Key role of the moiré potential for the quasi-condensation of interlayer excitons in van der Waals heterostructures

Interlayer excitons confined in bilayer heterostructures of transition metal dichalcogenides (TMDs) offer a promising route to implement two-dimensional dipolar superfluids. Here, we study the experimental conditions necessary for the realisation of such collective state. Particularly, we show that the moiré potential inherent to TMD bilayers yields an exponential increase of the excitons effective mass. To allow for exciton superfluidity at sizeable temperatures it is then necessary to intercalate a high-κ dielectric between the monolayers confining electrons and holes. Thus the moiré lattice depth is sufficiently weak for a superfluid phase to theoretically emerge below a critical temperature of around 10 K. Importantly, for realistic experimental parameters interlayer excitons quasi-condense in a state with finite momentum, so that the superfluid is optically inactive and flows spontaneously.

Introduction – Since seminal theoretical predictions were formulated in the 1960’s [1], semiconductor excitons have been at the focus of a long-lasting research aiming at Bose-Einstein condensation and its related superfluidity. Triggered by the proposal of Lozovik and Yudson [2], two-dimensional excitons confined in semiconductor bilayers have turned as the most favorable candidates to reach this objective. Such bilayer excitons are characterised by the separation enforced between their electron and hole constituents, which are each confined in a different layer. As a result they exhibit a long lifetime, a priori sufficient for cold gases to reach thermodynamically quantum degeneracy [3]. Furthermore, they all have an electric dipole oriented perpendicular to the bilayer, so that exciton-exciton interactions are governed by a repulsive dipolar potential stabilising cold and dense gases.

Relying on unmatched material quality thanks to molecular beam epitaxy, studies of bilayer excitons confined in GaAs coupled quantum wells have traced the path for engineering quasi-condensates [4]. Indeed, in GaAs bilayer excitons are studied in a homogeneously broadened regime [5] where the fingerprints of quasi-condensates are found in the photoluminescence radiated by optically bright states. Thus one observes algebraically decaying temporal coherence [5] combined to quasi long-range spatial coherence [6, 7]. Importantly, these signatures are consistent with a Berezinskii-Kosterlitz-Thouless transition [8, 9] expected for this two-dimensional geometry.

In GaAs, bilayer excitons have a binding energy of a few meV that limits the maximum exciton density to less than 10^{11} cm^{-2}. Therefore, the critical temperature for their quasi-condensation is bound to about 1K. This limitation does not arm fundamental studies but in practice precludes device applications for quantum technologies. In fact, these require much higher operating temperatures, which remarkably may be accessed by interfacing atomic layers of transition metal dichalcogenides (TMDs) [10], in so-called van der Waals heterostructures [11–13]. Thus, electrons and holes are possibly confined in a distinct layer thereby implementing bilayer (interlayer) excitons, whose binding energy is up to 50 times greater than in GaAs. As a result, interlayer excitons are possibly studied at higher densities, above 10^{12} cm^{-2}. Then, collective quantum phenomena potentially emerge below higher critical temperatures, the latter scaling proportionally to the density.

Unlike in GaAs, in TMDs bilayer excitons have their potential energy modulated spatially, due to the so-called moiré potential that results from a non-zero twist angle between interfaced mono-layers, and/or a mismatch between their lattice constants [12]. Thus, the electronic bandgap varies spatially, with a period typically around 10-30 nm and an amplitude governed by the exact heterostructure design. Precisely, when two TMD monolayers are interfaced directly the moiré potential has been measured as large as 150 meV [15]. On the other hand, when one or two hBN monolayers are intercalated between the TMDs confining electrons and holes, the moiré potential has an amplitude that is expected around 5 – 10 meV [14]. In general, the moiré potential offers formidable opportunities to spatially arrange electronic carriers, at the nanoscale: evidence for electron crystallisation in the moiré lattice of TMD bilayers were indeed reported very recently [14, 16–18], as well as the localisation of interlayer excitons [19–22].

In this work, we highlight that the moiré potential governs the parameter space where the quasi-condensation of interlayer excitons is accessible. By directly solving the Schroedinger equation, we first emphasize that interlayer excitons experience an exponential increase of their effective mass due to the moiré potential. In the regime where the latter has a large depth, the excitons effective mass is increased by orders of magnitude, so that the critical temperature for quantum degeneracy becomes practically inaccessible. On the other hand, for weak moiré potential depths, i.e. when the excitons effective mass is weakly varied, we determine the experimental parameters, e.g. the period and the depth of the moiré lattice potential, where exciton superfluidity may be accessed. For that, we rely on a mean-field treatment of the Bose-Hubbard model and show that exciton superfluidity is favourable when the moiré potential depth is less than 10 meV, below a critical temperature of around...
10 K. We then discuss our findings with regards to the experimental state-of-the-art, as well as accessible experimental signatures for exciton superfluids.

**Moiré potential and interlayer excitons luminescence** — For simplicity, let us consider an heterobilayer such as 

WXY

/

MoY

2,

each layer confining electrons or holes constituting interlayer excitons. Stacking two of such monolayers yields a moiré lattice with a period given by

\[ a_m \sim a_0/\sqrt{\theta^2 + \delta^2} \]

where \( \theta \) denotes the twist angle between the layers and \( \delta = |\alpha_0 - a_1|/a_0 \), \( a_0, \alpha_1 \) being the lattice constants of each layer. Interestingly, the lattice mismatch between the two monolayers is greatly reduced when the two chalcogen atoms X and Y are identical (\( \delta \sim 0.1\% \)), whereas it can reach a few \% otherwise. Figure 1.a illustrates the moiré lattice by depicting the real space arrangement of atoms for two monolayers stacked with a small twist angle, neglecting \( \delta \).

![Moiré lattice illustration](image)

**FIG. 1:** (a) Real space arrangement of atoms for two monolayers, red and blue respectively, stacked with a small twist angle \( \theta \), neglecting the lattice mismatch. The resulting moiré lattice is drawn in black. (b) Brillouin zones of the two monolayers together with the moiré Brillouin zone (black) resulting from the non-vanishing twist angle \( \theta \). The latter controls the momentum separation \( Q_m \) between the corners of the moiré Brillouin zone. (c) Dispersion of interlayer excitons for a non-vanishing twist angle (green) together with the photon dispersion (orange). Their intersection marks the optically active region of the exciton band.

An important consequence of the moiré lattice regards the optical activity of interlayer excitons. Indeed, these are made of electrons and holes each confined in a different layer, and by discarding \( \delta \) for simplicity we note that a finite twist angle between the monolayers implies that their reciprocal lattices experience a net relative rotation (Fig.1.b). As a result, the extrema of the valence and conduction bands of each monolayer are not aligned in reciprocal space. Thus, interlayer excitons have a lowest energy state lying at \( Q_m \) from the optically bright region with around zero momentum (Fig.1.c). For a WSe

2/ MoSe

2 hetero-bilayer with a typical twist angle \( \theta \sim 1^\circ \) we deduce that \( Q_m \sim 130 \mu m^{-1} \). Then, a quasi-condensate of interlayer excitons, necessarily occurring due to a macroscopic occupation of the lowest energy state [25], does not radiate any photoluminescence. Instead, it carries a finite momentum. Let us finally note that engineering an optically bright quasi-condensate, i.e. with around zero momentum, seems out of experimental reach since it requires a maximum twist \( \theta \sim 0.2^\circ \) considering a WSe

2/MoSe

2 hetero-bilayer.

**Exciton effective mass in a moiré potential** — Besides inducing a relative shift of conduction and valence bands in reciprocal space, the moiré potential also leads to a modulation of the excitons potential energy in real space. Considering this modulation is necessary to accurately model the optical selection rules of interlayer excitons [23, 24]. In the following we show that it is also necessary to carefully consider the depth of the moiré potential to accurately evaluate the excitons effective mass and therefore the critical temperature for their quasi-condensation.

The Hamiltonian for interlayer excitons exploring a moiré potential can be simply expressed as

\[
H = -\frac{\hbar^2}{2m} \frac{\partial^2}{\partial z^2} + sE_R \sin^2(qz)
\]

by restricting the excitonic motion to one direction \( z \) of the moiré lattice. In Eq.(1) \( m \) denotes the exciton mass, i.e. for a moiré potential with vanishing amplitude. In the second term \( sE_R \) provides the depth of the moiré lattice \( V_0 \), with \( q = \pi/a_m \) and \( E_R = \hbar^2 q^2/2m \). Of course, the hamiltonian (1) does not take into account the moiré potential in its full microscopic complexity. Nevertheless, Eq.(1) allows one to accurately extract the renormalised effective mass by a lattice potential, as shown for ultra-cold atoms confined in square optical lattices [26]. Therefore we follow this approach here in the context of interlayer excitons exploring a triangular moiré potential.

Using the above hamiltonian we look for the solutions of the eigen equation \( H\psi_p = E(p)\psi_p \). This turns into solving a Mathieu equation [27] so that the solutions \( \psi_p \) are Mathieu functions, having a period \( a_m \) by definition, while \( p \) denotes the excitons quasi-momentum. The excitons effective mass \( m^* \), accounting for the moiré potential, is then deduced from the energy dispersion by setting \( E(p) \sim E_0 + p^2/2m^* \). Let us note that this matching is accurate for both weak and deep moiré lattices, although in the former case one needs to include on-site interactions into the hamiltonian in order to exactly deduce \( m^* \) [26].

Figure 2.a presents the ratio \( m^*/m \) as a function of \( s \). As expected, for vanishing moiré potentials (\( s \sim 0 \)) we find that \( m^* \sim m \) whereas \( m^*/m \sim 2500 \) for deep moiré lattices (\( s \sim 50 \)). Indeed, Fig.2.a shows that the depth of the moiré lattice leads to an exponential increase of the excitons effective mass. This universal scaling as a function of \( s \) allows us to extract effective masses for heterostructures that are currently studied to explore the quasi-condensation of interlayer excitons. First, we consider a MoSe

2/WSe

2 heterobilayer as probed in Ref. [28]. In this device the electrons and holes have effective masses \( m_e \sim 0.49 m_0 \) and \( m_h \sim 0.35 m_0 \) respectively, leading to \( m = m_e + m_h \sim 0.84 \). Reference to the free electron mass. For a typical \( 1^\circ \) twist angle between stacked monolayers, the moiré lattice has a period \( a_m \sim 19 \) nm leading to \( E_R \sim 1.2 \) meV. The depth \( V_0 \) of the moiré lattice has not been measured for MoSe

2/WSe

2 heterobilayers, but for MoS

2/WSe

2 scanning tunneling microscopy.
FIG. 2: (a) Ratio between the excitons effective mass renormalised by the moiré lattice and the excitons bare effective mass, \( m^*/m \), as a function of the depth of the moiré potential \( s \), in units of \( E_R \). The green and orange shaded areas mark the parameter range for bilayers with and without hBN spacer respectively. (b) Excitons energy bands in the moiré Brillouin zone for \( s = 5 \) (red) and \( s = 50 \) (blue). The black dashed lines display the corresponding values of the potential depth \( s \). Energies are expressed in units of \( E_R \) and the quasi-momentum \( p \) in units of \( R^*_m \) which marks the corner of the moiré Brillouin zone.

has revealed that it is of around 150 meV depth [29]. Furthermore, DFT calculations have confirmed that \( V_0 \approx 110 \text{ meV} \) for MoSe\(_2\)/WSe\(_2\) [23]. This implies that \( s \sim 100 \) leading to \( m^*/m \sim 10^6 \). Moreover, independent experiments [30] have reported studies of a MoSe\(_2\)/WSe\(_2\) bilayer when two monolayers of hBN separate the TMDs. For such device the depth of the moiré potential is highly screened by hBN so that \( V_0 \) can not exceed 5-10 meV, leading to \( s \sim 5 - 10 \) and \( m^*/m \sim 1.5 - 5 \).

Having included the effect of the moiré lattice onto the effective mass of interlayer excitons we now deduce the critical temperatures where quantum degeneracy and superfluidity theoretically occur, \( T_d \) and \( T_{BKT} \) respectively. These are ruled by both the exciton density \( n \) and their effective mass \( m^* \). They read \( T_d = \frac{2\hbar^2 k_B^2 n}{k_B m^* g} \) and \( T_{BKT} \approx \frac{2 \hbar^2 k_B^2 n_s}{k_B m^*} \) [31], \( k_B \) being the Boltzmann constant while \( n_s = n / g \) denotes the superfluid density with \( n \) the total density and \( g \) the degeneracy of the lowest energy excitonic band. Taking into account the spin-orbit splitting of the conduction band, set \( g = 2 \) whereas for \( 10^{10} \lesssim n \lesssim 10^{12} \text{ cm}^{-2} \) \( \alpha \) ranges between 0.6 and 0.9 [31]. Figure 3.a displays the variations of \( T_{BKT} \) as a function of \( s \) and \( n \). For a MoSe\(_2\)/WSe\(_2\) heterobilayer we strikingly note that \( T_{BKT} \) lies in the milli-Kelvin range, so does \( T_d \). These magnitude directly reflect the exponentially increased \( m^* \). On the other hand, when a few hBN monolayers are intercalated between the two TMDs, Fig.3 shows that both \( T_d \) and \( T_{BKT} \) reach sizeable values, up to \( T_d \sim 30 \text{ K} \) and \( T_{BKT} \sim 7 \text{ K} \) when \( n \sim 10^{12} \text{ cm}^{-2} \) as shown in Fig.3.b.

Figure 3 illustrates that for bilayers including an hBN spacer \( T_{BKT} \) reaches sizeable values. Since this temperature scales linearly with \( n \) it is tempting to anticipate that \( T_{BKT} \) is directly enhanced for larger densities. However, we would like to point out that for two-dimension dipolar systems this assumption is not straightforward. Indeed, path integral Monte-Carlo calculations have shown that quasi-condensation of dipolar excitons is bound to a maximum density \( n \), defined by \( D \lesssim 15 \) when \( D = \frac{d^2}{\epsilon a^3} E_0 \), \( d \) being the exciton electric dipole moment while \( a = 1 / \sqrt{n} \) and \( E_0 = \hbar^2 / m^* a^2 \) [31]. Thus, we deduce that quasi-condensation becomes inaccessible beyond a maximum density of around \( 2.5 \times 10^{12} \text{ cm}^{-2} \) leading to \( T_{BKT} \sim 12 \text{ K} \), since in this situation the quasi-condensed fraction is reduced to around 60%. Note that \( n_s \) is maximised to about 90% for \( D \sim 1 \), obtained for \( n \sim 2 \times 10^{11} \text{ cm}^{-2} \) yielding \( T_{BKT} \sim 2 \text{ K} \). Let us then stress that experiments with bilayer excitons in GaAs have actually confirmed the breakdown of a quasi-condensate for \( D \gtrsim 12 \) [6], in relatively good agreement with these theoretical expectations.

**Mott insulator vs. superfluid of interlayer excitons**— Even if \( T_d \) and \( T_{BKT} \) are relatively high when hBN separates the monolayers confining electrons and holes, in the moiré lattice the emergence of exciton superfluidity is not necessarily favourable energetically below these critical temperatures. This actually depends on the competition between the excitons interaction strength in the lattice sites and the strength of exciton tunnelling between neighbouring sites. This competition is described by the Bose-Hubbard model [32] predicting that at least two antagonist states compete in the quantum regime. These are namely the Mott insulating phase characterised by a fixed number of particles in each lattice site whereas quasi long-range order is vanishing, and a superfluid phase marked by quasi long-range order and a fluctuating number of particles per lattice site. The Bose-Hubbard hamiltonian usually reads

\[
H_{BH} = -t \sum_{i,j} b_i^\dagger b_j + \frac{U}{2} \sum_i \hat{n}_i (\hat{n}_i - 1) - \mu \sum_i \hat{n}_i \tag{2}
\]

where the operator \( b_i^\dagger \) (\( b_i \)) creates (annihilates) an exciton at a site \( i \) of the moiré lattice, while \( \hat{n}_i = b_i^\dagger b_i \) denotes the number operator on the site \( i \). Furthermore, \( t \) represents the amplitude for tunnelling between two nearest neighbouring sites while \( U \) marks the strength of the on-site interactions between excitons. Finally
\( \mu \) provides the chemical potential. The tunneling \( t \) is controlled by the moiré lattice, i.e. its depth and period, since it is given by the width of the lowest energy band and thereby decreases exponentially with \( s \). Precisely, for a sinusoidal lattice in the limit \( V_0 \gg E_R \) the tunneling element reads \( t = \frac{1}{\sqrt{2}} E_R \exp \left( -2 \sqrt{\frac{s}{\pi}} \right) \).

On the other hand, at two dimensions the on-site interaction \( U \) is usually expressed as a function of a dimensionless number \( \tilde{g} \) and reads \( U = \frac{k^2}{m \pi \omega_0} \tilde{g} \) where \( a_{oh} = \sqrt{\frac{\hbar}{m \omega_0}} \), \( \omega_0 \) being the trapping frequency at the bottom of the moiré potential within a parabolic approximation [33].

For interlayer excitons of TMDs the parameter \( \tilde{g} \) quantifying on-site repulsive dipolar interactions has not been measured nor calculated to the best of our knowledge. Nevertheless, we can estimate it relying on experimental and theoretical studies realised in GaAs bilayers. There it was shown that \( \tilde{g} \sim 5 \) [5, 6, 34] for an exciton dipolar moment \( d \) equal to 12 nm-° whereas the medium dielectric constant \( \epsilon \) is around 12.5-\( \epsilon_0 \). On the other hand, in TMDs, the excitons have a dipolar moment of 1 nm-° and interact in a medium of dielectric constant of around 3-\( \epsilon_0 \), if we consider that the heterostructure is exposed to hBN and vacuum. Accordingly, the strength of repulsive interactions between excitons in TMDs bilayers is approximately 30 times smaller than in GaAs leading to \( \tilde{g} \sim 0.2 \). For example, for a MoSe\(_2\)/WSe\(_2\) bilayer separated by two monolayers of hBN, for \( V_0 = 10 \) meV and \( a_m = 20 \) nm we find \( U \sim 0.1 \) meV whereas \( t \sim 20 \) \( \mu \)eV.

Before proceeding, let us point out that the previous estimation of \( \tilde{g} \) is obtained by approximating the dipole-dipole interaction between interlayer excitons by a contact potential. This imposes that the mean spatial separation between excitons is larger than \( r_0 = m^2 d^2 / (4 \pi e \hbar^2) \) which characterises the dipolar interaction range (see Supplementals of Ref. [6]). For a moiré lattice with a period of 20 nm and a depth of 5 meV, using the above values for \( d \) and \( e \) we deduce that \( r_0 \sim 7 \) \( \mu \)m while the full width at half maximum of the lowest energy Wannier function (\( \sim 2.35 \) \( \mu \)m) is around 11 \( \mu \)m in each lattice site. Thus, \( \tilde{g} \sim 0.2 \) provides a reasonable estimate for the on-site interaction strength, up to the regime where at most two excitons are confined per site. This corresponds to a maximum density of about \( 10^{12} \) cm\(^{-2} \). Beyond this value the spatial separation between excitons in the lattice sites becomes of the order of \( r_0 \) and the spatial dependence of the dipolar potential can no longer be neglected. Describing this regime lies beyond the scope of the present work, that is why in the following we restrict our analysis to the situation where at most two excitons occupy individual lattice sites.

The Mott insulator/superfluid transition is possibly characterised simply when one restricts the analysis of the Bose-Hubbard hamiltonian to a single band [32]. First, this approach requires that \( V_0 \gg E_R \) so that the system evolves in the so-called atomic limit. Then, both the on-site interaction \( U \) and the thermal energy need to be small compared to the energy separation between the first two Bloch bands, thus ensuring that only a single band is indeed occupied. As shown in Fig. 2.b, all these conditions are fulfilled for relevant experimental parameters and at temperatures below \( T_d \) and \( T_{BKT} \). Accordingly, Eq.(3) can be treated within a mean-field expansion, i.e. by replacing the original hamiltonian by an effective single-site problem with a self-consistant condition. Thus, one locates the critical coupling for the transition between Mott-insulating and superfluid phases, namely \( \frac{\hbar}{|c|} = 1/(2N + 1 + 2 \sqrt{N(N + 1)}) \), where \( N \) denotes the occupation of lattice sites and \( z = 3 \) is the lattice connectivity. Figure 4 compares \( \frac{\hbar}{|c|} \) to this critical value for \( N = 2 \) and for a parameter space where \( T_d \) and \( T_{BKT} \) are maximised, i.e. for a bilayer device including a hBN spacer between two monolayers. Strikingly, we note that except for the largest periods and lattice depths where the Mott insulator phase is energetically favourable, the superfluid phase is accessible for a broad range of experimental parameters. Let us also note that for large potential depths, i.e. without hBN spacer intercalated between the monolayers, the superfluid phase is never accessed.

**Discussion** – Two independent experiments have recently reported observations interpreted as manifestations for Bose-Einstein condensation of interlayer excitons. One work was conducted in a MoSe\(_2\)/WSe\(_2\) bilayer without hBN spacer and concluded that quantum degeneracy is reached at bath temperatures lower than about 8 K for \( n \sim 10^{11} \) cm\(^{-2} \) [28]. Importantly, we have shown that in such structure the excitons effective mass is increased between 4\( \times 10^3 \) and 7\( \times 10^5 \) for \( s \) ranging from 50 to 100. Accordingly, for \( n \sim 10^{11} \) cm\(^{-2} \) quantum degeneracy is only expected below 900 \( \mu \)K and 5 \( \mu \)K respectively. This marks a disagreement as large as 4 to 6 orders of magnitude questioning the role of Bose statistics in the experiments discussed in Ref. [28]. The other experimental work empha-
sised a MoSe$_2$/WSe$_2$ bilayer where two monolayers of hBN are intercalated [30]. Then, the moiré lattice is highly screened and the exciton effective mass is varied much more weakly. These studies concluded that quantum degeneracy is reached for a density around 3 $10^{11}$ cm$^{-2}$ at 3.5 K. Figure 3 shows that this observation is consistent with our expectations. Indeed, we evaluate that $2 \lesssim T_s \lesssim 5K$ for $n \sim 3 \times 10^{11}$ cm$^{-2}$ and $5 \lesssim T_s \lesssim 10$. Moreover, in Ref. [30] it is argued that quantum degeneracy holds up to 150 K for $n \sim 8 \times 10^{11}$ cm$^{-2}$. Fig. 3 shows that this conclusion is however out of experimental reach, $T_s$ ranging from 5 to 14 K at this density, depending on the exact depth of the moiré lattice. Moreover, note that Ref. [30] reports that quantum degeneracy is lost when the twist angle between the MoSe$_2$ and WSe$_2$ layer is increased. Surprisingly this observation goes against our expectations since $s$ decreases for increasing twist angle, so that $T_s$ increases and so does then the degree of quantum degeneracy.

The above discussion underlines that identifying direct signatures for Bose-Einstein condensation of interlayer excitons is crucial. For finite twist angles lowest energy excitons are optically inactive so that photoluminescence studies are inefficient for that purpose. However, we have emphasised that quasi-condensation of interlayer excitons occurs in a ground state with finite momentum. This implies that the superfluid phase flows spontaneously, similarly to the conden-sation at the roton frequency recently observed with ultra-cold dipolar atoms [35]. In the superfluid regime we then expect counterflow electron super-currents in the monolayers confining electrons and holes, without any in-plane voltage difference. This behaviour provides an unambiguous signature of exciton superfluidity, in a similar way to quantum Hall bilayers [36] or twisted bilayer graphene [37].

**Conclusion** – We have highlighted that in TMD bilayers the moiré potential strongly varies the parameter space where exciton superfluidity is accessible. This is most importantly the case for heterobilayers that are realised without hBN spacer and for which superfluidity is practically out of experimental reach. On the other hand, when hBN is intercalated between the monolayers confining electrons and holes we find that exciton superfluidity is favorable below a critical temperature of slightly less than 10 K for realistic experimental parameters. In fact, the dipolar interaction between excitons limits both the maximum density and the fraction of the superfluid phase. Remarkably, the latter is characterised by a spontaneous flow, which allows one to unambiguously identify the quantum regime.
