Ecchymoses, caused by extravascular leakage of red blood cells into soft tissue, commonly develop as a result of accidental trauma during cosmetic procedures. Several therapeutic modalities, including topical vitamin K cream alone or in combination with retinol cream, oral arnica, and topical arnica have been reported to effectively reduce post-traumatic bruising. In addition, treatment of ecchymoses with a 595-nm pulsed-dye laser after facial cosmetic procedures has been shown to be safe and effective. In the current report, we treated a patient with bruising along the abdomen and flanks, which developed after a cryolipolysis procedure. We treated the ecchymotic lesions in our patient with a 595-nm pulsed-dye laser on postoperative day 1 and observed remarkable recovery of the bruising, compared to the untreated control lesions.

Key words
Pulsed-dye laser; Ecchymosis; Bruising
**INTRODUCTION**

Ecchymoses commonly develop as a result of accidental trauma that induces extravascular leakage of red blood cells into soft tissue during various cosmetic procedures. Although ecchymoses typically resolve spontaneously without the need for any specific treatment, in cases of severe lesions, social activity can be limited for up to 2-4 weeks. Meanwhile, several therapeutic modalities, including topical vitamin K cream alone or in combination with retinol cream, oral arnica, and topical arnica, have been reported to effectively reduce post-traumatic bruising.

Additionally, 595-nm pulsed-dye laser therapy for ecchymoses after facial cosmetic procedures has been shown to be safe and effective. Laser energy with a wavelength of 595 nm is also suggested to be preferentially absorbed by extravasated red blood cells that make up the ecchymotic lesions. In this report, we describe the case of a patient with post-cryolipolysis ecchymoses along the abdomen that were effectively treated by 595-nm pulsed-dye laser therapy.

**CASE REPORT**

A 43-year-old Korean male patient visited our clinic presenting with localized fat deposits along the abdomen and flanks. He had no pertinent family history or medical history, including essential hypertension, hypercholesterolemia, or bleeding tendency. Despite diet and exercise to reduce body fat, he reported experiencing no remarkable changes therein (Fig. 1A). Thus, after obtaining written informed consent, we performed cryolipolysis on the patient using the CoolSculpting (Zeltiq Inc., Pleasanton, CA, USA) procedure along the abdomen and both flanks. The cryolipolysis procedures were delivered over a treatment duration of 60 minutes with a cooling intensity factor of 42 [-72.9 mW/cm²] and 50% overlap between the treated regions. Immediately after the cryolipolysis, extensive ecchymotic patches developed along the abdomen and both flanks.

One day after the procedure, ecchymotic patches became more distinctive (Fig. 1B). Therefore, treatment with a 595-nm pulsed-dye laser (Vbeam; Candela Corporation, Wayland, MA, USA) was delivered on half of the lesions as a trial. The laser settings comprised a fluence of 7.5 J/cm², a 10-mm spot size, a pulse width of 6 milliseconds, and a single pass. An integrated dynamic-cooling device was used to protect the epidermis from burns at a setting of 20/20 milliseconds. One (Fig. 1C) and three days (Fig. 1D) after the pulsed-dye laser treatment, the ecchymotic lesions of the treated sites had remarkably improved, compared to those of the untreated sites, without any noticeable side effects.

**DISCUSSION**

Body contouring procedures can be performed via invasive or non-invasive methods. Although invasive methods, especially surgical liposuction, can provide more promising clinical outcomes, the risks of side effects associated with anesthesia and invasive procedure are
higher and downtime for recovery is longer, compared to non-invasive methods.6-9 Nevertheless, non-invasive body contouring methods, including infrared light, low-level laser, or light therapy, high-intensity focused ultrasound, radiofrequency, and cryolipolysis, have been performed with inconsistent clinical results.7-9

Cryolipolysis has been utilized to reduce body fat mass by selectively inducing cold panniculitis in targeted tissues, resulting in fat modulation and clearance without damage to surrounding tissues.9,10 Compared to other non-invasive methods that induce fat destruction or necrosis, cryolipolysis induces an apoptotic response in adipocytes, which are gradually removed over the following 3 months. Nevertheless, despite its non-invasiveness, cryolipolysis procedures are commonly and transiently associated with side effects of edema, erythema, neuralgia, and bruising.

A previous study reported on the clinical efficacies of 595-nm pulsed-dye laser therapy on 20 patients with ecchymoses, which developed after cosmetic procedures on the face, including thread lift, lipo-contouring or lipotransfer, and cervicofacial rhytidectomy.1 In their study, the authors administered pulsed-dye laser treatment with a fluence of 6 J/cm² over a 10-mm spot size and pulse duration of 6 milliseconds, with a cryogen spray/delay for 30/20 milliseconds.1 The lateral halves of ecchymotic areas were treated with the pulsed-dye laser on postoperative day 5 or 6, while the medial half was treated on days 7 to 10.1 Therein, ecchymosis scores improved by 60% within 2-3 days after the laser treatment, and the authors suggested that the maximal efficacy of this treatment can be obtained when pulsed-dye laser treatment is performed on postoperative days 5-10.1 In the present report, we treated a patient with bruising along the abdomen and flanks, which developed after a cryolipolysis procedure. We treated the ecchymotic lesions in our patient with a 595-nm pulsed-dye laser on postoperative day 1 and observed remarkable recovery of the bruising, compared to the untreated control lesions.

Although post-therapeutic ecchymoses or bruising is a transient, relatively mild side effect of cosmetic procedures, severe cases can experience psychological stress, social intimidation, and physical discomfort. Therefore, non-purpuragenic pulsed-dye laser treatment at a wavelength of 595 nm and low fluence can be used to treat ecchymoses with cosmetically acceptable clinical results.
