Initial step-up treatment changes in asthmatic children already prescribed inhaled corticosteroids: a historical cohort study

Steve W Turner1, Kathryn Richardson2, Annie Burden2, Mike Thomas3, Clare Murray4 and David Price2

BACKGROUND: When standard doses of inhaled corticosteroids (ICS) fail to control symptoms in children aged >4 years, guidelines recommend the addition of a long-acting β2-agonist (LABA), with other treatment options being available if symptoms persist.

AIMS: To determine the proportion of initial ‘step-up’ episodes where LABAs were prescribed and to describe characteristics of individuals not stepped up with LABA.

METHODS: Between 1999 and 2011, initial step-up episodes from ICS monotherapy were identified in children aged 5–12 years with asthma and in receipt of ICS. Data sources were the Clinical Practice Research Datalink and Optimum Patient Care Research Database.

RESULTS: Initial step-up episodes were identified in 10,793 children. ICS dose was increased in 6,252 children (58%), LABA was introduced in 3,436 (32%; including 1,107 where fixed dose combination inhaler (FDC) replaced the ICS inhaler), and leukotriene receptor antagonist (LTRA) was added in 1,105 (10%). Compared with children stepped up to any LABA, others were younger and prescribed lower doses of ICS and reliever medication. ICS dose increase was more likely in obese children and LTRA prescribing was more likely in children with rhinitis and in receipt of antibiotics. Compared with FDC, step-up to separate LABA inhaler was more likely in younger, obese children who were using less oral steroids.

CONCLUSIONS: One-third of initial step-up episodes in children with asthma treated with ICS are to add LABA. Different characteristics of children prescribed therapies other than LABA suggest that prescribers tailor treatment in some clinical settings.

INTRODUCTION

Asthma is a common condition1 and 5% of children in the UK are prescribed inhaled corticosteroids (ICS) to control asthma symptoms.2 Annually there are over 25,000 children admitted to hospital for asthma in England and Wales3 and the cost of asthma inhaler prescriptions issued in the UK to children aged 5–15 years is ~£37million,4 which is equivalent to £5 for every child in the population. Treatment with low dose ICS is effective in controlling symptoms for the majority of children but ~10% of children require one of four additional ‘step-up’ treatment options.1,2 Clinical trials have demonstrated that many children will benefit from more than one step-up option5–10 but equally, some will gain greatest benefit from one of the options.5,10

In the absence of evidence for a ‘best’ step-up option, guidelines for asthma management in children advocate either addition of LABA1,11 or increasing ICS dose12 as the first step-up option while highlighting the need to assess response and prescribe an alternative treatment for non-responders. More recent guidance recommends that step-up to fixed dose combination inhaler (FDC) containing ICS and LABA is preferable to addition of separate LABA inhaler due to better adherence to a single inhaler device.13 What is not known is whether these guidelines1,13 have been put into practice and our main research question was ‘in what proportion of first step-up episodes is LABA treatment added to ICS rather than ICS dose increased or LTRA added?’. Given the uncertainty as to which initial treatment step-up is most effective, we anticipated that some children would be stepped up to treatment other than LABA and tested the null hypothesis that children stepped up to LTRA or increased ICS would be no different to those stepped up to LABA; the presence of differences between those stepped up to LABA and to other medications would suggest that prescribers recognise subgroups who they feel are more likely to respond to options other than LABA. We tested our research question and hypothesis using routinely acquired ‘real life’ data from primary care, an approach which complements results from clinical trials14 and has been used in the paediatric setting15 and also, in adults, in the context of stepping up treatment.16

MATERIALS AND METHODS

Study population

Prescribing data were obtained from the CPRD and the OPCRD between 1 January 1990 and 23 December 2011 for OPCRD and 11 April 2011 for CPRD. Data before 1 January 1999 were not included since LTRA and FDC inhalers were not licensed for use in the UK until 1998 and 1999, respectively. Inclusion criteria were (i) asthma diagnosis, defined as a Read code for asthma and/or >1 prescription for asthma medications (including >1 for ICS) in the 12 months prior to the first step-up date (index date), (ii) aged 5–12 years when treatment stepped up to allow comparison with recommendations for this age range set out in the BTS/SIGN guideline,16 (iii) registered with the practice for at least 12 months prior to and post index date. Exclusion criteria were (i) other chronic respiratory disease, (ii) maintenance oral steroid prescribed in the 12 months prior to the index date, (iii) previous prescription for LABA.
(as separate or FDC inhaler), LTRA or theophylline in the year prior to the index date, (iv) multiple step-up therapies, multiple ICS, or prescription of both FDC and ICS inhalers at index date, (v) ICS step-up dose by < 50%,17 and (vii) prescribed theophylline at step-up (due to small numbers).

Study design
Patients were categorized according to their first step-up as: (i) addition of LABA, ICS dose unchanged, (ii) increase ICS dose, (iii) addition of LTRA, ICS dose unchanged, and (iv) replacement of ICS inhaler with FDC. Distinction was made between FDC and addition of separate LABA inhaler since the former is the recommended option.13 This study was approved in 2010 by the Independent Scientific Advisory Committee of the (then) General Practice Research Database.

Predictor variables (or patient characteristics)
Patient characteristics and asthma medication use were defined over the 12 months prior to step-up. Rhinitis diagnosis was ‘rhinitis ever’ as coded in primary care (Read) records. Eczema medications were those prescribed in the 12 months prior to step-up. SABA use was defined as any prescription in the baseline year. Body mass index (BMI) was derived from height and weight and converted to centiles and z-scores with reference to the 1990 UK standard18 applying clinical cutoffs for overweight (>91st centile) and obese (>98th centile). BMI z-scores outside the range ±5 were excluded as presumed data entry mistake.19 Paracetamol prescription in the previous year was included since this is a confounder in adult studies.20 Ethnicity data were not available. The online supplement describes the methods for deriving the following variables: average daily ICS dosage, average daily data were not available. The online supplement describes the methods for deriving the following variables: average daily ICS dosage, average daily

Clinical practice research database
The Clinical practice research database (CPRD), initially the General Practice Research Database, was established in 1990 and by 1999 included a stable population of 650 practices across the UK and provided primary care prescribing for ~5% of the population. (http://www.cprd.com/intro.asp).

Optimum patient care research database
The Optimum Patient Care Research Database (OPCRD) was established in 2008 and currently has 424 practices in the database. Patients with respiratory conditions are actively recruited. The OPCRD holds data from 2008 and currently has 424 practices in the database. Patients with respiratory conditions are actively recruited. The OPCRD holds data from 1,200,014 patients including 514,719 with asthma; therefore OPCRD has a population of 650 practices across the UK and provided primary care prescribing for ~5% of the population. (http://www.cprd.com/intro.asp).

Statistical analysis
Differences across the categories of ICS dose increases and also the univariate associations between first post ICS step-up therapy and each patient characteristic or baseline asthma medication variable were tested using a $\chi^2$-test for categorical variables and Kruskal–Wallis for variables measured on the interval or ratio scale. A multivariate regression model was built using multinomial logistic regression with FDC as the reference group, by first including age, sex, index year, and all variables with univariate associations with $P < 0.1$ in the model. Variables were examined for co-linearity and clinical importance then removed in a backwards stepwise procedure until all variables remaining in the multivariate model had $P < 0.1$. Since addition of LABA has until recently been the recommended first step-up option, we repeated analyses with this option as the reference. All analyses were carried out using SAS version 9.3 (SAS, Cary, NC, USA).

RESULTS
Study subjects
Data were available in 10,793 children (7,609 from OPCRD) whose median (interquartile range) age was 9 (6–11) years, 59% were male, 97% had a diagnosis of asthma, and 50% were prescribed eczema medications (Table 1). Figure 1 shows how individuals were identified from the databases. There were 6,252

Table 1. Characteristics of the 10,793 children with asthma in receipt of inhaled steroid treatment where a first step-up was made

| Characteristic                                      | n (%)       |
|----------------------------------------------------|-------------|
| Median age (Interquartile range), years             | 9 (6, 11)   |
| Female gender                                      | 4,457 (41.3%)|
| BMI centile                                        |             |
| < 91th                                             | 4,241 (39.3%)|
| 91–97th                                            | 825 (7.6%)  |
| ≥ 98th                                             | 869 (8.1%)  |
| Missing                                            | 4,858 (45.0%)|

The table displays number of children (n) unless specified otherwise. Abbreviations: A&E = accident and emergency; GP = general practitioner; ICS, inhaled corticosteroids; IPD = index prescribing date; SABA, short-acting β2-agonist.

*These variables are with respect to the 12 months prior to step-up.
Supplementary Table E1 presents the number of children in each of the possible 154 ICS step-up dose categories.

Changes over time and univariate differences between groups
The incidence of ICS step-up fell between 1999 and 2005, coinciding with a rise in overall LABA prescribing (that is, FDC plus separate LABA inhaler), but remained static between 2005 and 2011 (Figure 2). The incidence of all LABA prescribing fell and LTRA prescribing rose between 2005 and 2011 (Figure 2 and online Supplementary Table E2). In univariate analyses, the following characteristics at baseline differed across the four treatment groups: age, year when step-up was made, obesity, eczema, daily dose of ICS, medication possession ratio, need for SABA use, oral corticosteroid, and antibiotics in the previous year, primary care consultations, and data source (OPCRD versus CPRD) (Table 3).

Multivariate analysis
In the multivariate analysis and in comparison with all other groups, children in the FDC group were older and more likely to have seen the GP for asthma (Table 4). The FDC group was more likely to have received oral steroid treatment but less likely to have received antibiotics compared with the LABA and LTRA groups, less likely to be obese and more likely to have regular use of SABA

Figure 1. CONSORT diagram showing how the individuals included in the present study were identified within the CPRD and OPCRD databases. *IPD = index prescription date.
Figure 2. Proportion of step-up options over time in children with asthma already in receipt of inhaled corticosteroid treatment (ICS). All LABA, FDC plus LABA; FDC, fixed dose combination inhaler; LABA, addition of long-acting β2-agonist as separate inhaler; LTRA, leukotriene receptor antagonist. Data from 2010 and 2011 are combined since data from the whole of the calendar year 2011 were not available from CPRD. The vertical broken lines indicate when British Thoracic Society/Scottish Intercollegiate Guidelines network (BTS/SIGN) asthma guidelines were published.

**DISCUSSION**

Main findings

This is the first study to describe which initial ‘step-up’ asthma treatment options are made for 5–12-year-old children in the UK, and also the first to describe the characteristics of children who receive different step-up options. The first main finding was that step-up with increasing ICS dose remained the most popular step-up option between 1999 and 2011 despite national guidelines recommending step-up with LABA before considering increasing ICS dose to 400 µg BUD equivalent per day. The second novel finding was that children who were stepped up to medication other than LABA had a number of characteristics which were subtly different to those where LABA was introduced (Figure 3), and this suggests that clinicians may be making active decisions not to add LABA. Our results are based on observations from ~15% of children in England and are therefore likely to be generalisable. The hypothesis that children with some characteristics, for example, obesity and rhinitis, gain greater benefit from treatment other than LABA needs to be tested in large populations.

Strengths and limitations of this study

There are a number of strengths and limitations to this study. Strengths include the large number of individuals included, adjustment for health seeking behaviour, and collection of prescriptions and the use of routine data, which avoids the bias in recruitment which can occur in clinical trials making generalisation unreliable. A limitation of routinely entered data is that data are incomplete leading to some individuals being excluded. A second limitation to our study is that data were not complete for all individuals studied, for example, BMI was available for 65% of children, and while missing values might not be at random we have demonstrated that children with missing BMI data were equally distributed across step-up groups. A final limitation is that in an observational study such as ours, causation cannot necessarily be inferred from the associations described.

Interpretation of findings in relation to previously published work

The majority of initial step-up episodes were to increase ICS dose, and over 70% of these were increases to a daily dose of 400 µg budesonide equivalent. Approximately 10% of ICS step-ups were from a daily dose of 100 to 200 µg budesonide, and although these occurred in a younger group of individuals, suggesting that clinicians were being more cautious with ICS dose in younger children, it is possible that some incidents represented ‘fine tuning’ doses from an initially very low value to the dose suggested for step 2 treatment. Notwithstanding this small number of step-ups to 200 µg, the majority of ICS step-ups were consistent with a move to the BTS/SIGN step 3 treatment step but these episodes were not preceded with LABA treatment and this is not consistent with the guideline.

Table 2 demonstrates that the majority (69%) of ICS step-up options were from 200 to 400 µg budesonide per day, and this suggests that clinicians looking after patients in the real world have found that stepping up from low to intermediate ICS dose is a safe and effective option and that this accounts for its relative popularity. Eight percent of ICS step-ups were from low direct to high dose or to ICS dose in excess of the ceiling dose of 800 µg budesonide equivalent and these observations replicate our earlier work highlighting the prevalence of high ICS prescribing. The BTS/SIGN1 guideline suggests that children in receipt of high dose ICS (that is, 800 µg budesonide per day) should receive specific written advice about steroid replacement and be under the care of a specialist paediatrician.

Asthma prescribing is known to deviate from guidelines in the UK and other countries, and might in part be due to a delay between guidelines being published and implemented; other reasons for prescribing changes include falls in pricing as medications come off patent and concerns about adverse effects of LABA therapy raised by the United States Food and Drug Administration in 2005. The BTS/SIGN1 guidelines first recommend LABA addition rather than increasing ICS dose since 1995, and this change in advice might explain the continuing rise in LABA prescribing between 1999 and 2005. The 2003 BTS/SIGN guideline was the first to recommend inclusion of LTRA but this advice was anticipated since 100,000 LTRA prescriptions for children were made in 2003 and we see rising LTRA prescribing in the early 2000s. What is notable is that despite LABA being advocated as the first step by guidelines since 1995, the rise in LABA prescribing pre 2006 has faltered, as has been demonstrated previously and here we show a decline in LABA prescribing between 2006 and 2011; this study cannot explain why LABAs are less frequently prescribed but one explanation might be that prescribers find LTRA or increasing ICS dose to be more effective. An alternative explanation for increasing step-up by addition of LTRA or increasing ICS in younger children within the 5–12-year-old category may be ‘carry over’ of more recent BTS/SIGN and GINA12 guideline advice to use these step-up options in the <5-year-old category.

Implications for future research, policy and practice

The presence of differences between individuals in the step-up option groups suggests that prescribers perceive that some individuals gain benefit from specific step-up options. In a tertiary

Numbers denote n (%) unless specified otherwise.
Abbreviations: BMI, body mass index; CPRD, Clinical Practice Research Datalink; FDC, fixed dose combination inhaler; ICS, inhaled corticosteroids; IQR, interquartile range; LABA, long-acting β2-agonist; LTRA, leukotriene receptor antagonist; OPCRD, Optimum Patient Care Research Database.

*X2*-test for categorical variables and Kruskal–Wallis for variables measured on the interval or ratio scale.
care setting, clinicians have previously been shown to prescribe asthma medications by phenotype, that is, viral wheeze versus multitrigger wheeze, with the implication that some individuals are recognized as having preferential response to some asthma medications. In one study, differential response to step-up therapy has been linked to age, the presence of eczema and ethnicity, while in a second study increased reliever medication use, increased exhaled nitric oxide, and reduced lung function were more likely following increasing ICS dose compared with the addition of LTRA. Obese children are less responsive to ICS therapy, but obese children were 40% more likely to have ICS step-up rather than addition of FDC in our study. We observed that children stepped up to LTRA had a higher prevalence of rhinitis and a 70% increased risk for multiple prescriptions for antibiotics for respiratory symptoms, when compared with both LABA step-up options, and this decision may be justifiable since LTRA are known to be effective against upper and lower respiratory tract symptoms.

Table 4. Multivariate associations between patient characteristics and step-up treatment in children with asthma whose treatment was stepped up from ICS treatment with reference to change to fixed dose combination inhaler

|                          | Add LABA (n = 2,329) | Increase ICS dose (n = 6,252) | Add LTRA (n = 1,105) | P value |
