Abstract

Visual sensitivity, probed through perceptual detectability of very brief visual stimuli, is strongly impaired around the time of rapid eye movements. This robust perceptual phenomenon, called saccadic suppression, is frequently attributed to active suppressive signals that are directly derived from eye movement commands. Here we show instead that visual-only mechanisms, activated by saccade-induced image shifts, can account for all perceptual properties of saccadic suppression that we have investigated. Such mechanisms start at, but are not necessarily exclusive to, the very first stage of visual processing in the brain, the retina. Critically, neural suppression originating in the retina outlasts perceptual suppression around the time of saccades, suggesting that extra-retinal movement-related signals, rather than causing suppression, may instead act to shorten it. Our results demonstrate a far-reaching contribution of visual processing mechanisms to perceptual saccadic suppression, starting in the retina, without the need to invoke explicit motor-based suppression commands.
Introduction

Saccadic eye movements are a prominent feature of visual behavior; they allow successive sampling of visual information from the environment. However, from the perspective of the flow of visual information into the brain, these rapid eye movements constitute highly disruptive visual events, introducing spurious motions that should normally go unnoticed, or get canceled, at the level of perception. The question of how and why such perceptual cancelation takes place across saccades has intrigued philosophers and scientists for many decades\(^1\)–\(^4\). Indeed, visual sensitivity to brief visual probes is strongly impaired around the time of saccades, in a phenomenon known as saccadic suppression that has repeatedly been demonstrated in a multitude of experiments\(^5\)–\(^15\).

Despite the robustness of saccadic suppression as a perceptual phenomenon, the mechanisms behind it remain highly controversial. On the one hand, perceptual saccadic suppression may arise through internal knowledge of planned eye movements and their associated motor commands\(^5,13,16^-^19\). According to this popular view, internal knowledge of eye movement commands is a necessary prerequisite for saccadic suppression: a movement-related signal\(^17,18\), such as corollary discharge from (pre-)motor areas, may act as a suppressive command for visual neurons to cause perceptual suppression, and maybe even in a pathway-selective manner\(^11\).

On the other hand, perceptual saccadic suppression could alternatively, or additionally, arise as a result of the visual consequences of retinal image shifts caused by eyeball rotations\(^2,20^-^31\). After all, the early visual system, including the retina, is a highly sensitive light sensing device, and it therefore ought to capture visual transients associated with saccade-induced retinal image shifts. Such early
processing of visual transients could modulate the retinal output, jumpstarting an
image processing cascade to mediate perceptual saccadic suppression.

In this study, rather than arguing either strictly for or strictly against one of the above
two seemingly contrasting hypotheses, we instead asked to what extent they might
interact with and support each other for the ultimate service of perception. We were
specifically motivated by the fact that the very first visual processing stage in the
brain, the retina, is not only sensitive to visual transients (such as saccade-induced
image shifts), but it also possesses rich image processing circuitry that is capable, in
principle, of regularizing the visual disruptions\textsuperscript{32–37} caused by saccades. We therefore
asked: how much of the characteristics of perceptual saccadic suppression can be
explained by visual-only mechanisms? And, to the extent that there are visual-only
mechanisms underlying perceptual saccadic suppression, would the first neural locus
for such visual-only mechanisms indeed be the very first stage of visual processing in
the brain, the retina?

We used a multi-disciplinary approach in which we experimentally mimicked the
visual consequences of saccades and recorded neural activity from \textit{ex vivo} retinas of
different animal models. We also measured perceptual reports in humans using both
real saccades as well as simulated saccade-like image displacements. We found a
surprisingly far-reaching contribution of visual processing mechanisms to perceptual
saccadic suppression, starting in the retina, without the need to invoke explicit motor-
based suppression commands. Intriguingly, the role of motor-based commands
seems to be the opposite of what has been proposed before. Rather than sending an
explicit suppressive command to reduce the sensitivity of the visual system, motor-
based commands instead seem to minimize the duration of visually-derived saccadic suppression.

Results

Perceptual saccadic suppression depends on image content

We first asked human subjects to generate saccades across textured backgrounds, akin to how saccades may be made in real life. Subjects viewed coarse or fine textures (Fig. 1a, Methods and Supplementary Fig. 1). Starting from one of four locations on the display, subjects made 4.8 deg saccades towards display center (Fig. 1a, left). We varied saccade onset and endpoint locations, as well as texture images, across trials to avoid subjects remembering specific texture patterns (Methods). At a random time, a luminance pedestal (probe flash) was added to the texture background, for one display frame (approximately 12 ms; Methods), at one of four locations relative to the saccade endpoint (7 deg eccentricity; Fig. 1a, right). At trial end, the subjects were asked to localize the probe flash, and we analyzed how well they did so. We took care to ensure that the retinal region of flash location was stimulated with the background texture (rather than the edge of the monitor or the black surround of the dark laboratory) throughout any given trial (Methods). We also ensured that the size of the probe flash was larger than the image blobs in the coarse texture, such that average luminance variation within each flash was matched across trials and textures. Coarse and fine textures had blobs that approximated the sizes of retinal ganglion cell (RGC) or retinal bipolar cell receptive fields, respectively, at the retinal flash locations38 (Methods).

For both coarse and fine textures, subjects were strongly impaired in their ability to localize flashes presented peri-saccadically, thus experiencing strong perceptual
saccadic suppression (Fig. 1b, c). However, there was a clear dependence of the suppression on the background visual image: saccadic suppression started significantly earlier and recovered significantly later with saccades across coarse rather than fine textures (Fig. 1d; the highlighted time intervals show significant differences between coarse and fine textures at a p-value of p<0.001, cluster-based random permutation test\textsuperscript{39,40}; Methods). Moreover, the peak amount of suppression was stronger with the coarse textures (Fig. 1d). However, for both coarse and fine textures, performance reached a floor effect in this version of the experiment, masking an even larger difference (see below and Fig. 2). This dependence of perceptual saccadic suppression on background texture was robust across individual subjects (Supplementary Fig. 2a; also see Supplementary Fig. 4 for further individual subject effects).

To rule out the possibility that the difference in perceptual saccadic suppression profiles between the coarse and fine textures was due to the flashes being simply easier to see over the fine texture, we performed a control experiment in which we collected full psychometric curves of perceptual performance during simple fixation. We found that, without any saccades, the visibility of the probe flashes was identical over coarse and fine background textures (Supplementary Fig. 3a, b). Therefore, the image dependence of the results of Fig. 1 was related to saccadic suppression itself and not to the baseline visibility of brief flashes over the different textures. Similarly, we carefully analyzed eye movement properties, and we found that the results of Fig. 1 were also not due to different saccade kinematics for the different textures (Supplementary Fig. 3c, d).
To further explore the differences in suppression profiles that we observed in Fig. 1, we next employed a more sensitive procedure to evaluate perceptual thresholds. Specifically, we repeated the same experiment of Fig. 1 on five subjects (three of whom being the same as those who participated in the earlier experiment). This time, we collected full psychometric curves of perceptual performance (Methods; similar to Supplementary Fig. 3a, b). Because collecting full psychometric curves for each texture and each time point relative to saccade onset would be a very data-intensive endeavor, we reduced the number of time points relative to saccade onset at which we probed perception. We also expedited the data collection by implementing a real-time saccade detection algorithm, described by Chen and Hafed\textsuperscript{41}, and we presented the probe flash at four distinct times after online saccade detection. The four flash times were strategically chosen to evaluate peak suppression (shortly after saccade onset) as well as the time course of recovery after a saccade. We used an adaptive QUEST\textsuperscript{42} procedure to estimate the perceptual threshold per condition and flash time (Methods), with the perceptual threshold (for the purposes of QUEST) being defined as the flash contrast value resulting in 62.5% correct performance. Besides the QUEST procedure, we also collected more trials showing different flash contrast levels relative to estimated perceptual threshold, in order to obtain full psychometric curves. The results are shown in Fig. 2, and they match those of Fig. 1: relative to the baseline psychometric curves of flash visibility long after saccades (dashed curves), peri-saccadic psychometric curves were clearly shifted towards higher contrast thresholds (Fig. 2a-d), consistent with Fig. 1. More importantly, with the more sensitive approach of full psychometric curves, we could clearly see that perceptual saccadic suppression was much stronger for coarse than fine textures at peak suppression; that is, perceptual thresholds (defined as luminance increments required for a specific correct performance level; Methods) near peak suppression
were higher for coarse than fine textures (Fig. 2e). Supplementary Fig. 4 shows the corresponding individual subject psychometric curves and perceptual thresholds.

In summary, we found that perceptual saccadic suppression was associated with a visual component directly influencing its strength and time course: saccades across coarse textures were associated with both stronger and longer-lasting perceptual suppression than saccades across fine textures, even when the kinematics of the eye movements (and thus the underlying motor commands) did not differ across the two conditions.

Perceptual saccadic suppression originates in the retina

To test if this visual component of perceptual saccadic suppression originates in the retina, we isolated mouse and pig retinas and performed multi-electrode array recordings (Methods). We continuously exposed each retina to coarse and fine textures, matched to ganglion and bipolar cell receptive field sizes in the recorded species (Methods, Supplementary Fig. 1). We rapidly translated the textures globally to simulate saccade-like image displacements (Fig. 3a, Methods). Such displacements can robustly activate RGCs, as is evident from the example mouse RGC shown in Fig. 3b. In fact, most recorded RGCs (mouse: 83% of 1,423 cells, pig: 73% of 394 cells) responded robustly to texture displacements, indicating that saccade-induced visual transients during active gaze behavior can constitute strong signals to the retina. Next, at different times relative to texture displacements, we introduced a luminance pedestal (probe flash) to the entire texture for 16 or 33 ms, similar in principle to the perceptual experiments of Figs. 1, 2. Such flashes, when presented in isolation (that is, temporally removed from the texture displacement), elicited responses in a sizable fraction of RGCs (baseline response; mouse: 688 of
1,423 RGCs; pig: 228 of 394 RGCs). This allowed us to evaluate the consequences of texture displacements on flash responses in these cells, in a way that is conceptually similar to the experiments in Figs. 1, 2, in which we evaluated the consequences of saccades on flash perception. For example, the same RGC of Fig. 3b showed much suppressed neural responses to the flash when it was presented immediately after texture displacements compared to the baseline condition (Fig. 3c, d). This suppression of flash-induced responses (Fig. 3d) looks remarkably similar to suppression of visual responses in, say, macaque superior colliculus for stimuli presented after real saccades. Thus, neuronally, there does exist “saccadic suppression” of visual sensitivity at the very first stage of visual processing in the brain, the retina, and it looks qualitatively indistinguishable from saccadic suppression at downstream neural sites and, indeed, perception (Figs. 1, 2).

Importantly, retinal “saccadic suppression” strongly depended on background texture (Fig. 3e), exactly like in our human experiments (Figs. 1, 2). Specifically, we quantified retinal “saccadic suppression” by calculating a neuronal modulation index, defined as \( \frac{r_d - r_b}{r_d + r_b} \). Here, \( r_d \) is the response strength to the probe flash presented with a delay \( d \) relative to the texture displacement onset, and \( r_b \) is the response strength in baseline (Methods). This modulation index is, by definition, negative for suppressed flash-induced responses. The great majority of RGCs were strongly suppressed during and after texture displacements, with gradual recovery afterwards (Fig. 3e; Supplementary Fig. 5 shows the underlying population data), and the suppression was more pronounced for coarse than fine textures (Fig. 3e; Supplementary Fig. 5). These results are consistent with the dependence of human perceptual saccadic suppression on background texture statistics shown above (Figs. 1, 2), suggesting that this dependence starts already in the retina.
We also found that retinal “saccadic suppression” was a robust phenomenon across many different RGCs, with diverse properties (Supplementary Fig. 6). Further, it occurred both in mouse (Fig. 3e, left) and pig (Fig. 3e, right) retinae, two mammalian species with different native oculomotor behavior, different lifestyles, and different eye sizes. Thus, our results so far suggest that perceptual saccadic suppression (Figs. 1, 2), including its dependence on background texture statistics, most likely originates in the retina (Fig. 3), being the outcome of very general retinal-circuit mechanisms that are conserved across species.

Stimulus-stimulus interactions underlie retinal suppression

To understand the underlying mechanisms for retinal “saccadic suppression” in more detail, we explored its properties using different analyses and additional stimulus manipulations. First, we wondered about neural activity saturation, given that saccade-like texture displacements before flash onset could activate RGCs (e.g. Fig. 3b). Specifically, if RGC activity is elevated by the texture displacement alone (because it was a visual transient), then any subsequent flash-induced response could have caused the cell to reach activity saturation. However, this was not sufficient to explain our results. For example, we observed that suppression often also occurred in RGCs that did not respond strongly to the texture displacements in the first place (Fig. 4a).

Second, we investigated whether retinal “saccadic suppression” critically depended on particular saccade-like profile speeds. In the original experiments of Fig. 3, we simulated saccade-induced image translation speeds to the best of our abilities (given the sampling rate of our display; Methods). However, if we replaced the
original translation over 100 ms with a sudden texture jump from the start- to end-
position in one display update (an infinite-speed texture jump), then the same
suppression took place, with similar dependence on texture statistics (Fig. 4b).
Similarly, in yet another manipulation, when we presented first a flash and then a
texture displacement, then the second response (now to the texture displacement)
was suppressed (Fig. 4c). This suggests that retinal “saccadic suppression” can be
explained by general stimulus-stimulus interaction effects in the retina. As a result, it
is a phenomenon that is unlikely to critically depend, at least qualitatively, on the
specific oculomotor repertoire of either mice, pigs, or humans.

The most compelling evidence for stimulus-stimulus interactions underlying retinal
“saccadic suppression” came from experiments when we replaced the texture
displacements with a structure-free luminance step (Fig. 4d). Specifically, instead of
a background texture and a displacement of this texture, we exposed the retina to a
uniform gray background and introduced a sudden uniform luminance increase or
decrease as the visual transient. This luminance step was either of high contrast (+/-
0.20 to 0.40 Michelson contrast) or low contrast (+/- 0.03 to 0.15 Michelson contrast)
(Methods). The probe flash then followed the luminance step as in the original
experiments. We found that responses to probe flashes were indeed suppressed
after luminance steps. This suppression was stronger after high-contrast visual
transients than after low-contrast visual transients. Interestingly, the suppression
after high- and low-contrast luminance steps was quantitatively similar to the
suppression after coarse and fine texture displacements, respectively (e.g. Fig. 3),
both for the time course of suppression and its strength (Fig. 4e). Presumably,
moving the larger blobs of a coarse texture across the retina would result in high-
contrast changes within individual retinal receptive fields (e.g. from a bright blob in a
receptive field before the texture displacement to a dark blob after the displacement),
while the smaller blobs in the fine texture would be spatially averaged within
receptive fields, resulting in low-contrast changes.

When we next performed human psychophysical experiments mimicking the
luminance step retinal experiments, we found remarkably congruent results (Fig. 5).
Specifically, subjects maintained saccade-free fixation, and we simply changed the
luminance of the homogenous background (Methods). At random times relative to
the change in luminance, we presented brief probe flashes exactly like we did in Fig. 1. In all subjects, we found clear perceptual suppression in response to the
luminance steps. Importantly, we also found clear dependence of perceptual
suppression on the contrast of the luminance change: when there was a small
change in background luminance, suppression was minimal; when there was a large
change in background luminance, suppression was strong and long-lasting (Fig. 5).
As we discuss below, we observed perceptual suppression even for flashes before
the background luminance changes; this matters for interpretations of pre-movement
perceptual saccadic suppression (e.g. see Fig. 6 below).

Therefore, the most likely mechanism for our retinal “saccadic suppression” effect is
that such suppression emerges as a result of retinal-circuit image processing that is
initiated by visual transients; whether they be through texture displacements, infinite-
speed texture jumps, or luminance steps (Fig. 4e). It is very intriguing that such
stimulus-stimulus retinal effects may be inherited all the way deep into the brain’s
visual processing hierarchy, including cortical (frontal eye field) and subcortical
(superior colliculus) areas that are also implicated in saccadic suppression.
Motor-related signals shorten visually-derived suppression

In retina, we not only observed similarities to perceptual saccadic suppression (the presence of retinal suppression, and its dependence on texture statistics or luminance step contrast), but we additionally noticed that retinal “saccadic suppression” was particularly long lasting (e.g. Fig. 3e). To explore the potential perceptual implications of this observation, we next asked our human subjects to maintain fixation while we introduced saccade-like texture displacements in a manner similar to the retinal experiments of Fig. 3 (Fig. 6a, Methods); brief flashes occurred around the time of these “simulated saccades” exactly like in the first experiment (Fig. 1). This time, due to the absence of real saccades (trials with microsaccades were excluded; Methods), non-visual (motor-related) components could not influence flash-induced neural responses and their perception. Still, given the retinal results of Figs. 3, 4, we had three hypotheses on what to expect under these conditions, all of which we were able to validate: (1) strong perceptual suppression still occurred regardless of texture details (Fig. 6b, c); (2) suppression strength and duration depended on texture statistics (Fig. 6d); and (3) suppression outlasted the suppression with real saccades (Fig. 6e, f). This last point, in particular, suggests that motor-related signals associated with real saccades may act to shorten the perceptual interruption resulting from visually-induced saccadic suppression, while maintaining the putatively retinally-determined (Figs. 3, 4) dependence on image statistics. Note also that the first and third points above are consistent with earlier perceptual results shown by Diamond et al\textsuperscript{17}.

In humans, we observed perceptual suppression also prior to saccade-like texture displacements\textsuperscript{20,27} (Fig. 6). This was again consistently dependent on texture statistics (Fig. 6b-d; also see Fig. 7 below for additional evidence). Further, like the
suppression after saccade onset, this pre-saccadic perceptual suppression was also
shorter during real saccades than during simulated saccades (due to later onset of
suppression, Fig. 6e). Even in our retinal data, we found very slight “pre-saccadic”
suppression. However, the effect size of retinal suppression before texture
displacements was much smaller than after texture displacements: the strongest
“pre-saccadic” retinal effect occurred at -67 ms with a median population modulation
index of -0.024 (p = 6 x 10^{-8}, Wilcoxon signed-rank test) compared to -0.55 (p = 3 x
10^{-82}) for “post-saccadic” suppression at 150 ms delay (Fig. 3e, Supplementary Fig.
5b). It is therefore likely that this particular phenomenon, perceptual pre-saccadic
suppression (Fig. 6b-f), arises not in the retina, but from visual (not movement-
command-related) processing further downstream, perhaps through backwards
masking\(^{29,47}\). This also holds true for our perceptual experiments with background
luminance steps (Fig. 5), and it can also explain why the time of peak suppression in
our retinal experiments (Figs. 3, 4) may have been slightly different from the time of
peak suppression with real saccades (Figs. 1, 2).

Since the results of Fig. 6 did not explicitly report perceptual thresholds, we also
repeated the same experiment again, but this time using the QUEST and full
psychometric curve procedures described above for Fig. 2. In the current experiment,
we again picked 4 specific time points relative to texture displacement onset for
calculating perceptual thresholds (Methods). Like in the case of Fig. 2, we chose
these 4 time points strategically to highlight perceptual threshold elevations at
maximal suppression and also to highlight differences between coarse and fine
textures. We also explicitly sampled a negative time point close to texture
displacement onset, such that we could fill in the gap in the negative time courses
shown in Fig. 6. The net conclusion (Fig. 7) was the same as that in Fig. 6. There
was robust elevation of perceptual thresholds before, during, and after the texture
361 displacements. Most importantly, the elevation was much stronger and longer-lasting
362 (both before and after texture displacements) for coarse than for fine textures. The
effect was also robust across individual subjects (Supplementary Fig. 7).
364
Therefore, the long-lasting suppression effects that we observed in RGCs (Figs. 3, 4)
366 were not an idiosyncrasy of the ex vivo electrophysiological procedures that we used,
367 but they were reflected in the longer duration of perceptual suppression after
368 simulated saccades. Importantly, they were indicative of a potential shortening of
369 visually-derived suppression in association with real saccades.
370
Visually-derived suppression underlies even more phenomena
371 Our results so far suggest that visual contributions can go a very long way in
373 explaining properties of perceptual saccadic suppression (e.g. the presence of
374 suppression, and the dependencies on image content), without the need for invoking
375 mechanisms related to motor commands. We therefore wondered whether such
376 contributions can also explain classic suppression phenomena in experiments when
377 uniform, rather than textured, backgrounds are used. One such robust phenomenon
378 has been the selective suppression of low spatial frequencies. In a classic study by
379 Burr et al\textsuperscript{11}, subjects viewed briefly flashed Gabor gratings over a uniform
380 background. Around the time of saccades, visibility of low-spatial frequency gratings
381 was suppressed much more strongly than of high-frequency gratings, and this was
382 interpreted as a motor-related influence on magnocellular pathways\textsuperscript{17,18}. Still,
383 convincing neural mechanisms for this phenomenon remain elusive\textsuperscript{7,22,30,31,48–53}. Can
384 the strong prominence of visual contributions to saccadic suppression revealed in our
385 results so far also be extended to account for this classic phenomenon? In other

15
words, is the selective suppression of low spatial frequencies around the time of saccades intrinsically a visual, rather than motor, phenomenon?

The answer lies in considering this phenomenon from the perspective of visual input during such experiments: saccades across a uniform background invariably involve moving the image of the video monitor (or other form of display) in visual coordinates. Therefore, the image of any edge discontinuity associated with the display monitor (or with the surrounding cardboard paper around it) will invariably move across the retina because of the saccade. This allows us to ask if one can replicate selective suppression of low spatial frequencies without any saccades at all, solely based on the visual flow experienced during such experiments.

We first replicated the classic phenomenon itself. Our subjects localized briefly flashed vertical Gabor gratings with different spatial frequencies (Methods); the flashes occurred peri-saccadically as in Fig. 1a. Here, however, the screen was a homogeneous gray, like in the classic experiment, with the exception of a surround region showing a stationary texture (the coarse texture used in our earlier experiments, Fig. 8a). We call the large homogeneous central region of the screen (diameter: 20 deg) the "virtual monitor". The outcome confirmed the classic findings: Fig. 8b (left) shows localization performance for flashed gratings around saccade onset, compared to flashes without saccades (and without any other display transients; Methods), and Fig. 8b (right) plots the ratio of those percepts as a visualization aid. Perception of low spatial frequency gratings was selectively suppressed (relevant statistics are shown in Fig. 8; full time courses of these effects are shown in Supplementary Figs. 8, 9). These results are consistent with the classic phenomenon.
The presence of the textured surround allowed us to next isolate the effects of visual flow during these experiments. In separate trials, we asked subjects to fixate, and we presented saccade-like image motion. For example, in order to simulate a real saccade from the lower right corner to display center (Fig. 8a), the virtual monitor moved together with its textured surround from the top left corner towards display center (Fig. 8c). We then briefly presented the same Gabor gratings as in Fig. 8a, b. Relative to fixation position, this experiment was comparable to the situation with real saccades: there was a uniform background against which a brief Gabor grating was flashed. And, indeed, we observed the same selective suppression of low spatial frequencies despite the absence of saccades (Fig. 8d). Moreover, again consistent with our results from Figs. 1-7, the suppression with simulated saccades lasted longer than with real saccades (robust selective suppression in Fig. 8d occurred even 84 ms after simulated saccades; Supplementary Figs. 8, 9). Similar results were obtained with a uniform black surround around the virtual monitor, as might be the case in typical laboratory settings (Supplementary Fig. 10). Therefore, visual mechanisms account even for the results of Burr et al\textsuperscript{11} and similar experiments\textsuperscript{7} using uniform backgrounds, without the need to invoke non-visual (motor-related) mechanisms.

Motivated by the differences between coarse and fine textures in Figs. 1-7, we next replaced the coarse texture around the virtual monitor (Fig. 8c) with a fine texture, and we repeated the experiments with simulated saccades (Fig. 8f). In this case, surprisingly, we observed uniform suppression of gratings of all spatial frequencies (Fig. 8f). In other words, the specific suppression of low spatial frequencies observed earlier (Fig. 8c, with saccade-like visual flow, but without eye movements) depended
on the visual context containing a coarse pattern in the visual surround. This led us to make a strong prediction: if saccadic suppression properties do indeed rely on visual processing, then suppression during real saccades should depend mainly on visual context, and one should be able to easily violate the classic phenomenon (namely, the specific suppression of low spatial frequencies\(^1\)). This is exactly what we found (Fig. 8e): for real saccades across the virtual monitor, and with the surrounding visual context being a fine rather than coarse texture, we observed perceptual suppression for all gratings, abolishing suppression selectivity for low spatial frequencies. In all cases, the effects were not explained by motor variability across surround texture conditions (Supplementary Fig. 3e, f).

All of these observations were further confirmed when we repeated the same experiments but now collecting full psychometric curves (Methods), similar to Figs. 2 and 7 above: Fig. 9 shows results for real saccades, and Fig. 10 for simulated saccades. In both cases, when there was a coarse texture in the surround, perceptual threshold was elevated (i.e., perception was suppressed) more strongly for low-spatial frequency Gabor patches. With a fine texture surround, perceptual threshold was elevated non-specifically for all probe Gabor patches.

In summary, perceptual saccadic suppression occurred in all of our experiments, either with or without real saccades, simply as a function of visual flow (Figs. 1, 2, 6-10). Simple visual transients, without the need for saccade-like stimulus kinetics, were sufficient to elicit suppression in both retina and perception (Figs. 4, 5). Such suppression quantitatively depended on scene statistics, both for full-field textures (Figs. 1, 2, 6, 7) in a manner predicted by retinal processing (Figs. 3-5), and for
19

textures limited to the surround (Figs. 8-10). Even the suppression selectivity of low spatial frequency probes\textsuperscript{11} was determined by visual context (Figs. 8-10).

Discussion

We found that visual image processing accounts for a large component of classic perceptual demonstrations of saccadic suppression, and that such image processing occurs as early as in the very first stage of visual processing, the retina. This early neural implementation is interesting because it suggests that the image dependence of perceptual saccadic suppression that we observed (Figs. 1, 2) is derived, at least in part, from visual image processing starting in the retina. In fact, we found remarkable congruence between the image dependence of three seemingly disparate phenomena: perceptual suppression with real saccades (Figs. 1, 2), perceptual suppression with simulated saccades (texture displacements; Figs. 6, 7), and neural suppression patterns in RGCs, which carry the retinal output (Figs. 3, 4).

In all cases, modifying the background texture statistics resulted in highly predictable changes in suppression profiles. This was further corroborated when we replaced the texture displacements with simple luminance steps (instantaneous changes of background luminance) in both the retina (Fig. 4d) and perception (Fig. 5).

Key to all of our observations is the single insight that, from the perspective of visual image processing, a saccade is itself a potent stimulus to the visual system. For example, our RGCs often responded vigorously to saccade-like image displacements (Fig. 3b). Therefore, when probing perceptual sensitivity around the time of saccades using brief flashes, as in classic studies of perceptual saccadic suppression, the visual system is not only responding to the externally provided brief flashes, but it is also responding to the self-induced visual flows caused by eyeball rotations. These
saccade-induced rapid image shifts across the retina trigger visual mechanisms that can suppress the response to subsequent stimulation. Such suppression of neural responses is not exclusive to saccades. It instead occurs for any scenario that involves sequential visual stimulation, including visual masking paradigms\textsuperscript{2,28,29,47} and double-flash paradigms\textsuperscript{44}. It is therefore not surprising that the outcome is also comparable: the response to a second stimulus is suppressed by the presence of a first stimulus, be it a mask, a flash, or transients caused by saccade-induced image shifts across the retina. Indeed, our own results demonstrate that sequential visual stimulation (luminance step plus probe flash) shows qualitatively similar perceptual (Fig. 5) and retinal (Fig. 4d) suppression profiles to those seen with simulated saccades. Therefore, classic saccadic suppression paradigms, employing brief visual probes in the temporal vicinity of saccades, are essentially stimulus-stimulus paradigms from the perspective of visual flow on the retina.

Additional support for the above sentiment emerges from the time courses of stimulus-stimulus neural adaptation effects in areas like the frontal eye field and superior colliculus\textsuperscript{44}. These time courses are particularly intriguing to us, primarily because they agree with our observations that retinal (Figs. 3, 4) and perceptual (Figs. 6, 7) suppression with simulated saccades had longer suppression time courses than observed with real saccades (Figs. 1, 2). Indeed, the time courses of the neural adaptation effects in the frontal eye field and superior colliculus\textsuperscript{44}, and related brain areas, are similar to our observed perceptual time courses in the absence of real saccades. Given that both the frontal eye field and superior colliculus have previously been implicated in suppression with real saccades\textsuperscript{7,43,45,46}, it is thus conceivable that saccadic suppression in these areas is inherited, at least partially, from the retina.
Looking forward, we believe that it is imperative to also investigate the neural mechanisms behind visual masking in much more detail. In our perceptual experiments with simulated saccades (Figs. 6, 7), we saw clear suppression of perceptual performance even when the probe flashes appeared before texture displacement. That is, perceptual localization of the probes was masked, backwards in time, by the subsequent texture displacement. In the past, pre-saccadic suppression with real saccades (e.g. Fig. 1) has sometimes been taken as evidence that perceptual saccadic suppression is fundamentally driven by motor-related signals like corollary discharge. However, our results (Fig. 6, 7) show that motor activity is not required, and a visual transient is sufficient. Even simple background luminance steps were associated with pre-step perceptual suppression (Fig. 5). These effects have been described as backwards visual masking\textsuperscript{47}, but what are the underlying neural mechanisms? Such backwards masking was not present in our retinal results, certainly not as clearly as in perception, so it must emerge through visual mechanisms in other brain structures.

One possibility could be related to the fact that perception necessarily involves an interpretation of sensory evidence that is strongly dependent on priors. In the case of global retinal image motion, which is caused by eye movements in most real-world scenarios, priors could influence the percept of a flash occurring before a saccade or texture displacement. Specifically, such priors may cause perception to “omit” the pre-saccadic flash even though it evokes a strong retinal transient. This would happen exactly because of the pairing of the flash with a very likely occurrence of a saccade, interpreted as such due to the global image motion, even if its neural transient in the retina is weakened by the prior flash. This would result in a kind of
credit assignment problem due to a strong prior association of global image motion
with saccades.

More generally, our results suggest that visual flow matters a great deal in perceptual
saccadic suppression, even in paradigms that have often been taken as indication for
motor-related top-down suppression (Figs. 8-10). It would be interesting in the future
to further test the generalizability of this notion. We were indeed greatly surprised
when we performed the experiments of Figs. 8-10, and found that the classic
selective suppression of low spatial frequencies in perception around the time of
saccades\textsuperscript{11} can be violated in two important ways. First, the selectivity of suppression
can be abolished with a simple change of visual context. Second, the same selective
suppression of low spatial frequencies can be obtained without saccades at all. Thus,
with or without saccades, either selective or nonselective suppression could occur as
a function of visual flow. In hindsight, this might shed light on a somewhat surprising
recent finding in superior colliculus neurons\textsuperscript{7}. There, using essentially the same
paradigms, it was found that only one type of superior colliculus visually-responsive
neurons (so-called visual-motor neurons) exhibited selective suppression of low
spatial frequency sensitivity as in the classic perceptual phenomenon\textsuperscript{7}. The other
type of visually-responsive superior colliculus neurons (visual-only neurons) showed
mild suppression but, critically, no selectivity for spatial frequency\textsuperscript{7}. These two types
of neurons occupy different laminae of the superior colliculus and have different
patterns of lateral interactions from across the visual field representation of this
structure\textsuperscript{54}. It is now very conceivable, in light of our current results (Figs. 8-10), that
both patterns of suppression (selective or not) may be embedded simultaneously in
these different neuronal populations with specific circuitry and tuning for visual
peripheral contexts.
Finally, it should be emphasized that motor-related mechanisms still likely play an important role in perceptual saccadic suppression. In fact, such mechanisms seem to be equally important as the visual mechanisms, since motor-related mechanisms appear to shorten pre- and post-saccadic suppression originating from visual processing (Fig. 6), and might therefore minimize the duration of saccade-induced disruptions. Indeed, there is evidence for post-saccadic enhancement of excitability in a variety of cortical areas\textsuperscript{55–57}. It would be interesting to further investigate how such neural enhancement may contribute to the shortened time courses of perceptual saccadic suppression that we observed (e.g. Fig. 6e, f). Furthermore, besides just suppression, saccades are also associated with “omission”, the lack of awareness of intra-saccadic background image motion\textsuperscript{23,58}. It would, therefore, also be interesting to study the neural mechanisms through which strong neural transients in the retina in association with saccades (Fig. 3b) are perceptually “omitted” to give the illusion of continuous perception across saccades. More intriguingly, saccades also cause spatial updating of visual reference frames (due to the image shifts that they cause). Information contained in the motor command itself is likely critical for adjustments of spatial receptive fields across saccades, which have been observed in parietal and frontal cortices\textsuperscript{59,60}. Our findings leave open the possibility, however, that trans-saccadic image flow might play a role in this phenomenon as well.
Methods

Ethics approvals

We performed electrophysiological experiments on *ex vivo* mouse and pig retinas as well as non-invasive perceptual experiments on human subjects.

Animal use was in accordance with German and European regulations, and animal experiments were approved by the Regierungspräsidium Tübingen.

Human subjects provided written, informed consent, and they were paid 8-15 Euros per session of 45-90 minutes each. Depending on the experiment, each subject was measured for 2-10 sessions (detailed trial and session numbers are provided below). Human experiments were approved by ethics committees at the Medical Faculty of Tübingen University, and they were in accordance with the Declaration of Helsinki.

Retina electrophysiology laboratory setup

We used retinae extracted from *PV-Cre x Thy-S-Y* mice (*B6;129P2-Pvalbm1(cre)Arbr/J × C57BL/6-tg (ThystopYFPJS)*) (B6;129P2-Pvalbm1(cre)Arbr/J × C57BL/6-tg (ThystopYFPJS)), which are functionally wild type\(^{61-63}\). 23 retinae from 7 male and 15 female mice (3-12 months old) were used. We also replicated experiments on pig retinae obtained from domestic pigs after they had been sacrificed during independent studies at the Department of Experimental Surgery in our Medical Faculty. We used 9 pig retinae.

We housed mice on a 12/12 h light/dark cycle, and we dark adapted them for 4-16 h before experiments. We then sacrificed them under dim red light, removed the eyes, and placed eyecups in Ringer solution (in mM: 110 NaCl, 2.5 KCl, 1 CaCl\(_2\), 1.6
MgCl₂, 10 D-glucose, and 22 NaHCO₃) bubbled with 5% CO₂ and 95% O₂. We removed the retina from the pigment epithelium and sclera while in Ringer solution.

Pigs were anesthetized using atropine, azaperone, benzodiazepine (midazolam), and ketamine, and then sacrificed with embutramide (T61). Before embutramide administration, heparin was injected. The pigs were dark-adapted for 15-20 min before sacrifice. Immediately after sacrifice, the eyes were enucleated under dim red light, and the cornea, lens, and vitreous were removed. Eyecups were kept in CO₂-independent culture medium (Gibco) and protected from light. We transported eyecups to our laboratory and cut pieces from mid-peripheral or peripheral retinas.

We recorded retinal ganglion cell (RGC) activity using either low or high-density multi-electrode arrays (MEAs). The low-density setup consisted of a perforated 60-electrode MEA (60pMEA200/30ir-Ti-gt, Multichannel Systems, Reutlingen, Germany) having a square grid arrangement and 200 μm inter-electrode distance. We mounted an isolated retina on a nitrocellulose filter (Millipore) with a central 2 x 2 mm hole. The mounted retina was placed with the RGC side down into the recording chamber, and good electrode contact was achieved by negative pressure through the MEA perforation. We superfused the tissue with Ringer solution at 30-34 °C during recordings, and we recorded extracellular activity at 25 kHz using a USB-MEA-system (USB-MEA 1060, Multichannel Systems) or a memory-card based system (MEA1060, Multichannel Systems). More details are provided in Reinhard et al. The high-density MEA setup consisted of either a HiDens CMOS MEA (developed by the lab of Andreas Hierlemann, Basel, Switzerland) or a MaxOne system (Maxwell Biosystems, Basel, Switzerland). The HiDens CMOS MEA featured 11,011
metal electrodes with inter-electrode (center-to-center) spacing of 18 μm placed in a honeycomb pattern over an area of 2 x 1.75 mm. Any combination of 126 electrodes could be selected for simultaneous recording. The MaxOne MEA featured 26,400 metal electrodes with center-to-center spacing of 17.5 μm over an area of 3.85 x 2.1 mm. In this system, up to 1,024 electrodes could be selected for simultaneous recordings. For each experiment, a piece of isolated retina covering almost the entire electrode array was cut and placed RGC-side down in the recording chamber. We achieved good electrode contact by applying pressure on the photoreceptor side of the retina by carefully lowering a transparent permeable membrane (Corning Transwell polyester membrane, 10 μm thick, 0.4 μm pore diameter) with the aid of a micromanipulator. The membrane was drilled with 200 μm holes, with center-center distance of 400 μm, to improve access of the Ringer solution to the retina. We recorded extracellular activity at 20 kHz using FPGA signal processing hardware and custom data acquisition software.

In total, we performed 36 recordings, 24 from mouse and 12 from pig retina. 15 of the 36 recordings were done using low-density MEAs. Once a basic experimental protocol was established, we shifted to HiDens CMOS MEA providing much higher throughput. 12 experiments were done using this setup. We upgraded to the MaxOne MEA for even higher throughput and did our final 9 recordings using this setup.

We presented light stimuli to the retinal piece that was placed on the MEA using a DLP projector running at 60 Hz (Acer K11 for low-density MEA experiments and Lightcrafter 4500 for high-density MEA experiments). 60 Hz is above the flicker fusion frequency of both mouse and pig retinas; therefore, the framerate of these
projectors was adequate for our purposes. The Acer K11 projector had a resolution of 800 x 600 pixels covering 3 x 2.25 mm on the retinal surface. Lightcrafter 4500 had a resolution of 1280 x 800 pixels, extending 3.072 x 1.92 mm on the retinal surface. We focused images onto the photoreceptors using a condenser (low-density MEA recordings, illumination from below) or a 5x objective (high-density MEAs, illumination from above). In each case, the light path contained a shutter and two motorized filter wheels with a set of neutral density (ND) filters (Thorlabs NE10B-A to NE50B-A), having optical densities from 1 (ND1) to 5 (ND5). Light intensity was adjusted to be in the mesopic range.

We measured the spectral intensity profile (in \( \mu W \text{ cm}^{-2} \text{ nm}^{-1} \)) of our light stimuli with a calibrated USB2000+ spectrophotometer (Ocean Optics) and converted the physical intensity into a biological equivalent of photoisomerizations per rod photoreceptor per second (R\(^{-}\) rod\(^{-}\) s\(^{-}\)), as described before\(^{63}\). Light intensities of the projector output covered a range of 3 log units (i.e. 1,000-fold difference between black and white pixels, over an 8-bit range). We linearized the projector output, and we used only grayscale images of limited contrast, spanning at most the range from 0 to 120 in the 8-bit range of the projector (see stimulus description below for details). Absolute light intensities were set to the mesopic level, where a stimulus intensity of ‘30’ in our 8-bit DLP projector scale (0-255) corresponded to 225 to 425 R\(^{-}\) rod\(^{-}\) s\(^{-}\), depending on the experimental rig used for the experiment (i.e. different DLP projectors and MEAs). We pooled all data from the different rigs because separate individual analyses from the individual setups revealed no effects of recording conditions in the different setups.
Human psychophysics laboratory setup

We used a similar laboratory setup to our recent experiments. Briefly, subjects sat in a dark room 57 cm in front of a CRT monitor (85 Hz refresh rate; 41 pixels per deg resolution) spanning 34.1 x 25.6 deg (horizontal x vertical). Head fixation was achieved with a custom head, forehead, and chin rest, and we tracked eye movements (of the left eye) at 1 kHz using a video-based eye tracker (EyeLink 1000, SR Research Ltd, Canada). Gray and texture backgrounds (e.g. Figs. 1, 6, 8-10) were always presented at an average luminance of 22.15 cd m$^{-2}$, and the monitor was linearized (8-bit resolution) such that equal luminance increments and decrements were possible around this average for textures and gratings. For the experiments in which we used luminance steps of the background as the visual transients replacing saccade-induced transients (Fig. 5), details of the luminances used are presented below with the experimental procedures.

Human Experiment 1 (Fig. 1) was performed by eight subjects (two female) who were 21-25 years old. All subjects were naïve to the purposes of the experiment, except for subject MB (an author). For Human Experiment 2, the “simulated saccade” version of Human Experiment 1 (Fig. 6), six of the same subjects participated. A control experiment for testing visibility of flashes without saccades and without saccade-like texture displacements (Supplementary Fig. 3a, b) was performed by six of the same subjects plus one non-naïve subject, ZH (another author).

In the variants of Human Experiments 1 and 2 in which we collected full psychometric curves and perceptual thresholds (e.g. Figs. 2, 7 and Supplementary Figs. 4, 7), five subjects (24-29 years old; one female) participated. Three of these subjects were the same as those who performed Human Experiments 1 and 2 above, confirming that
both variants of the experiments (either with a fixed flash contrast or with full
threshold calculations) allowed similar conclusions.

In the control experiment (Fig. 5) mimicking the retinal results of Fig. 4d, we collected
data from 5 subjects (25-29 years old; 2 female). 2 of these subjects were the same
as those who performed all experiments.

Human Experiment 3 tested suppression selectivity for low spatial frequencies (Fig.
8). Six subjects (three females, 23-25 years old) participated, and only subject MB
was non-naïve. Three subjects had also participated in Human Experiments 1 and 2
and most of their control versions above. A control version of Human Experiment 3
was also performed with black surrounds (Supplementary Fig. 10). This control
experiment was performed by the same subjects that participated in Human
Experiment 3.

We also ran a variant of Human Experiment 3 describing full psychometric curves of
perceptual detectability (Figs. 9, 10). For each of the real (Fig. 9) or simulated (Fig.
10) variants, we ran 4 subjects (24-29 years old; 1 female; 3 being the same as those
who performed the experiments of Figs. 8).

Across all experiments, we ensured that the same subjects performed real and
“simulated” saccade versions of a given paradigm so that we could make meaningful
comparisons between these two eye movement conditions.

Coarse and fine textures
We created coarse and fine textures (Supplementary Fig. 1a) by convolving a random binary (i.e. white or black) pixel image with a two-dimensional Gaussian blurring filter with the kernel

\[ G(x, y) = e^{-\frac{(x^2+y^2)}{2\sigma^2}} \]

The parameter \( \sigma \) of the kernel influenced the amount of blurring. This resulted in textures having effectively low-pass spectral content (Supplementary Fig. 1b) with a cutoff frequency \( (f_c) \) depending on \( \sigma \). As we describe below, we picked cutoff frequencies for coarse and fine textures that resulted in dark and bright image blobs approximating the receptive field sizes of RGCs (for coarse textures) and retinal bipolar cells (for fine textures). In other words, for a given species, coarse textures matched the resolution of RGCs, and fine textures matched the resolution of one processing stage earlier, the retinal bipolar cells.

For the \textit{ex vivo} experiments with mouse and pig retinas, we assumed receptive field diameters for RGCs of at least 150 \( \mu m \) (Supplementary Fig. 1c; the parameter \( \sigma \) of the Gaussian blurring filter would be half that value), and diameters for bipolar cells of 25 \( \mu m \) (see Zhang et al\(^{70}\)). For human psychophysics experiments, we estimated, from the literature\(^{38}\), the sizes of human parasol RGC receptive fields at eccentricities >6 deg from the fovea (our flash eccentricities were 7 deg) to be around 200 \( \mu m \). This translated into a cutoff frequency of \( \sim 0.68 \) cycles per deg (cpd) (Supplementary Fig. 1b). Bipolar cell receptive field sizes at this eccentricity were estimated to be 10 \( \mu m \) (corresponding to a cutoff frequency of \( \sim 13.7 \) cpd), based on sizes of human midget RGC receptive fields in the fovea\(^{38}\). When calculating the textures, the actual value of the parameter \( \sigma \) (in pixel-dimensions) always incorporated the specific experimental magnification factor between the stimulation screen and the retinal
projection of the image. Calculating power spectra for coarse and fine textures
confirmed that cutoff frequencies for a given species were consistent with our aimed
designs described above (Supplementary Fig. 1b).

For both retinal and perceptual experiments, we normalized pixel intensities in the
textures to have uniform variations in luminance around a given mean. In the retinal
experiments, we used pixel intensities (from our 8-bit resolution scale) ranging from 0
to 60 around a mean of 30, or ranging from 30 to 90 around a mean of 60 (see
Retina electrophysiology experimental procedures below for when each paradigm
was used). For the human experiments, textures had a mean luminance of 22.15 cd
m\(^{-2}\) with undulations in luminance in the texture within the range of 7.5-35.5 cd m\(^{-2}\).

Because each texture, particularly when coarse, could have patterns of dark and
bright blobs that human subjects can remember or interpret as potential
shapes/objects/figures, we varied the displayed texture images from trial to trial. This
was also necessary to avoid afterimages. We generated sets of 20 coarse and 20
fine textures, which we randomly interleaved across trials. Moreover, the textures
themselves were designed to be larger than the viewable display area, allowing us to
jitter the displayed sub-rectangle of each texture (within the viewable area of the
display) from trial to trial (we jittered the displayed sub-rectangle within a range of 0.6
x 0.6 deg in steps of 0.024 deg). This way, even fine patterns at foveal fixation
locations could not be memorized by the subjects across trials.

Retina electrophysiology experimental procedures

To simulate saccades in our ex vivo retina electrophysiology experiments, we
displaced the texture across the retina in 6 display frames (100 ms at 60 Hz refresh
rate). For easier readability, we sometimes refer to these saccade-like texture displacements as “saccades”. The textures were displaced in each frame by a constant distance along a linear trajectory. While each “saccade” lasted 100 ms, displacement direction was varied randomly for each “saccade” (uniformly distributed across all possible directions), and “saccade” amplitude could range from 310 μm to 930 μm (corresponding to a velocity range of 3,100-9,300 μm s⁻¹ on the retinal surface). In visual degrees, this corresponds to a velocity range of 100-300 deg s⁻¹ and displacement range of 10-30 deg in mice, well in the range of observed mouse saccade amplitudes. In fact, similar to primates, mice also have oculomotor behavior, even under cortical control. For example, they make, on average, 7.5 saccade-like rapid eye movements per minute when their head is fixed (humans make several saccades per second). We used the same retinal displacement range of 310 μm to 930 μm for pig retinae. To the best of our knowledge, pig oculomotor behavior has not been documented in the literature. However, with their larger eyeball sizes, our translations of the retinal image would correspond to slower saccades (e.g. small saccades in humans and monkeys), which are also associated with saccadic suppression. Moreover, we showed (Fig. 4) that retinal “saccadic suppression” is not critically dependent on the details of movement kinematics.

Each “trial” consisted of 39 successive sequences that each combined a “saccade” with a probe flash, as follows: there was first a “pre-saccade” fixation of 2 seconds, then a 100 ms “saccade”, followed by “post-saccade” fixation. The background texture was switched on at the beginning of each trial and was translated across the retina during each “saccade”. At a certain time from “saccade” onset (delay d, range: -177 ms to 2,100 ms), we presented a probe flash. In most cases, the probe flash
had a duration of 1 frame (~16 ms). We used 2 frames (~33 ms) in a subset of experiments (mouse: 161 of 688 cells analyzed for “saccadic suppression”; pig: 112 of 228 cells). Results were pooled across these paradigms as they were indistinguishable. For sequences containing no probe flash, the next “saccade” happened 4 seconds after the previous one. The probe flash was a full-screen positive (“bright”) or negative (“dark”) stimulus transient. In different experiments, only a subset of possible delays was used within a given set of trials, depending on total recording time for a given retina (see below).

Bright or dark probe flashes could happen in two different ways across our experiments. The results were indistinguishable between the two ways, so we pooled results across them. Briefly, in one manipulation, the probe flash was a homogeneous bright (pixel intensity of 60 in our 8-bit projectors) or dark (pixel intensity of 0) full-screen rectangle replacing the background texture (in these experiments, the textures themselves had intensities ranging from 0 to 60 pixel intensity; see Coarse and fine textures above). This way, the flash contrast from the underlying background luminance was variable (e.g. a bright flash on a bright portion of a texture had lower contrast from the underlying texture than the same flash over a dark portion of the texture). In the second manipulation, the bright and dark flashes were simply luminance increments or decrements (by pixel values of 30 on our 8-bit projectors) over the existing textures (like in our human perceptual experiments). This way, local contrast relationships in the background textures were maintained. In these experiments, the textures themselves had a range of 30-90 pixel intensities and a mean pixel value of 60 (on our 8-bit projectors). 332 of 688 cells that we analyzed for “saccadic suppression” experienced such probe flashes, whereas the rest (356 cells) experienced the homogenous probe flash. For pig retina recordings,
we always used the homogenous framework. However, in the subset of pig experiments where the 2-frame probe flash was employed (112 of 228 RGCs), we used a high-contrast probe flash such that a bright flash would be achieved by first going completely dark in the first frame followed by the bright flash in the next frame and vice versa for a dark flash. Again, all data were pooled across these different paradigms because their outcomes were indistinguishable.

The number of trials required during a physiology experiment depended on the number of conditions that we ran on a specific day. For example, testing 7 different flash delays required 15 trials (7 with bright probe flashes, 7 with dark probe flashes, and 1 without probes). In a given experiment, we always interleaved all conditions; that is, in any one of the 15 necessary trials, each of the 39 "saccades" could be followed by a bright or a dark probe at any of the 7 delays, or no probe at all. Moreover, we repeated the total number of conditions (e.g. the interleaved 15 trials) 4 times per session, and we averaged responses across repetitions. Since one trial typically lasted for 2 minutes, the example of 15 trials repeated 4 times lasted for approximately 2 hours. This was usually combined with additional conditions (e.g. other background textures), such that typical recordings lasted 10-12 hours. If the combination of conditions would have required even longer recordings in a given session, we typically reduced the number of conditions (e.g. we presented flashes at fewer delays).

We sometimes replaced the 100 ms “saccade” with an instantaneous texture jump, to test the sensitivity of retinal “saccadic suppression” (Fig. 3) to the kinematic properties of saccade-like texture displacements (Fig. 4b). Here, the texture simply jumped, in one display frame, from the pre- to the post-displacement position. All
other procedures were like described above. 31 RGCs were recorded with this paradigm.

In the control experiments of Fig. 4d, we used no textures at all. The screen was always a homogenous gray field, and the visual event of a "saccade" was replaced by an instantaneous step to a different gray value. The gray backgrounds had intensities between 30 and 90 (on our 8-bit projector). This instantaneous change in intensity caused either a positive contrast step (+0.03 to +0.50 Michelson contrast) or a negative contrast step (-0.03 to -0.50 Michelson contrast). A “trial” consisted of either 57 or 157 successive sequences that each combined a contrast step with a probe flash, as follows: there was first a “pre-step” fixation of 2 seconds (analogous to “pre-saccade” fixation in texture displacements), then an instantaneous switch to “post-step” fixation. At a certain time from the contrast step (delay: 17, 33, 50, 100, 250, 500, 1000 or 2,000 ms), we presented a 2-frame (~33 ms) probe flash. For sequences containing no probe flash, the next contrast step happened 4 seconds after the previous one. The probe flash was either a uniform negative step of -0.33 Michelson contrast ("dark") or a uniform positive step of +0.33 Michelson contrast ("bright").

Finally, we used other stimuli unrelated to the main experiments to help us characterize RGC types and other receptive field properties (e.g. response polarity, latency, transiency, and spatial receptive fields). These stimuli had the same mean intensities and intensity ranges as the textures used in each experiment. Below, we describe these stimuli for the condition in which the texture intensities ranged from 0 to 60 pixel intensity (represented as grayscale RGB values in the units of our 8-bit projects). In experiments in which the textures ranged in intensity from 30 to 90, all
intensities reported below were shifted upward by 30. (1) Full-field contrast steps. ON steps: stepping from 0 to 30 (+1 Michelson contrast) and from 30 to 60 (+0.33) for 2 s. OFF steps: stepping from 60 to 30 (-0.33) and from 30 to 0 (-1) for 2 s. (2) Full-field Gaussian flicker, 1 minute. Screen brightness was updated every frame and was drawn from a Gaussian distribution with mean 30 and standard deviation 9. This stimulus was used to calculate the linear receptive field filters of ganglion cells through reverse correlation (spike-triggered averaging of the stimulus history). (3) Binary checkerboard flicker, 10-15 minutes. The screen was divided into a checkerboard pattern; each checker either covered an area of 55 x 55 μm, 60 x 60 μm, or 65 x 65 μm depending on the recording rig. The intensity of each checker was updated independently from the other checkers and randomly switched between 10 and 50 or 0 and 120. This stimulus also allowed us to calculate the linear filters of cells’ receptive fields.

Human psychophysics experimental procedures

In Human Experiment 1, we presented a coarse or fine background texture (Fig. 1) for 800-1,700 ms in every trial. Over the texture, a white fixation marker (square of 7.3 x 7.3 arcmin) surrounded by a uniform gray circle of 30 min arc radius was presented at one screen location in order to guide gaze fixation onto the marker. The fixation marker was always at 4.8 deg eccentricity from display center, but its specific location was varied from trial to trial (up-right, up-left, down-right, or down-left relative to display center; 45 deg direction from horizontal). After the end of the initial interval, the fixation marker jumped to display center, instructing subjects to generate a saccade.
At a random time from the saccade instruction (47, 94, 153, 200, 247, or 507 ms), a luminance pedestal (probe flash) was applied for one display frame (~12 ms) at one of four locations relative to display center (7 deg above, below, to the right of, or to the left of center). Note that because the display was rasterized (that is, drawn by the computer graphics board from the top left corner in rows of pixels), the actual exact flash time and duration depended on the location of the flash on the display (but in a manner like other psychophysical experiments studying the same phenomenon, and also in a manner that is unlikely to affect our results). The luminance pedestal consisted of a square of 147.8 x 147.8 min arc in which we added or subtracted a value of 4.8 cd m$^{-2}$ to the texture pattern. Therefore, local contrast within the luminance pedestal was the same as that without the pedestal. Since all of our analyses revealed identical results whether the pedestal was a luminance increment or decrement, we combined these conditions in all analyses. At the end of the trial, subjects had to report their perceived flash location by pressing one of four buttons, corresponding to the four possible flash locations, on a hand-held response box.

Because saccadic reaction times were 156.9 +/- 3.3 ms s.e.m. across subjects, our choice of flash times above meant that we could analyze trials in which flashes appeared before or after saccade onset, allowing us to obtain full time courses (e.g. Fig. 1). Also, because of the display geometry, the retinal region that experienced a flash before, during, or after a saccade was always a region that was visually-stimulated by the texture before flash onset (rather than by the monitor edge or the black surround of the laboratory). Therefore, we maintained pre- and post-flash visual stimulation by texture background, as in the retinal experiments. We also ensured that flash locations were not coincident with saccade goal locations both retinotopically and also in display coordinates. We confirmed in separate analyses...
that similar effects of suppression (e.g. Fig. 1) occurred for each flash location separately.

We collected 576 trials per session in this experiment. Six subjects participated in 6 sessions each, and the remaining two participated in 3 or 4 sessions.

Human Experiment 2 (Fig. 6) was identical, except that the initial fixation marker was presented at display center and remained there for the entire duration of a trial. Instead of instructing a saccade 800-1,700 ms after fixation marker onset, we translated the entire background texture (switched on at trial onset) rapidly to simulate a saccade-like image displacement. Texture displacement consisted of a 6-frame translation at a speed of 176 deg s\(^{-1}\). Note that, because of our display refresh rate and geometry, this meant a slightly larger displacement (of 12.4 deg) when compared to the saccade sizes in Human Experiment 1. However, we chose this translation because it resulted in a sufficiently fast average speed of the displacement (average speed in the real saccades of Human Experiment 1 was 160 deg s\(^{-1}\)). This choice is not problematic because our retinal experiments revealed that visual mechanisms related to saccadic suppression were not sensitive to parameters of individual motion patterns (Fig. 4b).

In this experiment, the texture displacement happened in a diagonal direction to simulate the directions of saccadic displacements of Human Experiment 1 (and also to dissociate the direction of motion flow from the locations of the flashes, again as in Human Experiment 1). For example, the texture could move globally down-right, as might be expected (in terms of image motion) if subjects made upward-leftward saccades in Human Experiment 1. Also, flash times were chosen relative to the onset
of texture displacement from among the following values: -35, -24, 24, 47, 84, 108, 141, 200, 259, 494 ms.

All subjects participated in 10 sessions each in this experiment.

We also performed a control experiment, in which there was neither a real saccade (Human Experiment 1) nor a texture displacement (Human Experiment 2), but otherwise identical to these 2 experiments. Subjects simply fixated display center, and we presented (after 1,200 to 2,400 ms from trial onset) a luminance pedestal exactly as in Human Experiments 1 and 2. To obtain full psychometric curves, we varied the luminance increment from among 6 values (Supplementary Fig. 3a, b). Subjects performed two sessions each of this experiment (600 trials per session).

To explore perceptual thresholds in a more quantitative manner for Human Experiments 1 and 2, we also performed additional real or simulated saccade experiments collecting full psychometric curves (Figs. 2, 7 and Supplementary Figs. 4, 7). The logic of both additional experiments (real or simulated) was the same as that of Human Experiments 1 and 2, except that we varied the luminance of the probe flash from trial to trial (like in the above control experiment of flash visibility; Supplementary Fig. 3a, b). Because this endeavor (allowing us to measure full psychometric curves) was very data intensive, we reduced the time samples relative to saccade onset or texture displacement onset at which we probed perceptual performance. For the experiment with real saccades, we used an automatic procedure to detect saccade onset in real time based on eye velocity, as described by Chen and Hafed. We then presented the probe flash at 42, 65, 88, or 148 ms after saccade detection. These times were chosen because they covered intervals of
maximum perceptual saccadic suppression as well as recovery, allowing us to get a
time course of perceptual threshold elevation associated with saccadic suppression.
In subsequent data analyses, we confirmed that these flash times were as planned
(within the expected variability due to the asynchronous nature of saccade times
relative to display update times; Fig. 2). For the experiment with simulated saccades,
we presented the probe flash at -24, -12, 48, or 96 ms relative to the onset time of
the texture displacement. In this case, we introduced a new negative time sample to
the set (-12 ms) because the original Human Experiment 2 did not probe this
particular time (e.g. Fig. 6). It was therefore important to clarify that the time course of
perceptual suppression for simulated saccades was continuous and well-behaved,
exactly like that for real saccades.
In order to also estimate perceptual thresholds online in these additional
experiments, and therefore optimize the numbers of trials needed, we applied an
adaptive QUEST procedure\textsuperscript{42} on each randomly interleaved condition. Specifically,
the first 40 trials of each randomly interleaved condition (e.g. flash time -24 ms and
coarse texture, or flash -12 ms time and fine texture, and so on) were part of the
QUEST procedure. The remaining trials in the session interleaved 4 additional flash
luminances per condition, which were chosen to lie around the threshold luminance
of each condition as detected by the QUEST procedure. These additional flashes
had luminances that were +/- 1 or +/- 2 times a pre-defined luminance increment for
a given condition, depending on the detected threshold and earlier pilot data.
Specifically, if the detected threshold (according to QUEST) was very low (e.g. no
suppression effect), the pre-defined luminance increment was 1 step of luminance
(dicted by the luminance resolution of our display; Supplementary Fig. 3a). That is,
the 4 additional flashes were at +/-1 and +/-2 display-determined luminance steps
from the detected threshold. If the detected threshold (according to QUEST) was high (e.g. strong suppression), we made the pre-defined luminance increment 2 or 5 display-determined luminance steps (that is, +/- 2 and +/-4 display-determined luminance steps or +/- 5 and +/-10 display-determined luminance steps, respectively). This allowed fitting the psychometric curves during subsequent data analyses, including measurements from the full dynamic range of perceptual performance. The reasoning behind this approach is as follows: depending on the amount of perceptual saccadic suppression to be expected per condition (e.g. peak suppression during saccades or texture displacements, or very weak suppression during recovery), it is expected that the psychometric curves would be shifted by different amounts from baseline depending on the particular condition (e.g. flash time or coarse versus fine texture). Finally, also note that we only used bright flashes in these particular experiments instead of both bright and dark flashes. In total, we collected 240 trials per condition per subject.

In yet another control experiment for Human Experiments 1 and 2, we mimicked the retinal results of Fig. 4d. Subjects fixated a central fixation spot over a gray background. The background had one of 8 luminances (22.4, 30.24, 38.08, 45.92, 53.76, 61.6, 69.44, 77.28 cd m⁻²). After a random initial fixation duration (similar to Human Experiment 2), the luminance of the background was changed suddenly (in one display frame update) to one of the remaining 7 luminances. This meant that across trials, we had 7 total levels of contrast change in the background as our visual transient. At one of 5 different possible times relative to the time of background luminance change (-24, -12, 36, 72, or 108 ms), a luminance pedestal was flashed briefly, exactly like in Human Experiments 1 and 2. We ensured that the contrast of the flash (relative to the currently displayed background luminance) was always the
same across all trials. We also ensured that baseline visibility of the pedestal in the absence of the contrast change was at ceiling performance (see the longest sampled time value in Fig. 5, demonstrating near perfect detection performance for all background luminance steps). Subjects maintained fixation throughout all trials and simply reported the locations of the brief flashes. Subjects performed 1 session, each, of this experiment, with 1,120 trials per session.

In Human Experiment 3 (Fig. 8), the flashes of Human Experiments 1 and 2 were replaced by vertical Gabor gratings having one of five different spatial frequencies (0.41, 0.85, 1.71, 3.42, 4.56, or 6.8 cpd). The contrast of the grating (defined as the difference between maximum and minimum luminance in the grating divided by the sum of the same luminances) was 14.3%. Spatial phase was randomized from trial to trial, and the $\sigma$ parameter of the Gaussian envelope was 0.49 deg. Also, a virtual monitor of 20 deg diameter was present at display center at the time of Gabor grating flashes. The virtual monitor had a uniform gray luminance equal to the average of the textures used in Human Experiments 1 and 2. Surrounding the virtual monitor, a coarse or fine texture could be visible.

In one block of trials, subjects generated saccades towards display center using the same procedures as in Human Experiment 1. Grating flash times were similar to Human Experiment 1, and the subjects performed 6 sessions each (576 trials per session).

In another block of trials, subjects maintained fixation at display center. In one third of the trials, the virtual monitor and surrounding texture did not move. These trials provided us with “baseline” visual performance (i.e. without saccades or virtual
monitor displacements). It was necessary to have these trials because perceptual visibility of different spatial frequencies is not equal due to the well-known human contrast sensitivity function\(^{73}\). Therefore, we needed to establish “baseline” grating visibility first and then compare the effects of saccades or saccade-like virtual monitor displacements on such visibility. In the remaining two thirds of the trials, the virtual monitor and surrounding texture initially appeared displaced from display center at a location near one corner of the display and along one of the diagonal directions. After 800-1,700 ms, the virtual monitor and surrounding texture were translated rapidly towards display center to simulate visual flow associated with the diagonal saccades of the real-saccade version of the paradigm (the translation parameters were similar to Human Experiment 2). Grating flashes happened 84 ms or 108 ms after virtual monitor and texture displacement. Note that we reduced the number of flash times here because of the larger number of conditions (5 different spatial frequencies of the Gabor gratings) that needed to be collected. However, our data were consistent with all other experiments in terms of recovery time courses of suppression (e.g. Figs. 1, 6, 8; Supplementary Figs. 8-10).

Because the initial displaced position of the virtual monitor (and texture) provided a cue to subjects that grating onset was expected soon, and because such a cue was not present in the one third of trials without image motion, we equalized subject expectations across these conditions by dimming the fixation point to black from the time of image motion onset until 200 ms after flash onset (equal timing was ensured in the one third of trials without image motions, such that the same expectation of grating onset was established by fixation marker dimming). The fixation marker then disappeared, and subjects had to report flash location.
Subjects performed 6 sessions each of this condition, with 576 trials per session (2 subjects performed 7 and 5 sessions each instead of 6).

We also repeated the same experiment but with a black surround around the virtual monitor instead of a coarse or fine texture. Note that a black surround is theoretically equivalent to an infinitely coarse surround. We therefore expected results conceptually similar to those with a coarse surround. Also, in this control experiment, we randomly interleaved all trial types together in the same session (fixation with virtual monitor displacement, real saccade, and fixation with neither virtual monitor displacement nor saccade). This allowed us to further confirm that our results from Human Experiment 3 were not influenced by the separate blocking of real saccade trials and virtual monitor displacement trials.

We also repeated Human Experiment 3 to collect full psychometric curves, like we did for Human Experiments 1 and 2 above. In these additional experiments, because of the data-intensive nature of full psychometric curves, we concentrated on the 3 lowest spatial frequencies of the Gabor gratings. This was sufficient to observe selectivity or lack of selectivity of perceptual suppression as a function of spatial frequency (e.g. Fig. 8). More importantly, these 3 lowest spatial frequencies were associated with ceiling baseline visibility (Fig. 8), thus simplifying interpretations of any suppression that we would observe. The experiments were the same as Human Experiment 3, except that the contrast of the flashed Gabor grating was varied from trial to trial. We used a similar adaptive procedure to that used in Figs. 2, 7 to select contrast from trial to trial, in order to optimize finding perceptual thresholds and fitting of psychometric curves (see procedures above). We also used the same online saccade detection algorithm as in the experiments of Fig. 2 to decide on the time of
Gabor grating flash onset (see procedures above). For both real and simulated
saccade variants of these experiments, we used two times relative to the “saccade”
event, one within a period associated with strong perceptual suppression and one at
a late time point associated with perceptual recovery (see Figs. 9, 10).

*Retina electrophysiology data analysis and statistics*

Low-density MEA recordings were high-pass filtered at a 500 Hz cutoff frequency
using a tenth-order Butterworth filter. We extracted spike waveforms and times using
thresholding, and we semi-manually sorted spikes using custom software. For high-
density MEA recordings, we performed spike sorting by an offline automatic
algorithm and assessed the sorted units using UnitBrowser. We judged the quality
of all units using inter-spike intervals and spike shape variation. Low quality units,
such as ones with high inter-spike intervals, missing spikes, or contamination, were
discarded. All firing rate analyses were based on spike times of individual units.

We first characterized the properties of RGCs. We calculated linear filters in
response to full-field Gaussian flicker and binary checkerboard flicker by summing
the 500-ms stimulus history before each spike. The linear filters allowed determining
cell polarity. Specifically, the amplitude of the first peak of the filter was determined. If
the peak was positively deflected, the cell was categorized as an ON cell; if
negatively deflected, the cell was an OFF cell. ON cells were later always analyzed
with respect to their responses to bright probe flashes in the main experiment, and
OFF cells were analyzed with dark probe flashes. We determined the spatial
receptive fields of RGCs by calculating the linear filters for each region (checker)
defined by the binary checkerboard flickering stimulus. The modulation strength of
each linear filter, measured as the s.d. along the 500 ms temporal kernel, is an
estimate for how strongly that region drives ganglion cell responses. We fitted the
resulting 2D-map of s.d. values with a two dimensional Gaussian and took the 2-σ
ellipse (long axis) as the receptive field diameter. For all other figures and analyses,
we converted spike times to estimates of firing rate by convolving these times with a
Gaussian of σ = 10 ms standard deviation and amplitude 0.25 σ⁻¹e¹/².

For each RGC, we used responses to full-field contrast steps to calculate an ON-
OFF index, a transiency index, and a response latency index. These indices were
used to characterize the properties of RGCs (Supplementary Fig. 6) that we included
in our analyses. The ON-OFF index was calculated by dividing the difference
between ON and OFF step peak response by their sum. The resulting index values
ranged between -1 (OFF) and +1 (ON) and were then scaled to span between 0
(OFF) and +1 (ON). The transiency index was defined as the ratio of the response
area within the first 400 ms and the total response area spanning 2,000 ms. The
resulting index had a value of 1 for pure transient cells. Response latency was
calculated as the time from stimulus onset to 90% of peak response. This value was
normalized to the maximum response latency in our dataset to create the response
latency index.

To quantify retinal “saccadic suppression”, we first determined a “baseline response”,
defined as the response to a probe flash approximately 2 s after texture displacement
onset (delay between 1,967 to 2,100 ms, depending on the specific flash times used
in a specific experiment). This baseline response was compared to responses of the
same cell to the same flash when it occurred at an earlier time (i.e. closer in time to
the “saccade”). Usually, the saccade-like texture displacements themselves caused
significant neural responses even without flashes (“saccade-response”, e.g. Fig. 3b),
and the responses to the flashes were superimposed on these “saccade-responses”
(Fig. 3c). We therefore first isolated the component of the responses caused by the
flashes by subtracting the “saccade-responses” from the composite responses.

To get a robust estimate of the response to “saccades” alone (i.e. without any
flashes), we averaged spike rate from before “saccade” onset up until the next
“saccade” onset for conditions in which no flash was presented, or until just before
the flash onset for conditions in which a “post-saccade” flash was presented. This
was done for each of the 39 successive “saccades” in a given trial.

We then computed a neural modulation index, ranging from -1 to +1. A value of -1
represents complete suppression of flash-induced responses, whereas +1 indicates
“complete enhancement” of flash-induced responses (that is, there was only a
response to a flash after saccades, but not to a flash in isolation). A modulation index
of 0 meant no change in flash-induced response relative to the “baseline” response.

The modulation index of an RGC for a given flash delay $d$ after “saccade” onset was
calculated as $(r_d - r_b)/(r_d + r_b)$ where $r_d$ is the peak firing rate for the flash-component
of the response (see above for how we isolated this from the composite
“saccade”+flash response) and $r_b$ is the peak firing rate for the baseline flash
response (i.e. the same flash but occurring ~2 s away from any “saccade”; see
above). In all cases, peak firing rate was estimated after averaging responses from
all repetitions of a given condition (delay d or baseline) for a given RGC. For ON
cells, the modulation index was based only on responses to bright flashes, and for
OFF cells, it was based on responses to dark flashes. For some analyses, we also
calculated modulation indices of RGCs for each of the 39 individual “saccades” using
the same procedure.

In some cells and trials, individual “saccades” from the sequence of 39 were
discarded. This happened when the baseline response peak was less than 60% of
the median baseline response peak across the 39 “saccades” of a given trial. We did
this to ensure that our modulation indices were not marred by a numerator and
denominator approaching zero (e.g. if both flash and baseline responses were weak).
We did, however, re-include sequences in which the peak response to the flash after
the “saccade” was above the median baseline response peak (across the 39
“saccades”). This was done in order to re-include sequences (if discarded by the first
step) for which the baseline flash response was weak but a flash after “saccades”
onetheless gave a robust response. For example, this could happen if a cell did not
respond to a flash in isolation but the “saccade” enhanced the response to a flash
following it. Our main results (e.g. Fig. 3) were highly robust to such scenarios.

Finally, to perform statistics, we applied tests at either the individual cell level or at
the level of the population. At the individual cell level, we determined whether a given
RGC’s modulation index for a probe flash presented at a given delay was
significantly different from 0 (i.e. “Is the response of this cell modulated by the
’saccade’?”). For this, we performed a one-tailed sign test of the null hypothesis that
the 39 individual modulation indices came from a distribution with zero median
against the alternative hypothesis that the median was below (for negative
modulation index) or above (for positive modulation index) zero. The modulation
index was considered significant (i.e. the flash response was modulated by the
“saccade”) at p<0.05 if the test had a power (1-β) of at least 0.8. At the population
level, we determined whether the retinal output as a whole was modulated by “saccades”. For this, we performed a two-tailed Wilcoxon signed rank test of the null hypothesis that the median of the distribution of modulation indices did not differ from 0. Lastly, we tested whether the modulation index of the population was significantly different across textures. For this, we performed a two-tailed Wilcoxon signed rank test of the null hypothesis that the median of the distribution of modulation indices did not differ across textures. Since our modulation index was based on responses to the brief probe flashes, it could only be computed for cells that did respond to these flash stimuli (mouse: N = 688 of 1,423 recorded cells; pig: N = 228 of 394). Only these cells, showing a measurable baseline flash response, were included in our analyses for retinal “saccadic suppression” (Fig. 3e, Supplementary Fig. 5).

To quantify retinal “saccadic suppression” in our control experiments with structure-free uniform backgrounds and luminance steps in place of textures and texture displacements (Fig. 4d), we used the same analyses and statistical procedures to those described above for the texture displacement paradigm. The only difference was that instead of 39 successive “saccades” in a trial, we now had either 57 or 157 successive full-field luminance steps (depending on experiment setting). 22 of 57 or 66 of 157 steps had a Michelson contrast in the range of +/- 0.03 to 0.15 and these steps were used to quantify suppression for low contrast luminance steps. 24 of 57 or 58 of 157 steps had a Michelson contrast in the range of +/- 0.20 to 0.40 and were used to quantify suppression for high contrast luminance steps. From the perspective of visual transients across the retina, low contrast luminance steps are equivalent to fine texture displacements over receptive fields, and high contrast luminance steps are equivalent to coarse texture displacements. This is simply because of the spatial relationship between receptive field sizes and texture spatial scales: a fine texture
presents both dark and bright blobs within individual receptive fields both before and after the texture displacement (resulting in a low contrast change in luminance over the receptive fields); on the other hand, a coarse texture has dark or bright blobs that are of similar size to the receptive fields (resulting in the potential for a very large contrast change in luminance over the receptive fields after the texture displacement). As shown in Fig. 4d, low and high contrast luminance steps resulted in the modulation of ganglion cell responses to the probe flashes that was reminiscent of the modulation observed after displacement of fine and coarse textures, respectively (also validated perceptually in Fig. 5). Similar to the texture displacement paradigm, the modulation index was based on responses to brief probe flashes, and it could therefore only be computed for cells that did respond to these flash stimuli (N = 376 of 650 recorded RGCs in mouse). The modulation index for ON RGCs was calculated from responses to bright probe flashes, and that for OFF RGCs was calculated from responses to dark flashes.

Human psychophysics data analysis and statistics

We analyzed eye movements in all trials. We detected saccades using established methods\(^{41,76}\), and we manually inspected all trials to correct for mis-detections. In experiments requiring a saccade (e.g. Fig. 1), we excluded from analysis any trials with premature (before saccade instruction) or late (>500 ms reaction time) saccades. We also rejected all trials in which saccades landed >0.5 deg from the saccade target. In experiments requiring fixation, we excluded from analysis any trials in which a saccade or microsaccade happened anywhere in the interval from 200 ms before to 50 ms after any flash or grating onset.
For experiments with saccades (e.g. Fig. 1), we obtained time courses of perception by calculating, for each trial, the time of flash or grating onset from saccade onset. We then binned these times into 50 ms bins that were moved in 5 ms bin-steps relative to saccade onset. Within each bin, we calculated the proportion of correct trials, and we obtained full time courses of this perceptual measure. We obtained time course curves for each subject individually, and we then averaged the curves for the individual subjects in summary figures. All of our analyses were robust at the individual subject level as well (e.g. Supplementary Fig. 2).

For experiments with simulated saccades (i.e. saccade-like texture displacements), or background luminance steps (Fig. 5), there were discrete flash or grating times relative to “simulated saccade” onset, so no temporal binning was needed. At each flash or grating time, we simply calculated the proportion of correct trials.

When we fitted performance to psychometric curves (e.g. Supplementary Fig. 3a, b), we used the psignifit 4 toolbox\textsuperscript{77}, and we used an underlying beta-binomial model. In all psychometric curve fits, we also included lapse parameters among the fitted parameters, in order to account for potential small deviations from either perfect ceiling performance or perfect floor (chance) performance at the extremes of the psychometric curves.

We also used the same toolbox to analyze the variants of Human Experiments 1 and 2 in which we collected full psychometric curves (Figs. 2, 7). For these experiments, we defined the threshold of an individual subject as the flash luminance level that resulted in correct perceptual performance at a value of 62.5% of the total dynamic range of the subject’s psychometric curve (that is, 62.5% of the dynamic range of the
fitted psychometric curve after the inclusion of lapse rates). We then plotted the value of such threshold as a function of flash time relative to real or simulated saccade time.

For some analyses of Human Experiment 3 and its control version, we calculated a “suppression ratio” as a visualization aid (e.g. Fig. 8). This was obtained as follows. For a given spatial frequency grating, we calculated the fraction of correct trials within a given time window (from either simulated or real saccade onset) divided by the fraction of correct trials for the same spatial frequency when there was neither a saccade nor a virtual monitor and texture displacement (i.e. baseline perception of a given spatial frequency). This ratio therefore revealed the effect of suppression independently from the underlying visibility of any given spatial frequency. However, note that we also report raw proportions of correct trials in all conditions.

All error bars that we show denote s.e.m. across individual subjects, except where we report individual subject analyses and control analyses. For individual subject performance, error bars denote s.e.m. across trials; for control analyses, error bars denote 95% confidence intervals (e.g. Supplementary Fig. 3a, b) or s.d. (e.g. Supplementary Fig. 3d, f). All error bar definitions are specified in the corresponding figures and/or legends.

To statistically validate if the time courses for perceptual localization performance for saccades across the different background textures (coarse versus fine) differed significantly from each other (e.g. Fig. 1), we used a random permutation test with correction for time clusters of adjoining significant p-values. First, for each time bin, we calculated a test statistic comparing performance for coarse versus fine
background textures. This test statistic was the difference between the proportion of correct responses for the different textures. Then, we performed a random permutation with 1,000 repetitions for each time bin; that is, we collected all trials of both conditions, within a given time bin, into a single large set, and we randomly assigned measurements as coming from either coarse or fine textures, while at the same time maintaining the relative numbers of observations per time bin for each texture condition. From this resampled data, we calculated the test statistic again, and we repeated this procedure 1,000 times. Second, we checked, for each time bin, whether our original test statistic was bigger than 95% of the resampled test statistics (i.e. significant), and we counted the number of adjoining time bins that were significant at this level (i.e. clusters of time bins in which there was a difference between coarse and fine textures). We then repeated this for all 1,000 resampled test statistics. The p-value for our original clusters was then calculated as the number of resampled clusters that were bigger or the same size as the original clusters, divided by the total number of repetitions (1,000). This procedure was described in detail elsewhere. We followed a conservative approach, paying no attention to which bins in the resampled data formed a cluster of time bins. As discussed elsewhere, our statistical analysis constituted a highly conservative approach to establishing significance of differences between time courses for coarse and fine textures. In Human Experiment 3, we used the same approach to compare time courses of suppression ratio for coarse and fine surround contexts with real saccades. For Human Experiment 2, we had discrete flash times relative to texture displacement onset. Here, the comparison between coarse and fine textures was tested with a Bonferroni-corrected $\chi^2$ test at corresponding flash times. To compare between real and simulated saccades in Human Experiments 1 and 2, we also ran a
Bonferroni-corrected $\chi^2$ test. We only considered time bins in the real saccade data that corresponded to the discrete flash times in the simulated saccade data. A Bonferroni correction was necessary because we tested the same data sets on multiple time bins with the same hypothesis (that there is a difference in time courses).

In Human Experiment 3, we also compared suppression ratios for real and simulated saccades for a given texture surround. We again used a Bonferroni-corrected $\chi^2$ test. This was justified because within a given surround, baseline data were the same for real and simulated saccades. Therefore, the relationship between the proportion of correct localizations and suppression ratio was identical. In contrast, testing suppression ratios between fine and coarse surrounds in the same experiment with a $\chi^2$ test was not applicable because baseline values differed. Therefore, we used instead a random permutation test with 5,000 repetitions. To compare the different spatial frequency Gabor gratings in one bin or time stamp, we used the Kruskal-Wallis test.

For the psychometric versions of Human Experiment 3 (Figs. 9, 10), we used similar analyses on perceptual thresholds to those used in the psychometric versions of Human Experiments 1 and 2 (Figs. 2, 7).

Data availability

All data presented in this paper are stored and archived on secure institute computers and are available upon reasonable request.

Figure 1 Image dependence of perceptual saccadic suppression. (a) Human subjects generated saccades from one of four diagonal locations towards display center (here: from the lower right). A luminance pedestal was flashed peri-saccadically at one of four locations around display center (right, left, up, or down; here: up). The example shows the coarse background texture (insets in c, d show fine textures for comparison; also see Supplementary Fig. 1 and Methods). (b, c) Subjects failed to localize peri-saccadic flashes with both coarse (b) and fine (c) textures (we binned perceptual reports as a function of flash time from saccade onset using 50-ms bins moved in steps of 5 ms). (d) Perceptual suppression started earlier and lasted longer with a coarse background (also see Fig. 2). The highlighted time points denote significantly different (p<0.001) time clusters between the coarse and fine conditions (Methods). Curves show averages (+/- s.e.m. bounds) of individual subjects’ suppression curves. Supplementary Figs. 2, 3 show individual subject results, as well as controls for flash visibility (in the absence of saccades) and saccade motor variability.
Figure 2 Image-dependent elevation of perceptual thresholds across saccades. (a-d) We repeated the experiment of Fig. 1 but collecting full psychometric curves of flash visibility. Solid curves: mean +/- s.e.m of the individual psychometric curves of five subjects (see Supplementary Fig. 4 for individual subject results). Dashed curves: psychometric curves near recovery from suppression long after saccades (same data as in d). Orange and light-blue indicate data for coarse and fine textures, respectively. (a) For flashes approximately 42 ms from saccade onset (Methods), strong perceptual saccadic suppression occurred (compare solid with dashed curves), and the psychometric curve for coarse textures was shifted to higher detection thresholds than that for fine textures, indicating stronger perceptual saccadic suppression. (b) At approximately 65 ms after saccade onset, substantial recovery was visible (note the different x-axis scale from a), but there was still stronger suppression for coarse than fine textures. (c, d) Recovery of visibility continued at later times after saccade onset (88 ms, c, and 168 ms, d), consistent with Fig. 1. (e) Perceptual detection thresholds (i.e. flash luminance levels needed to achieve a certain correct performance rate; Methods) from a-d as a function of flash times from saccade onset. Since flash times were determined using online saccade detection (Methods), there was some variability of actual displayed flash times; the gray histograms on the x-axis show the actual distributions of flash times for each group of data from a-d. The results confirm the interpretation of Fig. 1: perceptual saccadic suppression was stronger and lasted longer for coarse than for fine background textures. Asterisks denote significant differences between coarse and fine textures (two-sample t-test; \( p < 0.05 \)). The dashed horizontal lines show the detection thresholds at the longest flash times (d); note that these thresholds are also similar to those in the visibility control experiments of Supplementary Fig. 3a, b.
Figure 3 “Saccadic suppression” in retina. (a) We recorded RGC activity from ex vivo retinae placed on multielectrode arrays (MEA). A coarse (left) or fine (right) texture was repeatedly translated in a saccade-like manner (red or blue scan paths), and we presented brief visual flashes at different times relative to “saccades” (similar to Fig. 1). (b, c) Average activity of an example RGC to 39 texture displacements alone (b) or followed by probe flashes at different time delays (c). Red and blue bars show the timings of the texture displacements; orange bars indicate probe flashes. Flash-induced responses were strongly suppressed immediately following saccade-like texture displacements. (d) Isolated flash responses of the same RGC obtained by subtracting responses in b from those in c. Dashed colored lines highlight the time courses of retinal “saccadic suppression” relative to baseline flash-induced responses. (e) Modulation index highlighting retinal “saccadic suppression” (Methods; negative values indicate suppressed flash-induced neural responses). Both mouse and pig retinae showed strong suppression during and after texture displacements, which also depended on texture statistics (similar to perception; Figs. 1, 2). Error bars denote s.e.m., and asterisks/hashes indicate p < 0.001.
statistical significance (Methods). The numbers of recorded cells at each flash time in e were as follows. Mouse RGCs: N=179 (-177 ms, -84 ms, -50 ms), 161 (-67 ms), 136 (50 ms), 527 (117 ms), 520 (150 ms), 502 (200 ms, 600 ms), 688 (350 ms), 345 (1,100 ms); pig RGCs: N=228 for each time point. Figure 4 shows additional properties of retinal “saccadic suppression”, and Supplementary Figs. 5, 6 show the population data underlying panel e and different RGC types. Scale bars are defined in their respective panels.
**Figure 4** Stimulus-stimulus interactions in retinal "saccadic suppression". (a) Example RGC responding only weakly to texture displacements (top), but nevertheless exhibiting strong suppression of flash-induced neural responses (bottom; curves are plotted at the same scale). Suppression was much stronger than the response amplitude to the texture displacements alone. (b) Population modulation index (mean +/- s.e.m.) for a paradigm in which the textures jumped from their start to end positions instantaneously. Strong suppression (* p<0.01, two-tailed Wilcoxon signed-rank test) and significant differences between coarse (red) and fine textures (blue; # p<0.0001, Wilcoxon signed-rank test) were preserved. (c) Two example RGCs showing that a flash presented before saccade-like texture displacements suppressed the response to the displacements, supporting the notion that stimulus-stimulus interactions in the forward direction (first stimulus suppresses the response to the second stimulus) are the main drive for retinal "saccadic suppression". (d) Population modulation index (mean +/- s.e.m.) for a paradigm similar to panel b, but with textures replaced by spatially uniform backgrounds of different intensity. This created visual transients in the form of instantaneous luminance steps. Suppression of flash-induced responses was preserved (* p<10^-10, two-tailed Wilcoxon signed-rank test), and differences between low-contrast (light gray) and high-contrast (dark gray) luminance steps (# p<10^-10, two-tailed Wilcoxon signed-rank test) resembled the differences between fine and coarse texture jumps in b. (e) Overlaid modulation profiles from saccade-like texture displacements (Fig. 3e), texture jumps (b), and contrast steps (d). Coarse texture displacements, coarse texture jumps, and high contrast luminance steps had similar modulatory effects on probe flash responses; and so did fine texture displacements, fine texture jumps, and low contrast luminance steps.
Figure 5 Stimulus-stimulus interactions in perceptual suppression without saccades (similar experiment to the retinal paradigm of Fig. 4d). Subjects simply fixated and detected brief flash probes as in the experiments of Figs. 1, 2; here, the flashes happened around the time of a luminance step (i.e. a sudden change in background luminance) instead of a saccade. The title above each panel indicates the absolute value of the luminance change that took place. (a-g) Proportion of correct responses as a function of brief flash time from the time of background luminance change. There was progressively stronger perceptual suppression with increasing contrast of the luminance step, consistent with the retinal results of Fig. 4d. (h) Summary of panels a-g. Darker colors denote larger absolute values of background luminance changes. Since coarse textures (Figs. 1-4) presumably cause larger contrast variations over retinal receptive fields, this suggests that the image dependence of perceptual saccadic suppression (Figs. 1, 2) is mediated by stimulus-stimulus interaction effects originating in the retina (Fig. 4d).
Figure 6 Image dependence of perceptual suppression without saccades. (a) Rapid texture displacements simulated saccade-like image displacements, similar to the retina experiments (Fig. 3). We used the same flashes and simulated saccade directions as in Fig. 1. The example shows a coarse texture (fine textures are shown in insets in c, d, and f). (b, c) Pre-, peri-, and post-displacement perceptual suppression occurred for both coarse (b) and fine (c) textures without real saccades. (d) As with real saccades (Fig. 1), suppression started earlier and lasted longer with coarse textures (also compare to similar retinal effects in Fig. 3e). Notably, pre-displacement suppression depended on texture statistics, just like with real saccades (Fig. 1). (e, f) Simulated saccades were associated with significantly longer suppression than real saccades for both fine and coarse textures. For coarse textures (e, which were most effective in causing suppression overall), flashes presented before the “saccade” event were suppressed earlier in the simulated saccade condition than in the real saccade condition (also see Fig. 7); thus, prolonged suppression with texture displacements was not restricted to post-displacement flashes only. Error bars denote s.e.m. across individual subjects’ curves. Asterisks denote significant differences between coarse and fine textures (d) or between real and simulated saccades (e, f) at each indicated time point ($\chi^2$ tests with Bonferroni corrections; * $p<0.005$ in d and p<0.007 in e, f; *** $p<0.0001$ in d and p<0.000014 in e, f). Supplementary Fig. 2 shows individual subject results.
Figure 7 Image-dependent elevation of perceptual thresholds without saccades. Similar to Fig. 2, we collected full psychometric curves of flash visibility around the time of simulated saccades (similar paradigm to Fig. 6). (a-d) Solid curves: mean +/- s.e.m of individual psychometric curves of five subjects (see Supplementary Fig. 7 for individual subject results). Dashed curves: baseline data from the same subjects without simulated saccades and long after any real saccades (same data as in Fig. 2d; also similar to Supplementary Fig. 3a, b with additional subjects). Red and blue indicate data for coarse and fine textures, respectively. (a) For a flash 24 ms before texture displacement onset, the red curve was shifted rightward towards higher flash contrasts (that is, reduced sensitivity) relative to baseline. This effect was much weaker with fine textures. (b) For a flash closer in time to the texture displacement but still before its onset (12 ms before displacement onset), both coarse and fine textures were associated with significant perceptual suppression relative to baseline, consistent with Fig. 6. Moreover, once again, suppression was stronger for coarse than fine textures (evidenced by the larger rightward shift in the psychometric curve). (c) Perceptual suppression was the strongest (note the different x-axis scale from the other panels) immediately after texture displacement onset. (d) 96 ms after texture displacement onset, there was still significant perceptual suppression, again significantly stronger for coarse than fine textures. This result is consistent with Fig. 6 and highlights the longer-lasting suppression around simulated saccades compared to real saccades (Figs. 1, 2). (e) Detection thresholds from a-d as a function of flash time from texture displacement onset. Pre- and post-displacement perceptual suppression occurred, and suppression was stronger with coarse textures. Asterisks denote significant differences between coarse and fine textures (two-sample t-test; * p<0.05; ** p<0.01). Horizontal dashed lines show the baseline detection thresholds from Fig. 2d, e. All other conventions are similar to Figs. 1, 2, 6.
Figure 8 Selective peri-saccadic suppression of low spatial frequencies is a visual phenomenon. (a) Left: Subjects made saccades towards display center. Right: gratings were flashed peri-saccadically over a uniform gray background (circular “virtual monitor” surrounded by a coarse texture; saccade directions and flash locations were similar to Figs. 1, 6). (b) Left: proportion of correct localizations of gratings with different spatial frequencies during fixation (“Baseline”; dashed curve) and for peri-saccadic flashes (solid curve). Low spatial frequencies were associated with the strongest suppression relative to baseline. Right: ratio of peri-saccadic to baseline performance (highest spatial frequency not shown because it was at chance performance even in baseline). Suppression depended on grating spatial frequency ($\chi^2=13.46, p=0.0092, df=4, \text{Kruskal-Wallis test;} ** p<0.01$ for post-hoc pairwise comparisons between the lowest and highest spatial frequencies). (c) Left: we simulated saccade-induced image displacements by translating the virtual monitor and surrounding texture from one corner towards display center. Right: gratings appeared as in a (Methods). (d) The same selective suppression of low spatial frequencies as in b occurred. “Baseline” in this context means both no saccades and no virtual monitor and texture displacements. Suppression depended on spatial frequency ($\chi^2=25.33, p<0.0001, df=4, \text{Kruskal-Wallis test;} * p<0.05, ** p<0.01, *** p<0.001$ for post-hoc pairwise comparisons between individual spatial frequencies). (e, f) With a fine surround texture, both real (e) and simulated (f) saccades were associated with suppression for all spatial frequencies; suppression selectivity was eliminated ($\chi^2=0.8, p=0.938, df=4$ for e and $\chi^2=7.74, p=0.102, df=4$ for f, Kruskal-Wallis test). Error bars denote s.e.m. across individual subjects’ curves. Supplementary Figs. 8–10 show full time courses as well as controls with black surrounds around the virtual monitor. Note that in d, f, we exploited the longer time course of visual suppression (Fig. 6, Supplementary Figs. 8, 9) to probe perception at a later time than in b, e. This also explains why suppression appeared quantitatively weaker in d, f than in b, e.
Figure 9 Selective and unselective saccadic suppression measured using full psychometric curves. (a) We repeated the real saccade experiments of Fig. 8, but with different Gabor grating contrasts (Methods). Different colors indicate different spatial frequencies of the flashed gratings. When the gratings were flashed ~42 ms after saccade onset (Methods) and there was a coarse surround texture, perceptual suppression clearly depended on spatial frequency: detection thresholds were highest for the lowest spatial frequency, and they progressively decreased with increasing spatial frequency. Each curve shows the average of 4 subjects’ psychometric curves; error bars denote s.e.m. across subjects. Dashed psychometric curves show perceptual detectability without saccadic suppression (obtained similarly to Fig. 8). (b) When the surround context was fine, rather than coarse, perceptual suppression was not selective for low spatial frequencies (consistent with Fig. 8). (c) Detection thresholds from a, b as a function of grating spatial frequency for flashes ~42 ms after saccade onset. With a coarse surround, detection thresholds were highest for low spatial frequencies and progressively decreased with increasing spatial frequency (1-way ANOVA, p=0.0168, F=6.6608; p=0.0133 for post-hoc comparison between lowest and highest spatial frequency, indicated by *). With a fine surround, detection thresholds did not depend on spatial frequency. (d) Same as in c but now for grating flashes occurring ~65 ms after saccade onset. For both surround textures, detection thresholds decreased, indicating perceptual recovery. There was still a trend for dependence of perception on spatial frequency in the coarse condition, consistent with c.
Figure 10 Selective and unselective saccadic suppression without any saccades. This figure is identical to Fig. 9, except that real saccades were replaced (in the same subjects) with simulated saccades (exactly as in Fig. 8). All of the same conclusions were reached. There was selective suppression for low spatial frequencies when the texture surround was coarse (a); suppression was unselective for grating spatial frequency with a fine surround (b); and there was gradual recovery with time (c, d). In fact, perceptual suppression was clearer and longer lasting in this condition than with real saccades (also consistent with Figs. 1, 6, 8). All other conventions are as in Fig. 9. In c, the coarse texture surround showed a significant main effect of spatial frequency (1-way ANOVA, p=0.0113, F=7.6878; p=0.0092 for post-hoc comparison between lowest and highest spatial frequency, indicated by **). In d, the coarse surround also showed a significant main effect of spatial frequency (1-way ANOVA, p=0.0019, F=13.5276; p=0.0017 for post-hoc comparison between lowest and highest spatial frequency, and p=0.0186 for post-hoc comparison between lowest and intermediate spatial frequency).
