(Received 1 July 2019; revised 23 August 2020; accepted 25 August 2020; published 15 September 2020)

The Higgs mode in superconducting materials describes slowly decaying oscillations of the order parameter amplitude. We demonstrate that in superconductors with a built-in spin-splitting field the Higgs mode is strongly coupled to the spin degrees of freedom, allowing for the generation of time-dependent spin currents. Converting such spin currents to electric signals by spin-filtering elements provides a tool for the second-harmonic generation and the electrical detection of the Higgs mode generated by the external irradiation. The nonadiabatic spin torques generated by these spin currents allow for the magnetic detection of the Higgs mode by measuring the precession of the magnetic moment in the adjacent ferromagnet. We discuss also the reciprocal effect, which is the generation of the Higgs mode by the magnetic precession. Coupling the collective modes in superconductors to light and magnetic dynamics provides an opportunity for the study of superconducting optospintronics.

I. INTRODUCTION

Oscillations of the order parameter amplitude in condensed-matter systems are often called Higgs modes (HMs) [1–5], in analogy with the Higgs boson in particle physics [6]. These collective excitations are generic for ordered states such as antiferromagnets, charge density waves [7], superfluids [8–10], cold atomic gases [11,12] and superconductors [2,13–27]. In general, one can call HMs all the possible collective modes of the order parameter, other than the Nambu-Goldstone modes [4].

Higgs modes have been observed by Raman scattering in superconductors with charge density wave order [14,15,17,28] and by the nuclear magnetic resonance in superfluid 3He [8–10]. In usual superconductors the HMs are charge neutral and thus decoupled from charge current. In such systems the observation of HMs has been facilitated by the development of low-temperature terahertz spectroscopy [18,19,24,29–32]. With this technique, HMs have been observed in NbTiN and NbN compounds [18,19]. Higgs modes have been observed indirectly as the AC linear conductance peak in current-carrying films of NbN [24] and Al [33].

Here we suggest a different mechanism allowing electrical detection of HMs due to their coupling with spin and charge degrees of freedom in high-field superconductor/ferromagnet junctions. Unusual transport properties of such systems have attracted intense attention [34–37], stimulating both experimental [38–47] and theoretical efforts [34,48–57].

The underlying physical mechanism behind the suggested electrical measurement of the HM is rooted in the strong coupling between the superconducting order parameter dynamics and electron spins. The possibility to transmit spin signals by the order parameter excitations has been elucidated using the example of mobile topological defects, i.e., Abrikosov vortices [55,56]. Here we demonstrate that time-dependent spin currents can be generated by the collective amplitude modes in superconductors.

The structure of this paper is as follows. In Sec. II we introduce the setup and model. Section III shows the effect of the HM on AC spin and charge currents. Their use in accessing the HM either in second-harmonic generation or via the measurement of an avoided crossing between ferromagnetic resonance and HMs is discussed in Sec. IV. We conclude in Sec. V with an outlook to the range of phenomena affected by the HM.

II. SETUP AND MODEL

The generic setup that we study is shown in Fig. 1(a). Its basic element is a superconducting film placed in contact with a ferromagnetic (FM) material. An effective spin-splitting field $h$ entering as the Zeeman term in the Hamiltonian of the superconductor (SC) is induced by an external in-plane magnetic field. Alternatively, $h$ could be induced by the proximity to a ferromagnetic insulator [58–62]. The system is exposed to an external irradiation $E_0 e^{i\omega t}$ which generates a time-dependent perturbation of the order parameter amplitude $\delta \Delta(t) = \Delta_0 e^{i\omega t}$ through the second-order nonlinearity $\Delta_0 \propto E_0^2$ [63,64].

We model the SC/FM junction using the tunneling Hamiltonian approach [65,66], which has been used extensively to study both AC and DC tunnel currents [65,67–69],

$$H_T = \sum_{kk'aa} A_{ka}(\hat{\Gamma} B_{k'a}) + \text{H.c.}, \quad (1)$$

$$\hat{\Gamma} = \hat{T} \tau_3 + \mathbf{U} (\mathbf{m} \cdot \hat{\alpha}). \quad (2)$$

Here $A_{ka}$ ($B_{ka}$) annihilates an electron with momentum $k$ and spin $\alpha$ in the SC (ferromagnet), the unit vector $\mathbf{m}$ and $\mathbf{T}$ are the transfer matrix and the field at the interface, respectively, $\alpha = \{ \uparrow, \downarrow \}$ are the spin states and $\hat{\alpha}$ is the unit vector of the spin magnetic moment. The unit vector $\mathbf{m}$ is the magnetization of the ferromagnet, the field $\mathbf{U}$ is the applied external field, and $\hat{T}$ is the Pauli matrix. The corresponding states of spins at the interface are described by

$$\hat{\alpha} = \frac{1}{2} (\hat{\tau}_{\alpha \beta} + \hat{\tau}_{\alpha \beta} \hat{\tau}_{\beta \alpha})$$

where $\hat{\tau}_\alpha$ are the Pauli matrices. The field $\mathbf{U}$ is the applied external field, and $\hat{T}$ is the Pauli matrix. The corresponding states of spins at the interface are described by

$$\hat{\alpha} = \frac{1}{2} (\hat{\tau}_{\alpha \beta} + \hat{\tau}_{\alpha \beta} \hat{\tau}_{\beta \alpha})$$

The field $\mathbf{U}$ is the applied external field, and $\hat{T}$ is the Pauli matrix.
FIG. 1. (a) Setup of the superconductor/ferromagnet structure. The exchange field $\mathbf{h}$ is induced by an external magnetic field $\mathbf{B}$. The double-frequency gap modulation can be excited by the external electromagnetic irradiation $\Delta_{2\Omega} \propto E_{\Omega}^2$ and is enhanced due to the coupling to the HM. (b) Semiconductor model of the current generation by a slowly varying perturbation of the order parameter amplitude $\delta(t)$. Only the spin-down band is shown. The ferromagnet has an equilibrium distribution $n_0(\varepsilon)$, while the distribution $n(\varepsilon, t)$ of the semiconductor is shifted with respect to the equilibrium distribution (dashed line) by $\Delta(t)$ away from the Fermi level. Due to the Zeeman shift $h$, the perturbation in the number of excitations is asymmetric with respect to the Fermi level $\varepsilon_F$. This results in net spin and charge currents flowing into the attached FM electrode through the tunnel barrier (I).

defines the spin quantization axis of the barrier, $\hat{\tau}_k$ and $\hat{\sigma}_k$ are the Pauli matrices in Nambu and spin spaces, respectively, and $U$ and $T$ are the spin-independent and spin-dependent matrix elements of the tunneling Hamiltonian, respectively [70]. The matrix tunneling current through the spin-polarized barriers can be expressed through momentum-averaged Green’s functions (GFs) in the superconducting and FM electrodes $\nu_S \hat{g}_S = \hat{\tau}_3 \sum_k (\hat{T} \hat{A}_k(\tau) \hat{A}_k^\dagger(\tau'))$ and $\nu_F \hat{g}_F = \hat{\tau}_3 \sum_k (\hat{T} \hat{B}_k(\tau) \hat{B}_k^\dagger(\tau'))$, respectively. Here $\tau$ and $\tau'$ are imaginary times, $\hat{T}$ is the time-ordering operator, and $\nu_S$ and $\nu_F$ are the normal metal densities of states on the two sides of the junction. For simplicity, we assume momentum-independent tunneling coefficients [70,71]. The time-dependent tunneling current for the general nonequilibrium state in the electrodes derived in Appendix A reads

$$I(t) = -i \nu_S \nu_F \frac{\hat{\tau}_3}{2} \hat{g}_S \circ (\hat{\Delta} \hat{g}_F \hat{\tau}_3 \hat{g}_S^\dagger) \circ \hat{g}_S |_{\tau=t', \tau=\tau},$$

where $\circ$ denotes time convolution. The overall tunnel current amplitude is determined by $\kappa = \nu_S \nu_F (T^2 + U^2)$ and the effective spin-filtering polarization is $P = 2TU/m/(T^2 + U^2)$.

Tracing the general expression with appropriate Pauli matrices, we extract the charge current $I \equiv e \text{Tr}(\hat{\tau}_3 \hat{I})$ and the spin current $\hat{I}_s = \text{Tr}(\hat{\sigma} \hat{I})$. The real-time response is obtained by the method of analytic continuation, described in Appendix B.

We assume that the electrodes are in the diffusive regime and can be described by the time-dependent Usadel equation for quasiclassical GFs. In the imaginary-time representation it has the form (we set $\hbar = 1$ here and below)

$$-i \{ \hat{\tau}_3 \hat{\partial}_\tau, \hat{g} \} = D \hat{\partial}_\tau (\hat{g} \circ \hat{\partial}_\tau \hat{g}) - i \{ \hat{\tau}_3 \hat{H}, \hat{g} \},$$

where $D$ is the diffusion constant, $\hat{H} = \Delta \hat{\tau}_3 + \mathbf{h} \cdot \hat{\sigma}$, and $\mathbf{h}$ is the exchange field. The quasiclassical GFs also satisfy the normalization condition $\langle \hat{g} \circ \hat{g} \rangle_{\tau, \tau'} = \delta(\tau - \tau')$. The time derivative, convolution product, and differential superoperator in Eq. (4) are

$$\{ \hat{\tau}_3 \hat{\partial}_\tau, \hat{g} \} = \hat{\tau}_3 \hat{\partial}_\tau \hat{g} - \hat{\partial}_\tau \hat{g} \hat{\tau}_3, \quad (5)$$

$$\{ f \circ g \} = \int_0^\beta d\tau \sum_{\tau_1} \tau_1 g(\tau_1, \tau_2) f(\tau_2, \tau_3) \hat{g}_S(\tau_3, \tau_2), \quad (6)$$

$$\{ \hat{\partial}_\tau, \hat{g} \} = \{ \hat{\partial}_\tau, \hat{g} \} - i e \{ \hat{\tau}_3 A(\tau), \hat{g} \}, \quad (7)$$

respectively, where $e$ is the elementary charge and $c$ is the speed of light.

III. RESULTS

A. Qualitative description

In Fig. 1(b) we adapt the usual semiconductor picture of the tunnel current in superconductor junctions [72] to show how the time-dependent gap function creates a nonequilibrium state $n(\varepsilon, t)$ in the superconducting electrode. Due to the Zeeman shift $h$, this state is nonsymmetric with respect to the Fermi level $\varepsilon_F$ and therefore produces spin current through the tunnel barrier between the SC and the adjacent normal metal. This qualitative picture is based on the time-dependent energy spectrum $E_\sigma = \sqrt{\xi_\sigma^2 + \Delta(t)^2} + \sigma h$, with $\sigma = \pm 1$ for spin-up/down Bogoliubov quasiparticles, respectively, where $\xi_\sigma$ is the kinetic energy counted from the Fermi level $\varepsilon_F$.

For a slow time-dependent order parameter the spin-resolved perturbation of the quasiparticle distribution function can be written as $(\Delta/\Gamma) \frac{d^2}{d\varepsilon^2} N_\sigma$, where the number of thermally excited states in equilibrium is $N_\sigma = \int d\xi \rho(E_\sigma(E, \Delta))$, with $n(E) = \tanh(E/2T)$. The inelastic scattering relaxation rate $\Gamma$ is given by the Dynes parameter [73].

The spin-dependent perturbation of the distribution function results in the spin current

$$I_\sigma(t) = \frac{\kappa}{\Gamma} \frac{d}{d\Delta} (N_+ - N_-), \quad (8)$$

where $\kappa$ is the effective barrier transparency. As shown below, Eq. (8) is obtained in the low-frequency limit $\Omega \ll \Gamma$ from the general result (21). The advantage of Eq. (8) is that it allows for the cartoon interpretation in terms of the semiconductor model in Fig. 1(b). However, for the most interesting case when the frequency of the $\Delta(t) \sim e^{2\Omega t}$ oscillation is comparable to the gap $\Omega \sim \Delta$ and hence is coupled to the HM [13,16,74,75], the picture becomes more complicated and requires calculations using Eqs. (3) and (4) as described in Sec. III C.

B. Second-harmonic generation due to the broken particle-hole symmetry

Spin current generated by the HM can be converted to charge current using spin-filtering FM electrodes. In the setup shown in Fig. 1(a) the spin current is effectively converted to the charge current while passing through the spin-filtering barrier characterized by the polarization vector $\mathbf{P}$. The time-dependent charge current induced in this way by the order parameter amplitude oscillation is therefore qualitatively given by $I(t) \propto \mathbf{P} \cdot \hat{I}_s(t)$, which results in the
estimate \( I(t) \propto (P \cdot \mathbf{h}) \tilde{A} \Delta \). Modulation of the order parameter amplitude can be induced, for example, by an external irradiation \([63, 64]\) \( \Delta(t) \propto A^2(t) \), where \( A(t) \) is the vector potential of the external field. Hence this charge current \( I(t) \propto (P \cdot \mathbf{h}) \tilde{A} \Delta \), being quadratic in the vector potential, demonstrates the second-harmonic generation (SHG) controlled by the superconducting order parameter.

Despite the large amount of attention to the nonlinear effects in superconductors, SHG has not been obtained before.\(^1\) Hence only third-harmonic generation has been studied in superconductors \([19, 32, 63, 64, 76]\). We show below that such a kind of SHG is not prohibited by the generic symmetries of the problem, but is eliminated by the approximate symmetry of Fermi surface systems, made exact in the widely used quasiclassical approximation \([77]\).\(^2\) This additional symmetry of the GF satisfying the Usadel equation (4) is

\[
\hat{g}(A, \mathbf{h}, \Delta) = - \hat{\tau}_1 \hat{g}(-A, \mathbf{h}, \Delta^*) \hat{\tau}_1. \tag{9}
\]

The off-diagonal Nambu space Pauli matrix \( \hat{\tau}_1 \) interchanges the particle and hole blocks in the Hamiltonian \([77]\), so the physical interpretation of Eq. (9) is a particle-hole symmetry. For the nonstationary charge current generated by the time-dependent vector potential this symmetry yields \( I(A, \Delta) = -I(-A, \Delta^*) \). Further, in the absence of supercurrent or external orbital fields we can assume the order parameter to be real \( \Delta = \Delta^* \). Then even the broken inversion symmetry near surfaces does not help to produce SHG in superconducting systems in contrast to the normal metal counterpart of this effect. Because of this symmetry, the direct coupling between the HM and the charge current is prohibited. However, as we see below, it allows for the spin currents driven by the HM and external field even with a nonferromagnetic barrier, that is, at \( P = 0 \).

The particle-hole symmetry is broken in superconducting/FM systems leading to large thermoelectric \([34, 78, 79]\) and anomalous Josephson effects \([77]\). For real \( \Delta \) the transformation (9) applied to the general tunnel current yields

\[
I(A, \mathbf{h}, P) = -I(-A, \mathbf{h}, -P). \tag{10}
\]

This relation allows for SHG. Because the sign of \( P \) is inverted there is no longer a symmetry with respect to the mere flipping of the vector potential, \( I(A) \neq -I(-A) \). Hence, for the AC external field \( A_{\text{osc}} e^{i \omega t} \), Eq. (10) allows for the double-frequency charge current component \( I_{2\omega} e^{i \omega t} \) with the amplitude \( I_{2\omega} \propto |\Delta|^2 A_{\text{osc}}^2 (P \cdot \mathbf{h}) \) as well as the DC tunnel current \([51]\) \( I_{\text{DC}} \propto |\Delta|^2 A_{\text{DC}}^2 (P \cdot \mathbf{h}) \). The resonant SHG of spin and charge currents through the excitation of HM by electromagnetic irradiation is discussed below in Sec. III C.

C. Calculation of spin and charge currents

We assume that the superconducting electrode is driven out of equilibrium by the electromagnetic field described by the time-dependent vector potential \( A_{\text{osc}} e^{i \omega t} \). It produces the second-harmonic perturbation of the GF and tunnel current (3)

\[
\hat{g}_S(t, t') = T \sum_\omega \hat{g}_S(\omega_+, \omega_-) e^{i \omega t - i \omega_- t'}, \tag{11}
\]

\[
\hat{I}_{2\omega} = -i \nu_F T \sum_\omega \left( \hat{g}_S(\omega_+) \hat{g}_0(\omega_-) - \hat{g}_0(\omega_+) \hat{g}_S(\omega_-) \right). \tag{12}
\]

where \( \omega_\pm = \omega \pm \Omega \) are the fermionic Matsubara frequencies shifted by the frequency \( \Omega \) of the external field. We define \( \hat{g}_S = \hat{g}_S(\omega_+, \omega_-) \) and assume that the ferromagnet is in the equilibrium state determined by the GF \( \hat{g}_F(\omega) = \hat{g}_0(\omega) \equiv \text{sgn}(\omega) \hat{\tau}_3 \).

There are two qualitatively different terms in the nonequilibrium GF \( \hat{g}_S = \hat{g}_{\text{AA}} + \hat{g}_{\Delta} \). The first one is generated by the direct coupling to the external electromagnetic field. The second term is generated by the order parameter oscillations, which can be induced by either the electromagnetic field or other sources, for example, the spin current. Direct coupling to the electromagnetic field is described by the GF perturbations of second order by the vector potential.

From the Usadel equation (4) we find that the perturbation \( \hat{g}_{\text{AA}}(\omega_+, \omega_-) \) satisfies the equation

\[
s_+ \hat{g}_0(\omega_+) \hat{g}_{\text{AA}} - s_- \hat{g}_{\text{AA}} \hat{g}_0(\omega_-) = D \left( \frac{e A_\Omega}{c} \right)^2 \left[ \hat{g}_0(\omega_+) \hat{g}_0(\omega_-) \hat{\tau}_3 - \hat{g}_0(\omega_+) \hat{g}_3(\omega_-) \hat{g}_0(\omega_-) \right]. \tag{13}
\]

Expanding the normalizaton condition in perturbation series provides an anticommutation rule \( \hat{g}_{\text{AA}} \hat{g}_0(\omega_-) = -\hat{g}_0(\omega_+) \hat{g}_{\text{AA}} \), which can be used to solve Eq. (13).

\[
\hat{g}_{\text{AA}} = D \left( \frac{e A_\Omega}{c} \right)^2 \hat{g}_0(\omega_+) \hat{g}_0(\omega_-) \hat{\tau}_3 - \hat{g}_0(\omega_+) \hat{g}_3(\omega_-) \hat{g}_0(\omega_-) s_+ - s_- \tag{14}
\]

where \( s_\pm = \hat{s}(\omega_\pm) \) and \( \hat{s}(\omega) = \sqrt{\Delta^2 - (i \omega \cdot \mathbf{h} \cdot \hat{\sigma})^2} \). Above, we abuse the notation slightly by writing the matrix inverse \( [s_+ + s_-]^{-1} \) as a scalar division. No ambiguity is introduced as \( \hat{s}(\omega) \)'s commute with the terms in the numerator. Furthermore, in the final expression for the spin current (21) we shift the energy integration and remove the exchange field from the \( \hat{s}(\omega) \)'s, making their spin structure trivial.

Corrections to the GF induced by the time-dependent order parameter amplitude \( \Delta_{2\Omega} e^{i \omega t} \) can be found in the form \( \hat{g}_\Delta(\tau, t') = T \sum_\omega e^{i \omega (\tau - t')} \hat{g}_\Delta(\omega_+, \omega_-) \). From the Usadel equation (4) \( \hat{g}_\Delta(\omega_+, \omega_-) \) satisfies the equation

\[
s_+ \hat{g}_0(\omega_+) \hat{g}_\Delta - s_- \hat{g}_\Delta \hat{g}_0(\omega_-) = \Delta_{2\Omega} [\hat{g}_2(\omega_-) \hat{g}_0(\omega_-) - \hat{g}_0(\omega_+) \hat{g}_2(\omega_-)]. \tag{15}
\]

Again using the normalization condition, the solution of this equation is given by

\[
\hat{g}_\Delta = \Delta_{2\Omega} \frac{\hat{g}_2(\omega_+) \hat{g}_0(\omega_-) - \hat{g}_0(\omega_+) \hat{g}_2(\omega_-)}{s_+ + s_-}. \tag{16}
\]

The amplitude \( \Delta_{2\Omega} \) can be found from the self-consistency equation

\[
\Delta_{2\Omega} = -\lambda T \sum_\omega \text{Tr}[\hat{g}_2(\hat{g}_{\text{AA}} + \hat{g}_\Delta)]. \tag{17}
\]
where we introduce the dimensionless pairing constant \( \lambda \) and the Pauli matrix \( \vec{\tau}_2 \) corresponds to the superconducting amplitude vertex.

The part which is directly produced by the irradiation provides a source of the Higgs mode

\[
F_\Delta(2\Omega) = -\lambda T \sum_\omega \text{Tr}[\vec{\tau}_2 \hat{g}_{AA}].
\] (18)

The other part determines the self-induced corrections to the order parameter \( \Delta_2 \Omega = \Pi(2\Omega)\Delta_2 \Omega \) described by the polarization operator

\[
\Pi(2\Omega) = 1 + \pi \lambda T \sum_\omega \text{Tr}\left[\frac{\Delta^2 + \Omega^2}{e^{-\beta(\Delta_+ + \Delta_-)}}\right].
\] (19)

where the trace is taken over the spin degree of freedom. Collecting all the contributions to the self-consistency equation (17), we get

\[
\Delta_2 \Omega = F_\Delta/[1 - \Pi(2\Omega)].
\] (20)

This expression describes the HM excitation in the superconductor driven out of equilibrium by a continuous-wave irradiation as shown schematically in Fig. 1(a). The resonance condition corresponding to the HM is satisfied for \( \Omega = \Omega^* \) when \( 1 - \Pi(2\Omega^*) = 0 \). Hence the maximal amplitude of the order parameter oscillations is determined by the broadening parameter \( \Gamma \), leading to a sharp peak in \( \Delta_2 \Omega(\Omega, T) \) for \( \Omega \approx \Omega^*(T) \). In the absence of spin relaxation processes \( \Omega^* = \Delta(T) \).

Using the found GF corrections (14) and (16), we calculate the spin and charge components of the tunneling current (12). The HM contribution is determined by the term \( \hat{g}_{\Delta} \). Using the procedure of analytical continuation described in Appendix B, we obtain the amplitude of real-frequency spin current \( I_s(\Omega)e^{i2\Omega t} \) driven by the HM,

\[
I_s(\Omega) = i\hbar \Delta_2 \Omega \sum_\sigma \frac{\sigma}{\hbar} \int \frac{d\varepsilon}{2\pi} \varepsilon [n(\varepsilon_+) - n(\varepsilon_-)] s^\sigma_+ s^\sigma_-, (21)
\]

where \( n(\varepsilon) \) is the equilibrium distribution function. Here the spin splitting has been shifted from the spectral functions to the distribution functions, so \( \varepsilon_\pm = \varepsilon \pm \Omega \pm \sigma \hbar \) and \( g^{\sigma,\lambda} = -i\sqrt{\varepsilon \pm i\Gamma^2 - \Delta^2} \). In the low-frequency limit \( \Omega \ll \Gamma \) we obtain Eq. (8) when the spin current is driven by the adiabatic time dependence of \( \Delta \) in accordance with the qualitative picture shown schematically in Fig. 1(b).

In the presence of the HM, which is the slowly decaying oscillations of the order parameter \( \Delta(t) \) [13,16], the spin current is given by the sum of the corresponding Fourier components with the amplitudes given by (21). As a result of Eq. (21) we get slowly decaying oscillations of the spin current \( I_s(t) \) which can be measured using electrical probes after the superconductor is initially driven into a nonequilibrium state by a field pulse.

Taking into account the relation (20), we obtain the SHG spin and charge currents induced by the external irradiation in accordance with the qualitative discussion in Sec. III.B. The resonant behavior of the double-frequency spin current \( I_s(\Omega) \) resulting from the HM mode excitation is shown in Fig. 2.

**IV. DISCUSSION**

### A. Electrical detection of the Higgs mode

The suggested effect of SHG charge current coupled to the HM can be measured, for example, in thin films of Al superconductor placed in a tunnel contact with FM iron electrodes similar to the setups used in the measurement of the nonlocal spin signals [38–40,43–47]. With \( T_c = 1.6 \) K and gap \( \Delta_0 = 2 \times 10^{-4} \) eV, the spin-splitting field \( \kappa = 0.2 \Delta_0 = 0.2 \) can be obtained with an external in-plane magnetic field \( B \approx 0.5 \) T, and the polarization of this type of FM contact [44] is \( P = 0.2 \).

With large enough area, the normal-state tunnel conductance can be \( eK = 10^{-2} \) S. The electromagnetic part of the setup can be similar to the experiments on stimulated superconductivity [80,81]. The electromagnetic power is characterized by the parameter \( \alpha = D(eA_{\Omega}/c)^2 \), which can be made as large as \( \alpha = 0.1T \) without destroying the superconductivity. For Al it yields \( \alpha \approx 10^{-5} \) eV. With such parameters the charge current amplitude corresponding to Fig. 2 is \( eP_{\Omega \Omega} = 20 \) nA, which is two orders of magnitude larger than the nonlocal thermoelectric current measured recently in a similar setup [47]. The maximal HM resonance frequency in Al is \( 2\Omega = 100 \) GHz, which is within the capability of modern spectrum analysers. A 10-nA current across 50 \( \Omega \) corresponds to the signal amplitude \(-113 \) dBm, which means that the signal-to-noise level exceeding unity can be obtained within a 1-s measurement time with state-of-the-art high-frequency microwave spectrum analysers with a noise floor about \(-120 \) dBm/Hz.

### B. Spin torques generated by the Higgs mode

If the exchange field \( h \) in the SC is noncollinear with the magnetization \( m \) in the ferromagnet, the HM generates a spin torque acting on \( m \). The generic system which can realize this configuration is shown in Fig. 3(a). Here the exchange field \( h \parallel m_0 \) is created by the ferromagnetic insulator layer with a fixed magnetic moment \( m_0 \) [34].

The spin-transfer torque (STT) generated by the HM is shown schematically in Fig. 3(a). The polarization of the
nonequilibrium spin current \( I_s \) is determined by the direction of the exchange field \( h \). Assuming that the transverse component of the spin current is absorbed in the ferromagnet \([83–87]\), we obtain the STT \( \tau = I_s h_{\perp} / \hbar \), where \( h_{\perp} = h - m (m \cdot h) \) is the perpendicular component of the exchange field.

The reciprocal effect shown in Fig. 3(b) is the perturbation of the gap \( \delta \Delta \) by the magnetic precession. The pumped spin current \([83]\) \( I_s \propto m \times m \) has a longitudinal component \( I_s \parallel h \) which generates a time-dependent spin accumulation \( \mu_s \) in the SC. In combination with the spin-splitting field \( h \), this results in \([51,88]\)

\[
\delta \Delta = \frac{\lambda \Delta}{1 - \Pi} \mu_s \delta \Delta (N_+ - N_-),
\]

where \( 1 - \Pi \propto \lambda \) is the low-frequency asymptotic of the polarization operator. This expression demonstrates the possibility to couple the order parameter amplitude with the magnetization dynamics. Thus the higher-frequency magnetization precession with \( \Omega \sim \Delta \) generates the HM in the superconductor with a spin-splitting field.

This effect can be viewed as the HM-mediated transfer of the spin angular momentum from the ferromagnetic insulator to the metallic ferromagnet shown in Fig. 3(a). Oscillating STT generated by the order parameter amplitude mode can excite the ferromagnetic resonance (FMR) in the attached ferromagnet. Hybridization of the FMR and Higgs resonance should show up as the avoided crossing of the peaks in the second-harmonic response of the systems. Such an experiment will directly demonstrate the dynamical coupling of the magnetic and superconducting orders. Modification of the FMR linewidth by superconducting correlations in ferromagnet/SC structures has been observed \([89–91]\). In permalloy films the FMR has been measured in fields up to 0.3 T corresponding to a frequency of 20 GHz. For such a frequency the Higgs resonance in Al is expected to occur at \( T \approx 0.92T_c \). Thus varying the field, one can measure the temperature-controlled hybridization of the HM and FMR mode in Al/permalloy structures within the currently accessible range of parameters.

V. CONCLUSION

We have demonstrated that spin and charge currents can be effectively generated by the collective amplitude modes of the superconducting order parameter. Owing to the fact that the HM can be generated by external irradiation \([27,92]\), our result paves the way for a conceptually different direction of superconducting optospintronic: the study of spin currents and spin torques generated by light interacting with superconducting materials.

We have suggested a detection scheme for the HM based on measuring resonant electric signals, either the charge current or voltage generated across the spin-polarized tunnel junction by the external field. Because these signals appear at the doubled frequency of the external field, our setup introduces a system featuring second-harmonic generation controlled by superconductivity. The suggested SHG can be studied using optical or microwave detectors \([93]\) and the tunneling current \( I_{\Omega} \) can be detected using electrical probes. This feature of the SHG as compared to the previously known nonlinear response techniques allows for an electrical detection of the HM in superconductors.

Finally, a qualitatively similar effect should occur provided the ferromagnet is replaced by another spin-filtering element such as a semiconductor nanowire in proposed Majorana-based qubits \([94–97]\). The charge noise which is important in such devices \([97]\) can cause the order parameter oscillations coupled to the splitting of Majorana zero modes. This coupling opens possibilities for many interesting effects to study.

APPENDIX A: TUNNEL CURRENT

We model the spin-dependent tunneling through the SC/ferromagnet interface by the tunneling Hamiltonian (1). We calculate the tunneling current as a function of the time on the contour running along the imaginary axis from 0 to \( \beta = 1/T \).

The matrix tunneling current in terms of the imaginary time functions reads

\[
I(\tau) = \frac{i}{2} \sum_k \left[ \partial_\tau \tilde{G}_S(\tau, \tau', k, k) + \partial_{\tau'} \tilde{G}_S(\tau, \tau', k, k) \right]_{\tau = \tau'}.
\]

(A1)

To find the perturbation we consider the contour-ordered GF

\[
\tilde{G}_S(\tau_1, \tau_2, k, k') = \langle \mathcal{T} \tilde{\hat{S}}_k(\tau_1) \hat{A}^\dagger_k(\tau_2) \rangle,
\]

(A2)

where \( \mathcal{T} \) is the contour-ordering operator and

\[
\hat{S} \approx 1 - \int_0^\beta d\tau_3 H_T(\tau_3).
\]

(A3)
In the interaction representation with respect to the tunneling Hamiltonian the equation of motion is

$$\partial_\tau \hat{A}_k = [\hat{A}_k, H_T] = \sum_k (\hat{\Gamma}_{kk'} \hat{B}_{k'}).$$

(A4)

Using the equation of motion we get

$$-\partial_\tau \hat{G}_F(\tau_1, \tau_2, k, k') = -\sum_q \langle \hat{T} \hat{S} \hat{\Gamma}_{kk'} \hat{B}_q(\tau_1) \hat{A}_k^\dagger(\tau_2) \rangle$$

$$\approx \sum_q \left\langle \hat{T} \int_0^\beta d\tau_3 \hat{B}_{k'}(\tau_3) \hat{\Gamma}_{kk'}^\dagger \hat{A}_k(\tau_3) \hat{\Gamma}_{qk} \hat{B}_q(\tau_3) \hat{A}_k^\dagger(\tau_2) \right\rangle$$

$$= \sum_{k_1, k_1'} \int_0^\beta d\tau_3 \hat{B}_{k_1'}(\tau_3) \hat{\Gamma}_{k_1 k_1'} \hat{A}_k(\tau_3) \hat{B}_{k_1}(\tau_3) \hat{A}_k^\dagger(\tau_2) \hat{\Gamma}_{qk}$$

$$= \sum_{k_1, k_1'} \int_0^\beta d\tau_3 \hat{\Gamma}_{k_1 k_1'} \hat{B}_q(\tau_3) \hat{\Gamma}_{k_1 k_1'} \hat{A}_k(\tau_3) \hat{B}_{k_1}(\tau_3) \hat{A}_k^\dagger(\tau_2) \hat{\Gamma}_{qk}$$

$$= \sum_{k_1, k_1'} \int_0^\beta d\tau_3 \hat{G}_F(\tau_1, \tau_3, k, k') \hat{\Gamma}_{k_1 k_1'} \hat{G}_F(\tau_3, \tau_2, k_1', \tau, q, k) \hat{\Gamma}_{qk}.$$  

(A5)

Hence the matrix current is given by

$$\hat{I}(\tau) = \frac{i}{2} \sum_{k_1, k_1'} \int_0^\beta d\tau' \left[ \hat{G}_F(\tau, \tau', k, k_1) \hat{\Gamma}_{k_1 k_1'} \hat{G}_F(\tau', \tau, k_1', q) \hat{\Gamma}_{qk} \right.$$

$$- \hat{\Gamma}_{k_1} \hat{G}_F(\tau, \tau', q, k_1') \hat{\Gamma}_{k_1 k_1'} \hat{G}_F(\tau', \tau', k_1', k).$$  

(A7)

We assume that GFs are spatially homogeneous, so \(\hat{G}_F(\tau, \tau', q, k_1) = \delta_{q, k_1} \hat{G}_F(\tau, \tau', q)\) and the matrix element is momentum independent \(\hat{\Gamma}_{kk'} = \hat{\Gamma}\). Then we can introduce the quasiclassical functions \(\sum_q \hat{G}_{F,S}(\tau, \tau', q) = v_{F,S} \hat{T}_3 \hat{g}_{F,S}(\tau, \tau')\) to write the current as

$$\hat{I}(\tau) = \frac{i v_{F,S}}{2} \left[ \hat{g}_{F,S} \circ (\hat{T}_3 \hat{g}_{F,S} \hat{T}_3) - (\hat{T}_3 \hat{g}_{F,S} \hat{T}_3) \hat{g}_{F,S} \right]_{\tau=\tau'}.$$  

(A8)

Taking into account that the normal metal GF \(\hat{g}_F\) commutes with \(\hat{T}_3\), Eq. (A8) can be reduced to Eq. (3).

APPENDIX B: ANALYTICAL CONTINUATION

In order to find the real-frequency response we need to implement the analytic continuation of Eq. (12). These second-order responses are obtained by the summation of expressions which depend on the multiple shifted fermionic frequencies such as \(g(\omega_1, \omega_2, \omega_3)\). The analytic continuation of the sum by Matsubara frequencies is determined according to the general rule [98]

$$T \sum_\alpha g(\omega_1, \omega_2, \omega_3) \rightarrow \sum_{l=1}^3 \int \frac{d\epsilon}{4\pi i} n_0(\epsilon_l) \left[ g(\ldots -i\epsilon_l^R, \ldots) - g(\ldots -i\epsilon_l^A, \ldots) \right],$$

(B1)
where \( n_0(\varepsilon) = \tanh(\varepsilon/2T) \) is the equilibrium distribution function. On the right-hand side of (B1) we substitute in each term \( \omega_{kcl} = -i \varepsilon_k^R \) and \( \omega_{kuj} = -i \varepsilon_k^A \) for \( k = 1, 2, 3 \), and we define \( \varepsilon_k = \varepsilon + (2 - k)\Omega, \varepsilon^R = \varepsilon + i\Gamma, \) and \( \varepsilon^A = \varepsilon - i\Gamma. \) Here the term with \( \Gamma > 0 \) is added to shift the integration contour into the corresponding half plane. At the same time, \( \Gamma \) can be used as the Dynes parameter [73] to describe the effect of different deparing mechanisms on spectral functions in the superconductor.

We implement the analytical continuation in such a way that \( s(-i\varepsilon^R, A) = -i\sqrt{(i\varepsilon^R)^2 - \Delta^2} \), assuming that the branch cuts run from \( \Delta, \infty \) and \( (-\infty, -\Delta). \) In the presence of the spin-splitting field the energy in Eq. (B1) should be shifted to \( \varepsilon + \sigma h \), where \( \sigma = \pm 1 \) is the spin subband index.

The equilibrium GF in the imaginary frequency domain is given by \( \hat{g}_0(i\omega) = (\tilde{\varepsilon}_i - \tilde{\varepsilon}_i^\Delta)/s(i\omega). \) The real-frequency continuation reads \( \hat{g}^{R,A}_0(\varepsilon) = (\varepsilon^R \pm \varepsilon^A)/\sqrt{(i\varepsilon^R)^2 - \Delta^2}. \)

Example. To demonstrate the analytical continuation in practice we calculate the spin current driven by the Higgs mode. For real frequencies the spin current obtained from (A8) can be written in terms of the Keldysh component

\[
I_s = \frac{\kappa}{8\pi} \sum_\sigma \int d\varepsilon \text{Tr}[\hat{g}^{R}(\varepsilon_+)(\hat{g}^{S}(\varepsilon_+ - \varepsilon) + \hat{g}^{S}(\varepsilon_+ - \varepsilon))]K
\]

from which

\[
I_s = \frac{\kappa}{8\pi} \sum_\sigma \int d\varepsilon [n(\varepsilon_+ + \varepsilon_-, \Delta)]\text{Tr}[\tilde{\varepsilon}_i \hat{g}^{R}(\varepsilon_+)].
\]

where \( \varepsilon_\pm = \varepsilon + \sigma h \pm \omega. \) In deriving (B2) we used the fact that \( \hat{g}^{R}(\varepsilon) = \pm 1 \) do not depend on energy. The anomalous part of the nonequilibrium GF in the superconductor is

\[
\hat{g}^{S}_s = \Delta\Omega \frac{\hat{g}^{R}(\varepsilon_+ + \varepsilon, -\varepsilon_+, \Delta)}{\varepsilon^R + \varepsilon^A},
\]

where we define \( \varepsilon^{R,A} = \varepsilon^{R,A}(\varepsilon_\pm). \) Substituting the solution (B3) and using Tr[\( \tilde{\varepsilon}_i \hat{g}^{R}(\varepsilon_+ + \varepsilon, -\varepsilon_+, \Delta) \)] = \( 2i\Delta_0\varepsilon_0^{R,A}/(\varepsilon^R + \varepsilon^A), \) we get

\[
I_s = i\kappa \Delta_0\Omega \sum_\sigma \int d\varepsilon (\varepsilon + \sigma h)[n(\varepsilon_+ + \varepsilon) - n(\varepsilon_- + \varepsilon)]
\]

\[
= i\kappa \Delta_0 \Omega \int d\varepsilon \frac{1}{16\pi} \sum_\sigma [n(\varepsilon_+ + \varepsilon) - n(\varepsilon_- + \varepsilon)] \left( \frac{1}{\varepsilon^R + \varepsilon^A} \right),
\]

where we use \( (\varepsilon^R)^2 - (\varepsilon^A)^2 = 4(\varepsilon + \sigma h)(\omega + i\Gamma). \) In the low-frequency limit we can substitute \( n(\varepsilon_\pm + \varepsilon) \) and \( \varepsilon^{R,A} = -i\sqrt{(\varepsilon^R)^2 - \Delta^2}. \) Then the spin current can be written in the simple form

\[
I_s = \frac{\kappa}{\Gamma} \sum_\sigma \frac{d}{dt} \int d\xi \rho(E_\sigma(\xi, \Delta(t)))
\]

\[
= \frac{\kappa}{\Gamma} \Delta \frac{d}{d\Delta}(N_+ - N_-),
\]

where \( E_\sigma(\xi, \Delta(t)) = \sqrt{\varepsilon^R + \Delta^2(t)} + \sigma h \) is the spectrum of Bogoliubov quasiparticles shifted by the spin-splitting field \( h. \)
