) is to truncate $\pi(h)|Z)$. For each $h = 1, \ldots, H$, solving the ranked optimal assignment problem with cost matrix $C_Z^{(I(\xi), \xi(h))}$ discussed in subsection IV-A yields $\delta^{(h,j)}$, $j = 1, \ldots, T(h)$, the $T(h)$ hypotheses with highest weights in non-increasing order, as illustrated in Figure 2. Consequently, the truncated version of $\pi(h)|Z)$ is

$$\tilde{\pi}(h) X|Z) = \Delta(X) \sum_{j=1}^{T(h)} \omega^{(h,j)} \delta^{(h,j)}[\ell, \theta] \right)^X \quad (36)$$
Table 1. Update

- input: \{(I^{(h)}, \xi^{(h)}, \omega^{(h)}, p^{(h)}, T^{(h)})\}_{h=1}^H, Z
- output: \{(I^{(h,j)}, \xi^{(h,j)}, \omega^{(h,j)}, p^{(h,j)})\}_{(h,j)\in\{1,1\}}

for \( h = 1 : H \)
\[ C^{(h)}_{Z} := C^{(h)}_{Z}^{(I^{(h)}, \xi^{(h)})} \text{ according to (23), (26)/(29)} \]
\[ \{g^{(h,j)}_{1}\}_{j=1}^T := \text{ranked_assignment}(Z, T^{(h)}) \]
for \( j = 1 : T^{(h)} \)
\[ \eta^{(h,j)}_{Z} := \eta^{(h,j)}_{Z} \text{ according to (27)/(30)} \]
\[ p^{(h,j)} := p^{(h,j)} \text{ according to (28)/(31)} \]
\[ \omega^{(h,j)} := \omega^{(h)} \left[ \eta^{(h,j)}_{Z} \right]_{I^{(h)}} \]
\[ I^{(h,j)} := I^{(h)} \]
\[ \xi^{(h,j)} := \xi^{(h,j)} \]
end
normalize weights \( \{\omega^{(h,j)}\}_{(h,j)\in\{1,1\}} \)

It follows from Proposition 5 that the truncated density \( \hat{\pi}(\cdot|Z) = \sum_{h=1}^H \hat{\pi}^{(h)}(\cdot|Z) \) minimizes the \( L_1 \)-distance from the posterior \( \delta \)-GLMB over all truncations with \( T^{(h)} \) components for each \( h = 1, ..., H \). The truncated density, with a total of \( T = \sum_{h=1}^H T^{(h)} \) components, is normalized by the sum of the weights to give the truncated posterior \( \delta \)-GLMB. Table 1 summarizes the update operation via pseudo code.

Specific values for the number of requested components \( T^{(h)} \) are generally user specified and application dependent. A generic strategy is to choose \( T^{(h)} = \max_{i \in I} J_{\max} \) where \( J_{\max} \) is the desired overall number of hypotheses. The alternative strategy of keeping the \( T = J_{\max} \) strongest components of \( \pi(\cdot|Z) \) would yield a smaller \( L_1 \)-error. However, in addition to an \( H \)-fold increase in the dimension of the resulting ranked assignment problem, parallelizability is lost.

V. DELTA GLMB PREDICTION

This subsection presents an implementation of the \( \delta \)-GLMB prediction using the \( K \)-shortest path algorithm to truncate the predicted \( \delta \)-GLMB without computing all the prediction hypotheses and their weights.

The prediction density given in Proposition 4 has a compact form but is difficult to implement due to the sum over all supersets of \( L \) in (19). We use an equivalent form for the prediction, eq. (58) in (29):
\[
\pi_{+}(X_{+}) = \Delta(X_{+}) \sum_{(I, \xi) \in F(I) \times \Xi} \omega^{(I, \xi)} \sum_{J \in F(I)} \left[ \eta^{(\xi)}_{S} \right]_{J}^{I - J} \cdot \frac{1}{\eta^{(\xi)}_{S}} \sum_{L \in F(\Xi)} w_{B}(L) \psi_{J \cup L}(C^{(\xi)}(X_{+})) \left[ p^{(\xi)}_{+} \right]^{X_{+}},
\]
(33)

Note that analogous to the update, each current hypothesis \( (I, \xi) \) with weight \( \omega^{(I, \xi)} \) generates a set of prediction hypotheses \( J \cup L, \xi, J \subseteq I, L \subseteq \mathbb{B} \), with weights \( \omega^{(I, \xi)}_{S}(J) w_{B}(L) \), where
\[
\omega^{(I, \xi)}_{S}(J) = \omega^{(I, \xi)} \left[ \eta^{(\xi)}_{S} \right]_{J}^{I - J} \cdot \frac{1}{\eta^{(\xi)}_{S}}
\]
(34)

Intuitively, each predicted label set \( J \cup L \) consists of a surviving label set \( J \) with weight \( \omega^{(I, \xi)}_{S}(J) \) and a birth label set \( L \) with weight \( w_{B}(L) \). The weight \( \omega^{(I, \xi)}_{S}(J) \) can be interpreted as the probability that the current label set is \( I \), and the labels in \( J \) survive to the next time while the remaining labels \( I - J \) die. The birth label set \( L \) and the surviving label set \( J \) are mutually exclusive since the space of new labels \( \mathbb{B} \) cannot contain any existing labels. Since the weight of \( J \cup L \) is the product \( \omega^{(I, \xi)}_{S}(J) w_{B}(L) \), we can truncate the double sum over \( J \) and \( L \) by separately truncating the sum over \( J \) and the sum over \( L \).

Subsection V-A discusses the \( K \)-shortest paths problem in the context of truncating the \( \delta \)-GLMB prediction. Subsection V-B details the computation of the prediction \( \delta \)-GLMB parameters and subsection V-C present the \( \delta \)-GLMB prediction algorithm.

A. K-Shortest Paths Problem

Consider a given hypothesis \((I, \xi)\), and note that the weight of a surviving label set \( J \subseteq I \) can be rewritten as
\[
\omega^{(I, \xi)}_{S}(J) = \omega^{(I, \xi)} \left[ 1 - \eta^{(\xi)}_{S} \right]^{J} \frac{1}{\eta^{(\xi)}_{S} \eta^{(\xi)}_{S}} \]

If we can generate the surviving label sets \( J \subseteq I \) in non-increasing order of \( \left| \eta^{(\xi)}_{S} \right|^{J} \), then the highest weighted survival sets for hypothesis \((I, \xi)\) can be selected without exhaustively computing all the survival hypotheses. This can be accomplished by solving the \( K \)-shortest path problem in the directed graph of Figure 3.

![Fig. 3. A directed graph with nodes \( \ell_1, \ldots, \ell_{|I|} \subseteq I \), and corresponding costs \( C^{(I, \xi)}(\ell_1), \ldots, C^{(I, \xi)}(\ell_{|I|}) \)].

S and E are the start and end nodes respectively.
Define a cost vector \( C^{(I, \xi)} = [C^{(I, \xi)}(\ell_1), \ldots, C^{(I, \xi)}(\ell_{|I|})] \), where
\[
C^{(I, \xi)}(\ell_j) = -\ln \left[ \frac{\eta^{(\xi)}_{S}(\ell_j)}{1 - \eta^{(\xi)}_{S}(\ell_j)} \right]
\]
(35)
is the cost of node \( \ell_j \in I \) (the numerical computation of \( C^{(I, \xi)}(\ell_j) \) is detailed in Subsection V-B). The nodes are ordered in non-decreasing costs and the distance from node \( \ell_j \) to \( \ell_{j'} \) is defined as
\[
d(\ell_j, \ell_{j'}) = \left\{ \begin{array}{ll}
C^{(I, \xi)}(\ell_{j'}) & \text{if } j' > j \\
\infty & \text{otherwise}
\end{array} \right.
\]
Hence, a path from $S$ to $E$ which traverses the set of nodes $J \subseteq I$ accumulates a total distance of
\[
\sum_{\ell \in J} C^{(I,J)}(\ell) = -\sum_{\ell \in J} \ln \left( \frac{\eta_S^{(\ell)}}{1 - \eta_S^{(\ell)}} \right) = -\ln \left( \frac{\eta_S^{(\ell)}}{1 - \eta_S^{(\ell)}} \right)^J.
\]

The shortest path from $S$ to $E$ traverses the set of nodes $J^* \subseteq I$ with the shortest distance $\sum_{\ell \in J^*} C^{(I,J)}(\ell)$ and hence largest $\eta_S^{(\ell)}/(1 - \eta_S^{(\ell)})$. The $K$-shortest paths problem seeks $K$ subsets of $I$ with the shortest distances in non-decreasing order. Consequently, solving the $K$-shortest path problem generates, starting from $J^*$, an enumeration of subsets $J$ of $I$ in order of non-increasing $\eta_S^{(\ell)}/(1 - \eta_S^{(\ell)})$.

For the target births we use a labeled multi-Bernoulli birth model where
\[
w_B(L) = \prod_{\ell \in \mathbb{B}} \left( 1 - r_B^{(\ell)} \right) \prod_{\ell \in L} \frac{1_B^{(\ell)} r_B^{(\ell)}}{1 - r_B^{(\ell)}},
\]
\[p_B(x, \ell) = p_B^{(\ell)}(x).
\]
Thus, solving the $K$-shortest paths problem with cost vector $C_B = [C_B(\ell_1), ..., C_B(\ell_{|\mathbb{B}|})]$, where
\[C_B(\ell_j) = -\ln \left( \frac{r_B^{(\ell_j)}}{1 - r_B^{(\ell_j)}} \right)
\]
is the cost of node $\ell_j$, yields the subsets of $\mathbb{B}$ with the best birth weights.

Remark: It is possible to obtain the overall $K$ best components by extending the directed graphs to include birth nodes with appropriate costs. However, our experience indicated that since the birth weights $w_B(L)$ are quite small compared to surviving weights $\omega_S^{(\ell)}(J)$, many components with births will be discarded and new births may not be detected by the filter. To avoid dropping new tracks, a very large $K$ is required to retain hypothesis with births. On the other hand the proposed separate truncation strategy ensures that there are hypotheses with births to accommodate new tracks, and is highly parallelizable.

The $K$-shortest paths algorithm is a well-known solution to the combinatorial problem of finding the $K$ paths with minimum total cost from a given source to a given destination in a weighted network. This problem can be solved with complexity $O(|I| \log(|I|) + K)$. In our case the nodes have negative values, hence the Bellman-Ford algorithm was employed. This problem can also be solved by ranked assignment algorithms, however $K$-shortest paths algorithm is much more efficient.

**B. Computing prediction parameters**

This subsection details the computation of the parameters $\eta_S^{(\ell)}(\ell)$ and $p_S^{(\ell)}(\cdot, \ell)$ of the prediction $\delta$-GLMB components.

1) Gaussian mixture: For a linear Gaussian multi-target model, $p_S(x, \ell) = p_S$, $f(x|x, \ell) = N(x+; Fx, Q)$, where $F$ is the state transition matrix, $Q$ is the process noise covariance and the birth density parameter $p_B^{(\ell)}(x)$ is a Gaussian mixture. If the single target density $p^{(\ell)}(\cdot, \ell)$ is a Gaussian mixture of the form \(25\). Then,
\[
\eta_S^{(\ell)}(\ell) = p_S,
\]
\[p_S^{(\ell)}(x, \ell) = 1_S(\ell) \sum_{i=1}^{J(\ell)} w_i^{(\ell)}(\ell) N(x; m_S^{(\ell)}, P_S^{(\ell)}(\ell)) + 1_S(\ell) p_B^{(\ell)}(x)
\]
where
\[
m_S^{(\ell)}(\ell) = F m_i^{(\ell)}(\ell),
p_B^{(\ell)}(x) = Q + F P_B^{(\ell)} F^T.
\]

When the motion model parameters depend on the label $\ell$, we simply substitute $p_S = p_S(\ell)$, $F = F(\ell)$, $Q = Q(\ell)$ into the above equations. With $\eta_S^{(\ell)}(\ell)$ evaluated, the node cost $C^{(I,J)}(\ell)$ for the $K$-shortest paths problem can then be computed by \(25\).

2) Sequential Monte Carlo: For a sequential Monte Carlo approximation, suppose that each single target density $p^{(\ell)}(\cdot, \ell)$ is represented as a set of weighted sample \(\{(w_i^{(\ell)}(\ell), x_i^{(\ell)}(\ell))\}_{i=1}^{J(\ell)}\) and that the birth density $p_B^{(\ell)}(\cdot)$ is represented by \(\{(w_B^{(\ell)}(x), x_B^{(\ell)}(x))\}_{i=1}^{B(\ell)}\). Then,
\[
\eta_S^{(\ell)}(\ell) = \sum_{i=1}^{J(\ell)} w_i^{(\ell)}(\ell) p_S(x_i^{(\ell)}(\ell), \ell)
\]
and $p_S^{(\ell)}(x, \ell)$ is represented by
\[
\{ (1_S(\ell) w_S^{(\ell)}(x, \ell), x_S^{(\ell)}(x, \ell)) \}_{i=1}^{J(\ell)} \cup \{ (1_S(\ell) w_B^{(\ell)}(x, \ell), x_B^{(\ell)}(x, \ell)) \}_{i=1}^{B(\ell)} \}
\]
where
\[
w_S^{(\ell)}(x, \ell) \sim q^{(\ell)}(\cdot|x^{(\ell)}(\ell), \ell, Z), i = 1, ..., J(\ell),
\]
\[w_B^{(\ell)}(x, \ell) = \frac{q^{(\ell)}(x^{(\ell)}(\ell)|x_B^{(\ell)}(\ell), Z)}{\sum_{i=1}^{J(\ell)} w_S^{(\ell)}(x, \ell)} \]
and $q^{(\ell)}(\cdot|x^{(\ell)}(\ell), \ell, Z)$ is a proposal density.

**C. Prediction Density Truncation**

Given the current $\delta$-GLMB posterior density $\pi(\cdot|Z)$ with enumerated parameter set \(\{(h), (h), (h), p^{(h)}\}_h\), then the $\delta$-GLMB prediction becomes
\[
\pi_+ (X_+) = \sum_{h=1}^{H} \pi_+^{(h)} (X_+),
\]
where
\[
\pi_+^{(h)} (X_+) = \Delta(X_+) \sum_{J \subseteq I(h)} \sum_{L \subseteq \mathbb{B}} \omega_S^{(h)}(J) w_B(L) \delta_{J \cup L}(X_+) \left[ p^{(h)} \right]^{X_+}
\]
The $\delta$-GLMB posterior component (indexed by $h$) $h$ generates $2^{J(h)} + |\mathbb{B}|$ components for the $\delta$-GLMB prediction.

A simple and highly parallelizable strategy for truncating the prediction $\delta$-GLMB $\pi_+$ is to truncate each $\pi_+^{(h)}$ as follows. For each $h = 1, ..., H$, we solve the $K$-shortest paths problem with cost vector $C^{(I(h), h)}$ to obtain $J(h)$, $j = 1, ..., K(h)$.
Moreover, the truncated density minimizes the resulting truncation captures a desired proportion (say 99%) of the probability mass of the birth density. The alternative strategy of keeping the $T = J_{\text{max}}$ strongest components of $\pi_+$ would yield a smaller $L_1$-error than the proposed strategy. However, in addition to an $(H + K_B)$-fold increase in the dimension of the resulting problem, parallelizability is lost.

Remark: As noted previously, the actual value of the association history $\xi(h)$ is not needed in the update and prediction calculations, it is used merely as an index for the track density $p(\xi(h))$. Since the track density is now equivalently indexed by $h$, i.e. $p(h) \equiv p(\xi(h))$, in practice it is not necessary to propagate $\xi(h)$. Nonetheless, for clarity of exposition we have retained $\xi(h)$ in the update and prediction pseudo codes.

VI. DELTA GLMB FILTER

The main steps of the $\delta$-GLMB filter algorithm is summarized in the following pseudo code:

```
Main Loop (Filter)

for k = 1 : K
    Prediction
    Update
    Compute State Estimates
end
```

In Subsection VI-A we describe the multi-target state estimation process in the "Compute State Estimate" module. Subsection VI-B presents look-ahead strategies to reduce number of calls to the ranked optimal assignment and K-shortest paths algorithms.
Table 3. Compute State Estimate

- input: \(N_{\text{max}}\), \(\{I^{(h,j)}, \xi^{(h,j)}, \omega^{(h,j)}, p^{(h,j)}\}_{(h,j) = (1, 1)}\)
- output: \(\hat{X}\)

\[
\rho(n) := \sum_{h=1}^{H} \sum_{j=1}^{T^{(h)}(\hat{h}, \hat{j})} \omega^{(h,j)} \delta_n(I^{(h,j)}) ; n = 0, \ldots, N_{\text{max}}
\]

\[
\hat{N} := \arg \max \rho
\]

\[
(\hat{h}, \hat{j}) := \arg \max_{h,j} \omega^{(h,j)} \delta_{\hat{N}}(I^{(h,j)})
\]

\[
\hat{X} := \{ (x, \ell) : \ell \in I^{(h,j)}, x = \int y^{(h,j)}(y, \ell) dy \}
\]

A. Multi-target state estimation

Given a multi-target posterior density, several multi-target state estimators are available. The Joint Multi-object Estimator and Marginal Multi-object Estimator are Bayes optimal, but difficult to compute [3]. A simple and intuitive multi-target and Marginal Multi-object Estimator are Bayes optimal, but states of the tracks, the maximum estimate of the states of the hypothesis with the highest weight. However, minimizing the number of prediction components to be updated can be readily computed with (say 95%) of the total updated PHD mass. These PHD masses would generate significant update components will save substantial computations. Similarly, further saving in computations can be achieved by knowing in advance which update components would generate significant prediction components.

The PHD/CPHD filter is a good approximation to the multi-target Bayes filter and is inexpensive compared to the \(\delta\)-GLMB update. Moreover, integration of the PHD filter within the \(\delta\)-GLMB filter is seamless as both filters are developed from the same RFS framework. Indeed, the PHD of (the unlabeled version of) a \(\delta\)-GLMB of the form (9) is given by (29):

\[
v(x) = \sum_{(I,\xi) \in \mathcal{F}(L) \times \Xi} v^{(I,\xi)}(x)
\]

where

\[
v^{(I,\xi)}(x) = \sum_{\ell \in I} \omega^{(I,\xi)} p^{(\ell)}(x, \ell).
\]

is the PHD of hypothesis \((I,\xi)\). Assuming that the detection probability and single measurement likelihood do not depend on the labels, the updated PHD is given by (see [5], [46], [47])

\[
v(x|Z) = \sum_{(I,\xi) \in \mathcal{F}(L) \times \Xi} \bar{v}^{(I,\xi)}(x|Z),
\]

where the constituent updated PHD \(\bar{v}^{(I,\xi)}(\cdot|Z)\) due to hypothesis \((I,\xi)\) is given by

\[
\bar{v}^{(I,\xi)}(x|Z) = (1 - p_D(x)) v^{(I,\xi)}(x)
\]

\[
+ \sum_{z \in Z} \frac{p_D(x) p(z|x) v^{(I,\xi)}(x)}{\kappa(z) + \sum_{(I,\xi) \in \mathcal{F}(L) \times \Xi} \langle p_D g(z|\cdot), v^{(I,\xi)} \rangle}.
\]

Note that \(\bar{v}^{(I,\xi)}(\cdot|Z)\) is not the same as the updated PHD of \(v^{(I,\xi)}\) given by

\[
v^{(I,\xi)}(x|Z) = (1 - p_D(x)) v^{(I,\xi)}(x)
\]

\[
+ \sum_{z \in Z} \frac{p_D(x) g(z|x) v^{(I,\xi)}(x)}{\kappa(z) + \langle p_D g(z|x), v^{(I,\xi)} \rangle}.
\]

The ratio of the constituent updated PHD mass \(\int \bar{v}^{(I,\xi)}(x|Z) dx\) to the total updated PHD mass \(\int v(x|Z) dx\) can be thought of as a selection criteria and is a good indicator of the significance of hypothesis \((I,\xi)\) after the update. A higher score indicates a greater significance. The proposed look-ahead strategy selects prediction hypotheses with highest constituent updated PHD masses that together makes up most (say 95%) of the total updated PHD mass. These PHD masses can be readily computed with \(O(|Z|^3)\) complexity, using SMC [46] or Gaussian mixtures [47]. Further improvement can be achieved by replacing the PHD update with the CPHD update with \(O(|Z|^3)\) complexity [26], [48]. Note that the \(\delta\)-GLMB update can reuse the computations in the PHD/CPHD update such as the Kalman gain and other variables.

A similar strategy can be employed to identify updated components that generates weak prediction hypotheses. Using the constituent predicted PHD masses as the selection criterion, we select updated hypotheses whose combined predicted PHD mass makes up most of the total predicted PHD mass.

A parallelizable look-ahead strategy can be formulated using the updated PHD \(v^{(I,\xi)}(\cdot|Z)\). The relative cardinality error \(\int v^{(I,\xi)}(x|Z) dx - |I|/|I|\) of hypothesis \((I,\xi)\) is a
measure of how well it explains the observed data $Z$, and is a possible selection criterion. Additional selection criteria are possible with the CPHD update since the cardinality distribution is available. Consider the PHD $\nu(I, \xi)$ of hypothesis $(I, \xi)$ and a Poisson cardinality distribution $\rho(I, \xi)$ with mean $\int \nu(I, \xi) | x | dx$. If hypothesis $(I, \xi)$ explains the observed data well, then the CPHD updated cardinality distribution $\rho(I, \xi) | Z \rangle$ should be close to $\delta_{\xi I}$. Hence, a possible selection criterion is the Kullback-Leibler divergence between $\rho(I, \xi) (| Z \rangle$ and $\delta_{\xi I}$. In both cases a lower score indicates a greater significance for hypothesis $(I, \xi)$ after the update.

Regardless of the particular look ahead strategy used, the selection criterion yields an unnormalized score for each hypothesis or component, which generally indicates how well the component explains the observed data. Thus for implementation a normalized score for each component can be derived such that a higher score indicates a better fit. A generic method for setting $T(h)$ is then to choose its value to be proportional to the normalized score for component $(I(h), \xi(h))$ and the desired overall number of components $J_{\text{max}}$.

VII. Numerical Example

We compare the performance of the $\delta$-GLMB and CPHD filters with a linear Gaussian example and hence Gaussian mixture implementation. A typical SNR scenario is employed to highlight the susceptibility of the CPHD filter to the so-called “spooky effect” [50]. The term spooky effect refers to phenomenon where the CPHD filter encounters a missed detection for a particular track and significantly reduces the weight of the undetected track by shifting part of its mass to other targets. The $\delta$-GLMB filter is generally immune to the spooky effect since it does not use an i.i.d. approximation of the posterior and hence cannot shift the probability mass of individual tracks between each other. Furthermore the $\delta$-GLMB filter is generally able to correct for CPHD look ahead errors.

Consider a set of multi-target trajectories on the two dimensional region $[-1000, 1000] m \times [-1000, 1000] m$. The duration of the scenario is $K = 100$. All targets travel in straight paths and with different but constant velocities. The number of targets is time varying due to births and deaths. There is a crossing of 3 targets at the origin at time $k = 20$, and a crossing of two pairs of targets at position $(\pm 300, 0)$ at time $k = 40$. The targets also become more dispersed as the time increases in order to elucidate the estimation errors caused by the spooky effect. The region and tracks are shown in Figure 5

The kinematic target state is a vector of planar position and velocity $x_k = [p_{x_k}, p_{y_k}, \dot{p}_{x_k}, \dot{p}_{y_k}]^T$. Measurements are noisy vectors of planar position only $z_k = [z_{x_k}, z_{y_k}]^T$. The single-target state space model is linear Gaussian according to transition density $f_{x_k | x_{k-1}}(x_k | x_{k-1}) = N(x_k; F_k x_{k-1}, Q_k)$ and likelihood $g_{z_k}(z_k | x_k) = N(z_k; H_k x_k, R_k)$ with parameters

$$F_k = \begin{bmatrix} I_2 & \Delta I_2 \\ 0_2 & I_2 \end{bmatrix}, \quad Q_k = \sigma_n^2 \begin{bmatrix} \Delta^2 I_2 & \Delta \dot{I}_2 \\ \Delta \dot{I}_2 & \dot{I}_2 \end{bmatrix},$$

$$H_k = \begin{bmatrix} I_2 \\ 0_2 \end{bmatrix}, \quad R_k = \sigma_n^2 I_2$$

where $I_n$ and $0_n$ denote the $n \times n$ identity and zero matrices respectively. $\Delta = 1 s$ is the sampling period, $\sigma_n = 5 m/s$ and $\sigma_z = 10 m$ are the standard deviations of the process noise and measurement noise. The survival probability is $p_{S,k} = 0.99$ and the birth model is a Labeled Multi-Bernoulli RFS with parameters $\pi_B = \{ r_B^{(i)}, p_B^{(i)} \}_{i=1}^3$ where $r_B^{(1)} = 0.04$ and $p_B^{(i)}(x) = N(x; m_B^{(i)}, P_B)$ with $m_B^{(1)} = [0, 0, 0, 0]$, $m_B^{(2)} = [-100, 0, -100, 0]^T$, $m_B^{(3)} = [100, 0, -100, 0]^T$, $P_B = \text{diag}([10, 10, 10, 10])^T$. The detection probability is $p_{D,k} = 0.88$ and clutter follows a Poisson RFS with an average intensity of $\lambda_c = 6.6 \times 10^{-5} m^{-2}$ giving an average of 66 false alarms per scan.

The $\delta$-GLMB filter is capped to 7777 components and is coupled with the parallel CPHD look ahead strategy described in the previous section. The CPHD filter is similarly capped to 7777 components through pruning and merging of mixture components. Results are shown over 100 Monte Carlo trials. Figures 6 and 7 show the mean and standard deviation of the estimated cardinality versus time. Figures 8 and 9 show the OSPA distance [51] and its localization and cardinality components for $c = 100 m$ and $p = 1$.

It can be seen that both filters estimate the target cardinality accurately, with the $\delta$-GLMB exhibiting better estimated cardinality variance. However the $\delta$-GLMB filter significantly outperforms the CPHD filter on the overall miss distance. Examination of the localization and cardinality components reveals that the $\delta$-GLMB filter outperforms the CPHD filter on both components. The improved cardinality performance is attributed mainly due to a lower estimated cardinality variance. The improved localization performance is attributed to two factors: (a) the spooky effect causes CPHD filter to temporarily drop tracks which are subjected to missed detections and to declare multiple estimates for existing tracks in place of the dropped tracks, and (b) the $\delta$-GLMB filter is generally able to better localize targets due to a more accurate propagation of the posterior density.
VIII. CONCLUDING REMARKS

This paper detailed the first implementation of the δ-GLMB multi-target tracking filter that is general enough to accommodate unknown and time-varying number of targets, non-linear target dynamics, non-uniform probability of detection and clutter intensity. A salient feature of this implementation is the high parallelizability. The key innovation lies in the truncation of δ-GLMB densities without exhaustive computation of all the components and the integration of PHD look-ahead to reduce the number of computations. Furthermore, it is established that truncation of a δ-GLMB density by keeping the highest weighted components minimizes the $L_1$-error in the multi-target densities.

It is also of interest to examine information theoretic criteria, such as the Kullback-Leibler divergence, for δ-GLMB truncation/approximation. Implementations using other multi-target filters (in place of the ranked assignment algorithm) to generate the significant δ-GLMB components can be explored to reduce numerical complexity. Approximation of δ-GLMB by other families, for example the labeled multi-Bernoulli, is another venue for further work.
