ABSTRACT

We study the capture of interstellar objects (ISOs) by a planet-star binary with mass ratio $q \ll 1$, semi-major axis $a_p$, orbital speed $v_c$, and eccentricity $e_p$. Very close (slingshot) and wide encounters with the planet are amenable to analytic treatment, while numerically obtained capture cross-sections $\sigma$ closely follow the analytical results even in the intermediate regime. Wide interactions can only generate energy changes $\Delta E \leq q v_c^2$, when $\sigma \propto v_c^{-2} \ln |\Delta E|^{2/3}$ (with $v_c$ the ISO’s incoming speed far away from the binary), which is slightly enhanced for $e_p > 0$. Energy changes $\Delta E \gtrsim q v_c^2$, on the other hand, require close interactions when $\sigma \propto (v_c \Delta E)^{-2}$ hardly depending on $e_p$. Finally, at $\Delta E \gtrsim v_c^2$, the cross-section drops to zero, depending on the planet’s radius $R_p$ through the Safronov number $\Theta = q a_p / R_p$. We also derive the cross-sections for collisions of ISOs with planets or moons.

Key words: celestial mechanics — comets: general — comets: individual: 2I/Borisov — minor planets, asteroids: general — minor planets, asteroids: individual: 1I/'Oumuamua — Oort Cloud.

1 INTRODUCTION

The recent discovery of the first two known interstellar objects (ISOs) to visit the Solar system – 1I/'Oumuamua (Meech et al. 2017; 'Oumuamua ISSI Team et al. 2019) and 2I/Borisov (Jewitt & Luu 2019) – has raised many more questions than it has answered. The likely origin for such objects is that they form around alien stars just as asteroids and comets in the Solar system – as a part of the planet formation process – and are left as debris when this process is completed. They are then ejected from their home system by some dynamical event – be it a stellar fly-by/intra-cluster interaction (see e.g., Hands et al. 2019) or interaction with a giant planet (see e.g., Raymond et al. 2018) – and travel through interstellar space until they have a chance encounter with another star. This unique origin has led to a great deal of interest from the planet formation community. Studying ISOs that transit through the Solar system affords us for the first time the opportunity to glimpse material and therefore chemistry directly from the planet formation environment around distant stars. There have been multiple fruitful Earth-based observations of transient ISOs (see e.g., Jewitt et al. 2017; Bannister et al. 2017; Trilling et al. 2018, for a selection of 'Oumuamua observations), as well as suggestions of future sample return missions (Hein et al. 2019). However, with the only two known ISOs currently moving away from the Solar system, chances to study them remain few and far between.

The identification of a population of unequivocally interstellar objects residing within the Solar system would enable study on a longer time-scale than waiting for a chance encounter. Due to the time-reversible nature of Hamiltonian dynamics, it is clear that if ISOs can be ejected by giant planets in their host systems, they can also be captured by the giant planets in the Solar system. The purpose of this study is to systematically investigate, both analytically and numerically, the cross-section for capturing ISOs by a planet-star binary in general and the Solar system in particular. Previous analytical studies (Radzievskii 1967; Bandermann & Wolstencroft 1970; Heggie 1975; Radzievskii & Tomanov 1977; Pineault & Duquet 1993) were limited to close interactions with a planet on a circular orbit. Here, we extend this previous work to non-circular orbits and also consider wider interactions, which are relevant for capturing ISOs at very small incoming asymptotic speeds $v_\infty$ and/or onto orbits with large semi-major axis. Previous numerical studies (Valtonen & Innanen 1982; Hands & Dehnen 2020; Napier et al. 2021) generally focused on the Solar system and used a rather limited number of simulated trajectories. Here, we extend these to numerically derive the capture cross-section $\sigma$ as function of the incoming asymptotic speed $v_\infty$ of the ISO, the semi-major axis $a$ of the orbit onto which the ISO is captured, the planet-to-star mass ratio $q$, and the eccentricity $e_p$ of the planet’s orbit.

This paper is organised as follows. In Section 2 we use analytic approximations to obtain the capture cross-section in the limits of close (slingshot) and very wide encounters of the ISO with the planet. Then, in Section 3 we perform numerical simulations to obtain the capture cross-section for planets of various masses and orbital eccentricities. Section 4 briefly discusses two related processes: the collision of ISOs with Solar system planets and the ejection of bound objects by exoplanets. Finally, Section 5 summarises and concludes this paper, while in an accompanying paper (Dehnen et al. 2021, hereafter paper 2), we use the cross-section calculated here to evaluate the capture rate and the population of captured ISO with particular emphasis on the Solar system.
We consider a planet-star binary with masses $m_p \ll m_s$ encountering a test particle, hereafter *interstellar object* (ISO), with incoming asymptotic speed $v_{\infty}$. In this section, we summarise and derive analytic results regarding collision with the planet (§2.1) as well as capture by a close (§2.2) or by wide (§2.3) encounter with it. Table 1 summarises most symbols used.

For collisions and close encounters with the planet, we use the *impulse approximation*, which models the ISO orbit as a barycentric hyperbola instantaneously deflected by the planet. In §2.3 we use perturbation theory to shed light on the behaviour at very wide encounters, when the ISO passes the planet at distances comparable or even larger than its semi-major axis. In the intermediate regime analytic insight is limited, but our numerical results in the next section indicate that the actual capture cross-section is well described by either of these limiting cases.

In the impulse approximation, the deflection by the planet is itself modelled as that between incoming and outgoing asymptotic of an hyperbolic planetocentric orbit. If the peri-centre of this orbit is within the planet, the ISO is not deflected but collides with the planet. This limits the ability of large planets to inflict strong deflections and hence to capture ISOs with large $v_{\infty}$ or onto strongly bound orbits.

The impulse approximation accounts for the gravity of the planet twice: once as part of the barycentric total mass $M \equiv m_s + m_p$ and once for calculating the deflection. The error made by this is $O(q)$ with the mass ratio $q \equiv m_p/m_s$ and cannot be neglected in applications to binary stars (even though this has been done). However, for planet-star systems considered here $q \ll 1$ and we can safely neglect this error. In the following we shall replace $1 + q \rightarrow 1$ and use $\pm^*$ instead of ‘=’ to denote relations that are exact up to this approximation.

Let $\alpha$, $\epsilon$, and $\eta_p$ denote, respectively, the planet’s semi-major axis, eccentricity, and eccentric anomaly at the moment of the impulsive encounter with the planet. Then the planet’s barycentric radius and speed at that moment are, respectively,

$$r_p \pm (1 - \epsilon_p \cos \eta_p) a_p \quad \text{and} \quad v_p \pm \sqrt{1 + \epsilon_p \cos \eta_p} v_c$$  \hspace{1cm} (1)

with $v_c \equiv \sqrt{GM/\alpha_p} \pm \sqrt{GM/\alpha_p}$. The speed of the ISO when it enters the planet’s sphere of influence (which is approximated to be of negligible size) follows from energy conservation as

$$v^2_c = 2v^2_{\infty} + v^2_{esc}.$$  \hspace{1cm} (2)

where

$$v^2_c \equiv \frac{GM}{\alpha_p} \pm \frac{v^2_{\infty}}{1 - \epsilon_p \cos \eta_p}. $$  \hspace{1cm} (3)

In the frame of the planet, the ISO has incoming and outgoing velocities

$$w_{1,2} = v_{1,2} - v_p$$  \hspace{1cm} (4)

and speed $w \equiv |w_2| = |w_1|$ satisfying

$$w^2 = v^2_{\infty} + 2v^2_{\text{esc,p}} - 2v_{\text{esc,p}} v_1 \cos \alpha,$$  \hspace{1cm} (5)

where $\alpha$ is the angle between the ISO’s and planet’s barycentric velocities just before the encounter, see also Figure 1.

### 2.1 Cross-section for collision with the planet or a moon

Collisions are important in the context of captures, as they compete with those captures that require large energy changes, see also Section 2.2.2. Therefore, first we derive the cross-section for collisions of ISOs with the planet.

If $b_p$ is the impact parameter of the ISO’s hyperbolic planetocentric orbit, then its distance of closest approach to the planet is

$$d_p = \frac{1}{w^2} \left( b^2_{\text{p}} w^4 + G^2 m^2_p - G m_{\text{p}} \right)$$  \hspace{1cm} (6)

(see also equation C12). The ISO will collide if $d_p \leq R_p$, the radius of the planet. Solving (6) for $b_p$ at $d_p = R_p$ gives the local cross-section

$$\sigma_p = \pi b^2_p = \pi R^2_p \left( 1 + \frac{v^2_{\text{esc,p}}}{w^2} \right)$$  \hspace{1cm} (7)

for collisions of ISOs with the planet. Here, $v_{\text{esc,p}} \equiv \sqrt{2GM/R_p}$ is the escape speed from the surface of the planet. If $n_1$ is the number density of ISOs at the planet, the flux of colliding ISOs is $F = n_1 w \sigma_p$ and depends on the relative orientation $\alpha$. From equation (5),

$$d \cos \alpha = \frac{w}{v_1 v_p} dw$$  \hspace{1cm} (8)

and averaging over all directions (assuming the distribution of $v_1$ is isotropic, which holds if the distribution of $v_{\infty}$ is isotropic) obtains

$$\langle F \rangle_\alpha = \frac{1}{2\pi} \int_0^{2\pi} \langle F \rangle_\alpha (1 - \epsilon_p \cos \eta_p) d\eta_p$$  \hspace{1cm} (9)

Next, we must average the flux over the eccentric planet orbit:

$$\langle F \rangle \equiv \frac{1}{2\pi} \int_0^{2\pi} \langle F \rangle_\alpha (1 - \epsilon_p \cos \eta_p) d\eta_p$$  \hspace{1cm} (10)

$$\pm \frac{d_{\text{ISO}} \pi b^2_p}{v_{\infty}} \left( \frac{v^2_{\infty} + v^2_{\text{esc,p}} + v^2_c}{v_{\infty}} \right),$$  \hspace{1cm} (11)

where we have used equations (1-3) and exploited that for a monoenergetic population of ISOs $n \propto \delta(E - \frac{1}{2} v^2_{\infty}) d^3 v \propto v$, such that

### Table 1. Summary of most stars used.

| Symbol | Meaning |
|--------|---------|
| $m_s$, $m_p$ | masses of star and planet |
| $M$, $q$ | $m_s + m_p$ (total binary mass), $m_p/m_s$ (binary mass ratio) |
| $R_p$, $v_{\infty}$, $a_p$, $\epsilon_p$, $\eta_p$ | planet’s radius, $\sqrt{2Gm_p/R_p}$ (escape speed from its surface), stellar radius, $\sqrt{2Gm_p/R_p}$ (escape speed from its surface), planet’s semi-major axis and eccentricity, planet’s eccentric and mean anomaly |
| $\Delta \rho_m$ | planet’s mean motion $\sqrt{GM/\alpha_p}$ |
| $v_p$, $r_p$ | planet’s barycentric orbital radius and velocity (equation 1) |
| $n_{\text{iso}}, n_1$ | number density of ISOs in interstellar space and near planet |
| $\alpha$, $\epsilon$, $\eta$ | semi-major axis of captured ISO, $\sqrt{GM/\alpha}$ asymptotic speed $\alpha$, $\theta$ | ISO's barycentric velocity just before and just after deflection |
| $v_{1,2}$ | ISO's barycentric velocity just before and just after deflection |
| $\theta$, $\omega$, $\nu$ | angle between $v_p$ and $v_1$, angle between $v_p$ and $w_1$, ISO's barycentric impact parameter and impact angle |
| $b_p$, $\theta_p$ | ISO’s planetocentric impact parameter and impact angle |
| $d_p$, $\rho_p$ | offset and radius of planetocentric impact disc (equations 23) |
| $s_p$, $\theta_p$ | barycentric and planetocentric semi-latus rectum of ISO |
| $\Theta$ | $\frac{Gm_p}{R_p v^2_p}$ (Saffronov number) |

MNRA 000, 1–16 (2021)
Figure 1. Swing-by of the ISO by the planet. In the frame moving with the planet (left) the ISO is deflected by angle \( \theta_{\text{def}} \) but retains its speed \((|\mathbf{v}_1| = |\mathbf{v}_2|)\). If the ISO passes in front of the planet, the outgoing barycentric speed \(|\mathbf{v}_2|\) (and hence energy) is smaller than the incoming speed \(|\mathbf{v}_1|\), enabling capture. The depicted example trajectory has \( \psi_p = 0 \) in equation (15) when the vectors \( \mathbf{v}_p, \mathbf{w}_1, \) and \( \mathbf{b}_p \) are co-planar.

\[ n_1/v_1 = n_{\text{iso}}/v_{\infty}. \]

Finally, the cross-section for collisions with the planet follows as

\[ \sigma_{\text{coll,p}} = \sigma_{\text{iso}}v_{\infty}^{2} \left[ 1 + \frac{v_{\text{esc,p}}^2}{v_{\infty}^2} + \frac{7}{3} \frac{v_2^2}{v_{\infty}^2} \right] \]  

\[ \text{(12)} \]

independent of the planet’s eccentricity \( e_p \). This differs from the collision cross-section for a free-floating planet (equation 7 with \( w = v_{\infty} \)) by the additional term involving \( v_c \). For Jupiter \( v_c = 13.1 \text{ km s}^{-1} \) and \( v_{\text{esc,p}} = 60.2 \text{ km s}^{-1} \), such that this makes no big difference, but does for Earth as \( v_c = 29.8 \text{ km s}^{-1} \) and \( v_{\text{esc,p}} = 11.2 \text{ km s}^{-1} \).

We also calculate the cross-section for collisions of ISOs with a moon, using the subscript ‘m’ for properties of the moon and its orbit around the planet. After replacing \( v_{\infty} \rightarrow w \), \( R_p \rightarrow R_m \), \( v_{\text{esc,p}} \rightarrow v_{\text{esc,m}} \), and \( v_2 \rightarrow v_{2,m} \) \( G(m_p + m_m)/a_m \), equation (12) also gives the local cross-section for lunar collisions of ISOs entering the planet’s Roche sphere with speed \( v \). After averaging over the orientation of incoming ISOs and the planet orbit the cross-section for ISO collision with a moon is obtained as

\[ \sigma_{\text{coll,m}} = \sigma_{\text{iso}}v_{\infty}^{2} \left[ 1 + \frac{v_{\text{esc,m}}^2}{v_{\infty}^2} + \frac{7}{3} \frac{v_2^2}{v_{\infty}^2} \right] \]  

\[ \text{(13)} \]

This result holds as long as \( m_m \ll m_p \ll m_s \) and the lunar and planetary orbits are not in resonance.

The collision probability per unit surface area scales as \( \sigma_{\text{coll}}/\pi R_p^2 \), corresponding to the square brackets in equations (12) and (13). For all moons in the Solar system, this quantity is smaller than for their host planets, because the large gulf between the respective escape speeds exceeds the additional contribution involving \( v_c \) in equation (13). See also Section 4 for an application of equations (12) and (13) to the Solar system.

2.2 Capture by close encounters (slingshot)

We now use the impulse approximation to derive an analytic estimate for the capture cross-section in the limit of large \( v_{\infty} \). This extends previous studies (e.g. Radzievskii 1967; Bandermann & Wolkencroft 1970; Radzievskii & Tomanov 1977; Pineault & Duquet 1993) to planets on eccentric orbits. We also estimate the maximum captureable \( v_{\infty} \) and the maximum binding energy of captured ISOs.

If the captured ISO has semi-major axis \( a = GM/v_2^2 \), energy conservation implies its barycentric speed just after the impulsive encounter with the planet to be

\[ v_2^2 = 2v_r^2 - v_a^2 \]  

\[ \text{(14)} \]

and the energy change required for capture \( \Delta E = -(v_{\infty}^2 + v_a^2)/2 \).

The ISO trajectory in the planetocentric and barycentric frames is sketched in Figure 1. The incoming planetocentric asymptote of the ISO is characterised by the velocity \( \mathbf{v}_1 \) and offset \( \mathbf{b}_p \), such that \( r(t) = \mathbf{b}_p + \mathbf{w}_1 t \) at \( t \rightarrow -\infty \). Since \( \mathbf{b}_p \perp \mathbf{w}_1 \), the directions \( \mathbf{w}_1, \mathbf{b}_p \), and \( \mathbf{w}_1 \times \mathbf{b}_p \) form a triad and we can express the planet’s direction of motion uniquely as

\[ \dot{\psi}_p = \cos \theta \dot{\mathbf{w}}_1 + \sin \theta (\cos \psi_p \dot{\mathbf{b}}_p + \sin \psi_p \dot{\mathbf{w}}_1 \times \dot{\mathbf{b}}_p). \]  

\[ \text{(15)} \]

Here, \( \theta \in [0, \pi] \) is the angle between \( \mathbf{v}_p \) and \( \mathbf{w}_1 \) and \( \psi_p \in [0, 2\pi] \) the angle in the impact plane (perpendicular to \( \mathbf{w}_1 \)) between \( \mathbf{b}_p \) and the projection of \( \mathbf{v}_p \) onto the impact plane (\( \mathbf{\psi}_p \) is the tilt between the orbital plane and the plane spanned by \( \dot{\mathbf{w}}_1 \) and \( \mathbf{b}_p \)). After the hyperbolic deflection by the angle \( \theta_{\text{def}} \) the ISO’s outgoing planetocentric velocity is (see also Figure 1)

\[ \mathbf{w}_2 = w \left[ \cos \theta_{\text{def}} \mathbf{w}_1 - \sin \theta_{\text{def}} \mathbf{b}_p \right] \]  

\[ \text{(16)} \]

and the ISO’s barycentric speeds \( v_{1,2} \) before and after encountering the planet are obtained by inserting equations (15) and (16) into (4):  

\[ v_1^2 = v_p^2 + w^2 + 2v_pw \cos \theta, \]  

\[ v_2^2 = v_p^2 + w^2 + 2v_pw (\cos \theta \cos \theta_{\text{def}} - \sin \theta \sin \theta_{\text{def}} \cos \psi_p). \]  

\[ \text{(17a)} \]  

\[ \text{(17b)} \]

Using the relations (see equations C11 and C9)

\[ \cos \theta_{\text{def}} = \frac{b_p^2 w^4 - G^2 m_p^2}{b_p^2 w^4 + G^2 m_p^2}, \]  

\[ \sin \theta_{\text{def}} = \frac{2b_p w^2 G m_p}{b_p^2 w^4 + G^2 m_p^2}, \]  

\[ (18) \]

the capture condition is obtained by inserting equations (17) and (18) into \( v_1^2 - v_2^2 = v_{\infty}^2 + v_2^2 \):

\[ v_1^2 + v_2^2 = 4Gm_p v_p w \left[ Gm_p \cos \theta + b_p w \sin \theta \cos \psi_p \right]/(G^2 m_p^2 + b_p^2 w^4). \]  

\[ \text{(19)} \]

The orientation \( \theta \) and speed \( w \) are related via equation (17a), which together with (2) gives

\[ 2v_p w \cos \theta = C \mp 2v_2^2 - v_1^2 - w^2 + v_{\infty}^2. \]  

\[ \text{(20)} \]

We may use this relation to eliminate \( \theta \) from equation (19) and obtain the capture condition for \( w, b_p, \) and \( \psi_p \) at given \( v_{\infty} \) and \( v_2 \):

\[ v_{\infty}^2 + v_2^2 = \frac{2G^2 m_p^2}{G^2 m_p^2 + b_p^2 w^4} \left[ C + \cos \psi_p b_p w^2 \right]/\left[ GM_p \sqrt{4v_2^2 w^2 - C^2} \right]. \]  

\[ \text{(21)} \]

2.2.1 The capture cross section

The calculation of the cross-section at infinity for capture is analogous to that for collision: after obtaining the local cross-section \( \sigma_p \) the flux is averaged over all orientations and along the planet orbit. To find \( \sigma_p \), we note that the solutions for \( b_p \) and \( \psi_p \) to equation (21) at fixed \( w, v_p, v_{\infty}, \) and \( v_2 \) lie on the circle

\[ (b_p \cos \psi_p - b_0)^2 + b_p^2 \sin^2 \psi_p = \rho^2 \]  

\[ \text{(22)} \]
in the impact plane with offset and radius

\[ b_0 = \frac{Gm_p}{(v_{\infty}^2 + v_a^2)w^2} \left( 4w^2v_p^2 - C^2 \right), \]

\[ \rho = \frac{Gm_p}{(v_{\infty}^2 + v_a^2)w^2} \left( 4w^2v_p^2 - D^2 \right) \]

with

\[ D \equiv v_a^2 + v_p^2 - C = -2v_r^2 + v_a^2 + w^2 + v_a^2 \]

(equivalent to relations given by Bandermann & Wolstencroft 1970 and Radzievskii & Tomanov 1977). Since \( \partial \rho / \partial v_a < 0 \), the cross-section of the planet to scatter an ISO onto a bound orbit with semi-major axis \( 0 < a \leq GM/v_{\infty}^2 \) is \( \sigma_{\infty} = \pi p^2 \) and the local flux of ISOs scattered by the planet onto bound orbits is \( F = n_1 w \pi p^2 \). Both depend (through \( w \)) on the orientation of the ISO orbit relative to the planet’s direction of motion. Only those values of \( w \) for which \( b_0 \) and \( \rho \) remain real correspond to orientations that lead to capture, which implies \( w_{-} \leq w \leq w_{+} \) with

\[ w_{-} = \max \left( \sqrt{2v_r^2 + v_{\infty}^2 - v_p^2}, v_{\infty} - \sqrt{2v_r^2 - v_a^2} \right), \]

\[ w_{+} = v_{\infty} + \sqrt{2v_r^2 - v_a^2}. \]

To average the flux over all orientations \( \alpha \), we use equation (8) with these limits, which gives

\[ \langle F \rangle_\alpha = \frac{8\pi}{3} \frac{n_1 G^2 m_p^2 v_a^2}{v_{\infty}^2 + v_a^2} \frac{Y}{v_1} \frac{1}{1 + e_p \cos \theta_p} \frac{v_{\infty}^2}{v_p^2}, \]

where

\[ Y(u, x, z) = \left[ \frac{3}{16y} (2u - 1 - z)^2 + \frac{3y}{8} (2u + 1 - z) - \frac{y^3}{16} \right]^{y_a} \]

with \( y_{-} = \max \left( \sqrt{2u + x - 1, 1 - \sqrt{2u - z}} \right) \) and \( y_{+} = \max \left( \sqrt{2u + z} \right) \). As can be seen in Figure 2, the transfer function \( Y \) essentially truncates the flux at the maximum possible \( v_{\infty} \) and \( v_a \), but for \( v_{\infty}^2 + v_a^2 \lesssim v_p^2 \), deviates only little from \( Y(u, 0, 0) = 1 \), see also Figure 2. Incidentally, the corresponding transfer function for the reverse process, ejection of a bound object, is generally larger than \( Y \) (but of course has the same domain), see Appendix A.

Finally, we must average the flux also over the eccentric planet orbit as in equation (10) for the case of collisions. Unfortunately, owing to the complex dependence of \( Y(u, x, z) \) on \( \theta_p \), through all three arguments, the integral over \( \theta_p \) does not result in a closed expression. For \( v_{\infty}^2 + v_a^2 \lesssim v_p^2 \), however, \( Y \sim 1 \) varies only weakly along the orbit (for mild eccentricities) and the behaviour of the flux is completely dominated by the remaining factors. For \( v_{\infty}^2 + v_a^2 \gtrsim v_p^2 \), on the other hand, collisions with the planet, which have been neglected so far (but see below), become important rendering an exact average of the flux (26) inaccurate. Therefore, a reasonable approximation for weakly eccentric orbits and \( v_{\infty}^2 + v_a^2 \lesssim v_p^2 \) is to exempt \( Y \) from the orbit average and replace \( v_p^2 \) in the arguments to \( Y \) by its orbit average. We have

\[ \left\{ \frac{n_1 v_p^2}{v_1} \right\} = \frac{n_{iso}}{v_{\infty}} (v_p^2) + \frac{n_{iso}}{v_{\infty}} v_c^2, \]

independent of \( e_p \). Dividing the average flux by \( n_{iso}v_{\infty} \) finally obtains the cross-section for capture from close encounters

\[ \sigma(v_{\infty} | v_a) \approx \frac{8}{3} \frac{a_p^2}{\nu(v_{\infty}^2 + v_a^2)^2} Y \frac{v_{\infty}^2}{v_c^2} \frac{v_1^2}{v_p^2}, \]

For \( v_a \ll v_{\infty} = v_c \), the capture cross-section is roughly the area of a disc with radius \( 1.5a_p \). For Jupiter (\( v_c = 13.1 \text{ km s}^{-1} \)), this is 0.0075 au, 16 times its radius, while the collision cross-section (12) for this speed corresponds to a disc of 5 Jupiter radii. At fixed \( v_a \) and \( v_{\infty} \) (in the regime where the impulse approximation applies), capture cross-sections from planets within the same system scale roughly as \( q^2 / a_p \), which for Saturn, Uranus, and Neptune is, respectively, 0.048, 0.00056, and 0.00078 times that for Jupiter. Thus, except for a 5% contribution from Saturn, slingshot captures into the Solar system are governed by Jupiter.

For circular binaries, a slightly wrong version of equation (29) has been derived previously by Pineau & Duquet (1993, eqs. 11), who used an incorrect version of equation (25a), resulting in \( Y < 0 \) above the yellow curve in Figure 2. In his investigation of the dynamical evolution of binaries in stellar clusters Heggie (1975) considered the capture of a third body the “most difficult to treat by any analytical means”. Nonetheless, integrating his equation 4.10 for the differential cross-section \( \text{d} \sigma / \text{d} (\Delta E) \) obtains the form (29) in the appropriate limit (as already noted by Pineau & Duquet), except for the transfer function \( Y \) and a factor of two.

### 2.2.2 Collisions and the maximum \( v_a \) and \( v_{\infty} \)

The maximum \( v_{\infty} \) at given \( v_a \) or the maximum \( v_a \) at given \( v_{\infty} \) are obtained by equating \( w_{-} = w_{+} \), giving

\[ v_{\infty,r_{\text{max}}} = 4v_p \sqrt{2v_r^2 + v_a^2 + v_{\infty}^2} - v_a^2, \]

\[ v_a^2_{\text{max}} = 4v_p \sqrt{2v_r^2 + v_{\infty}^2} - v_{\infty}^2 \]

for \( v_{\infty} \geq \sqrt{2} v_c \) otherwise.
To this end we find, for every combination of $v_\infty$ and $v_a$, the largest $d_p$ of all possible capture orbits. At fixed $v_\infty$, $v_a$, and $w$, the largest $d_p$ is given by equation (6) with impact parameter $b_p = b_0 + \rho$. We then numerically find the maximum $d_p$ over all $w \in [w_-, w_+]$. Clearly, planets with radius $R_p$ larger than that maximum cannot effectuate the corresponding capture. Expressing this in terms of the Safronov number, capture requires that

$$\Theta > \Theta_{\text{min}} \left( \frac{v_p^2}{v_\infty^2}, \frac{v_p^2}{v_a^2}, \frac{v_p^2}{v_\infty^2} \right),$$

with

$$\Theta_{\text{min}}(u, v, z) \equiv \min_{-\infty < y \leq 0} \left\{ \frac{1}{y^2} \left( \frac{B^2(u^2 + 1)}{y^2 + 1} - 1 \right)^{-1} \right\},$$

$$B \equiv \sqrt{4u^2 - (2u - 1 - y^2 - z)^2 + \sqrt{4u^2 - (2u - 1 - y^2 + x)^2}}.$$  

Figure 3 shows the contours of $\Theta_{\text{min}}(u, v, z)$ obtained by numerical optimisation, corresponding to the situation of a circular planet orbit. These contours are the extremal curves (like the red rim in Figure 2) for slingshots by planets with given Safronov number $\Theta$. Obviously from Figure 3, the ability of a planet to capture an interstellar ISO, rather than collide with it, is diminished the smaller $\Theta$. First this affects only the maximum captureable speed $v_\infty$ (right edge in Figure 3), but for $\Theta \leq 2.5$, also the maximum $v_a$ is reduced.

For Jupiter, Saturn, Uranus, and Neptune, $\Theta \approx 10.6, 7.04, 4.93$, and 9.43, respectively, all of which are well above unity, implying that captures by these planets are only mildly reduced by collisions. More detailed calculations for these planets, taking their eccentricities into account gives $v_\infty$, max = 32.5, 22.3, 14.5, and 13.0 km s$^{-1}$.

2.2.3 Limitation of the impulse approximation

We already discussed the limitations of validity of the capture cross-section (29) at high $v_\infty^2 + v_a^2$ owed to the neglect of collisions. We now consider the situation at low $v_\infty^2 + v_a^2$ i.e. small changes in the orbital energy. Such small changes can be effectuated already in rather wide encounters when the approximation of the planetary influence as an impulsive change of the barycentric orbit is clearly incorrect.

The assumptions underpinning the impulse approximation are only valid as long as most of the deflection occurs within the planet’s Roche sphere with radius $R_{\text{Roche}} = q^{1/3} R_p$. We may estimate the size of the deflection region by the semi-latus rectum $s_p = b_p^2 w^2 / G M_p$ of the planetocentric ISO orbit. From equations (23) we find for $v_\infty^2 + v_a^2 < v_p^2$ that $s_p \approx 2 G M_p v_p / (v_\infty^2 + v_a^2)^2$ and hence $s_p \approx 4 G M_p v_p^2 (v_\infty^2 + v_a^2)^2$, such that $s_p \leq R_{\text{Roche}}$ implies

$$-2\Delta E = v_\infty^2 + v_a^2 \geq 2 q^{1/3} v_p^2.$$  

However, our numerical results in the next section indicate that equation (29) remains valid down to much smaller values for $|\Delta E|$, namely for

$$-2\Delta E = v_\infty^2 + v_a^2 \geq 3 q v_p^2.$$  

This is astonishing, since even allowing $s_p \leq a_p$, i.e. the deflection to occur over a region as large as the planet orbit, one only finds $v_\infty^2 + v_a^2 \geq 2 q^{1/3} v_p^2$, still much larger than (36). Alternatively, if one

\[ \text{Figure 3. Contours of } \Theta_{\text{min}}(u, v, z), \text{ defined in equation (33). Planets with radius } R_p, \text{ mass } m_p, \text{ and speed } v_p \text{ can only capture ISOs incoming with } v_\infty \text{ and onto orbits with } a < GM / v_p^2 \text{ if } \Theta \equiv G m_p / R_p v_p^2 > \Theta_{\text{min}}. \text{ For trajectories not allowed by this criterion but within the red rim, the capture would require passage closer than the planets radius (see also text). The same condition is also required for the ejection of a bound object with semi-major axis } GM / v_p^2 \text{ onto a hyperbolic orbit with asymptotic speed } v_\infty \text{ via a single slingshot (see Figure 9 for the values of } \Theta \text{ of known exoplanets). The red rim, corresponding to } \Theta_{\text{min}} = \infty, \text{ is identical to that in Figure 2.} \]
dems that the capture cross-section (29) is smaller than that for crossing the planet’s Roche sphere (estimated via equation 12 with $R_p$ replaced by $R_{Roche}$), one finds $v_{\infty}^2 + v_{p}^2 \geq q^2/3 v_{p}^2$ still larger than the numerical result (36).

2.3 Capture by wide encounters

Small changes $\Delta E = -\frac{1}{2}(v_{\infty}^2 + v_{p}^2)$ to the orbital energy of the ISO can already be effectuated by weak interactions, when the actual ISO orbit deviates only little from that in the absence of the planet. The natural tool for estimating the energy change during such a wide encounter is perturbation theory. In barycentric coordinates the Hamiltonian can be split as $H(x, v, t) = H_0(x, v) + H_1(x, t)$ with $H_0 = \frac{1}{2}v^2 - GM/|x|$, when to first-order the energy change is

$$\Delta E \approx \int \left( \frac{\partial H_1}{\partial t} \right)_{x(t)} \, dt,$$

(37)

i.e. $\partial H_1/\partial t$ is evaluated along the unperturbed barycentric hyperbola instead of the true trajectory. The integral (37) is not expressible in closed form and requires numerical treatment (see Breakwell & Perko 1974, for a similar approach). We may simplify the problem by assuming a circular planet orbit and replacing $H_1$ with its quadrupole approximation (e.g. Aly et al. 2015, equation A9)

$$\frac{\partial H_1}{\partial t} \approx -\frac{3GM}{2r^3}a_p^2 q \Omega_p \sin^2 \theta \sin 2(\varphi - \phi_0 - \Omega pt),$$

(38)

where $\phi_0$ is the planetary azimuth at ISO periapse and $(r, \varphi, \theta)$ are the polar coordinates of the ISO along its orbit. At $v_{\infty} \to 0$, we may approximate the ISO orbit as parabolic (see Appendix C2), when for the most favourable situation of a co-planar ISO orbit ($\sin \theta = 1$) we obtain (using equations C13-C17)

$$\Delta E \approx \frac{1}{2}a_p^2 \frac{v_{\infty}^2}{s^3} \sin 2\phi_0 \left( \frac{\sin^2 \theta}{a_p^2} \right)$$

(39)

with $s = b^2 v_{\infty}^2 / GM$ the ISO’s semi-latus rectum. Here,

$$I(x) \equiv 12 \int \frac{\pi/2}{\pi/2} \cos^2 u \cos \left[ 4u - x \left( \tan u + \frac{1}{4} \tan^3 u \right) \right] \, du,$$

(40)

which is always positive, but decays very quickly with increasing $|x|$, which is essentially the ratio $[\Omega_p / \Omega_c]$ between the azimuthal frequencies of planet and ISO. The larger this ratio, the more strongly the integrand in (40) oscillates, when negative and positive contributions mostly cancel. The maximum negative energy change occurs for planetary phases $\phi_0 = -\frac{3}{4} \pi$ and $\frac{5}{4} \pi$, but beyond the quadrupole approximation the former is favourable, which corresponds to passing the star on the same side as the planet. For retrograde encounters, $\Delta E$ is given by the same expression with $I(x)$ replaced with $I(-x)$. This is also positive but much smaller than $I(x)$, such that capture by wide interactions occurs preferentially from prograde orbits.

Defining

$$J(x) \equiv x^{-3/2} I(x^{-3/2})$$

(41)

and inverting equation (39) for $\sin 2\phi_0 = -1$, obtains the maximum semi-latus rectum for capture

$$s_{\max} = a_p J^{-1}(X),$$

(42)

with the dimensionless measure

$$X \equiv \sqrt{\frac{1}{q} \frac{1}{v_{\infty}^2} + \frac{q}{2} \frac{\Delta E}{v_{p}^2}}$$

(43)

for the energy change. Figure 4 plots the relation (42) obtained in this way and by numerical quadrature of (40) as points. Obviously, the semi-latus rectum (and hence peri-centre) of incoming ISO orbits that can just be captured increases only very slowly towards vanishing $\Delta E$, i.e. $X \to 0$; the red curve in Figure 4 asymptotes to $s_{\max} \propto |\ln X|^p/|P|^p$ with $p \approx \frac{3}{2}$ in that limit.

The contribution to the capture cross-section in the limit $v_{\infty} \to 0$ is $\sigma = \pi b^2 = \pi a_p^2 v_{\infty}^2 / v_{\infty}^2$. Hence,

$$\sigma = \pi a_p \frac{v_{\infty}^2}{v_{\infty}} \int \frac{dp(s|X)}{ds} s \, ds,$$

(44)

where $dp(s|X)$ is the probability that an ISO orbit with semi-latus rectum $s = b^2 v_{\infty}^2 / GM$ suffers an energy change $\Delta E \leq -\frac{1}{2}v_{p}^2 q X$ (note that $\int dp < 1$). From simple scaling relations we expect that $dp/ds$ depends only on the ratio $s / s_{\max}(X)$, i.e. is of the form

$$\frac{dp(s|X)}{ds} = \frac{1}{a_p} P_s \left( \frac{s}{s_{\max}(X)} \right),$$

(45)

with some function $P_s(\xi)$ which accounts for the averaging over ISO orientations and planetary phase. While $P_s(\xi)$ cannot be worked out analytically, it must be a decreasing function and vanish for $\xi > 1$. Inserting (45) and (42) into (44) obtains

$$\sigma(v_{\infty}|v_p) = \pi a_p^2 \frac{v_{\infty}^2}{v_{\infty}} \left( \langle \xi \rangle \right) p J^{-1}(X),$$

(46)

where our ignorance of the function $P(\xi)$ has been reduced to the single factor

$$\langle \xi \rangle p \equiv \int P_s(\xi) \xi \, d\xi,$$

(47)

The numerical experiments in the next section confirm this approximation and suggest that $\langle \xi \rangle p \approx \frac{1}{12}$. Other than for close encounters, where according to equation (29) $\sigma$ scales like $X^{-2}$, the dependence of $\sigma$ on $X$ for wide encounters is rather weak, increasing shallower than a power law towards $X \to 0$.

2.4 Capture by the star?

Since the star is not at rest but also moves in the barycentric frame, it can in principle also effectuate capture. We now assess the importance of this possibility. First, we note that captures by wide

---

Figure 4. The maximum semi-latus rectum $s = b^2 v_{\infty}^2 / GM$ of incoming ISO orbits for which the energy change can be as large as $\Delta E = -\frac{1}{2} q v_{p}^2$. This maximum is obtained for a prograde co-planar orbit leading the planet (assumed on a circular orbit) by $-\phi_0 = \pi/4$ at peri-centre. Points: relation from numerically obtained $\Delta E$ (see text), curve: parametric fit with asymptote $s_{\max} \propto |\ln X|^p/|P|^p$ with $p \approx \frac{3}{2}$ in that limit.
interactions are always dominated by the planet, simply because the contributions of planet and star to the binary quadrupole moment scale as $q$ and $q^2$, respectively.

For close interactions with the star, the impulse approximation used in our treatment of close interactions with the planet is not really appropriate. However, we may still estimate an upper limit for the maximum energy change by assuming that the star moves with constant barycentric velocity and speed $v_\infty \approx q v_C$. Then the maximum energy change occurs if the ISO passes just in front of the star on a grazing orbit, when

$$[\Delta E] \leq \frac{-2q v_\infty v_C}{1 + 2v_\infty^2/v_{esc}^2} < 2q v_\infty v_C$$

(48)

where $v_{esc}^2 = 2G m_s/R_s$ is the escape speed from the stellar surface. Thus, the maximum $v_\infty$ that can just be captured is $v_\infty, \text{max} \approx 4q v_C$, which is smaller than for capture by the planet by a factor $\sim q$. Thus, capture by the star is insignificant compared to that by the planet.

3 SIMULATIONS OF ISO CAPTURE

We now numerically calculate the cross-section for capturing an ISO and compare it to the analytical estimates (29) and (46). Following Valtonen & Innanen (1982), we integrate many orbits from random incoming trajectories, i.e. we randomly throw test particles at the planet-star binary and record those that ‘stick’, but do not restrict ourselves to circular planet orbits. We use barycentric coordinates with the planet orbit in the $x$-$y$ plane, when the asymptotic impacting ISO orbit at $t \to -\infty$ is specified as

$$r(t) = b + v_\infty t$$

(49)

with vectors $b \perp v_\infty$, which are parameterised as

$$b = \begin{pmatrix} -\sin \psi \cos \phi - \cos \phi \sin \beta \sin \psi \\ \sin \psi \cos \phi - \sin \phi \sin \beta \sin \psi \\ \cos \phi \sin \beta \sin \psi \end{pmatrix}, \quad v_\infty = \begin{pmatrix} \cos \phi \cos \beta \\ \sin \phi \cos \beta \\ \sin \beta \end{pmatrix}.$$  

(50)

Here, $\beta$ is the ecliptic latitude and $\phi$ the azimuth of the direction $v_\infty$, while $\psi$ is the angle in the impact plane perpendicular to $v_\infty$. The incoming orbit (49) is the asymptote of a unique hyperbolic orbit around the binary’s barycentre, hereafter denoted the incoming hyperbola. We choose $t = 0$ to refer to the periapse of this hyperbola. With these specifications the capture cross section is

$$\sigma(v_\infty|v_\infty) = \int_0^\infty db \int_0^{2\pi} d\phi \int_{-\pi/2}^{\pi/2} \cos \beta d\beta \int_0^{\pi/2} \frac{2\pi d\phi}{2\pi} H(-\frac{1}{2} v_{esc}^2 - E_{\text{final}}),$$

(51)

where $E_{\text{final}}$ denotes the Heaviside function (mean anomaly) of the planet at $t = 0^4$. $H$ denotes the Heaviside function and the final energy $E_{\text{final}}$ is a (non-trivial) function of $b$, $v_\infty$, and $\ell_p$ obtained via numerical orbit integration.

3.1 Numerical method

We now describe the numerical method to estimate the cross section in sufficient detail for anybody to reproduce it. Readers who are merely interested in the results may skip this sub-section.

3.1.1 Initial conditions

We evaluate the integral (51) via Monte-Carlo integration with the main difference to Valtonen & Innanen that we use many more individual orbits, enough to have at least $10^5$ capture events for each speed $v_\infty$ considered. The Monte-Carlo estimate for the capture cross-section is simply

$$\sigma = \pi b_{\text{max}}^2 \frac{N_{\text{captured}}}{N_{\text{sampled}}},$$

(52)

where $b_{\text{max}}$ is the maximum impact parameter $b$ sampled. We use

$$b_{\text{max}} = p_{\text{max}} \left[ 1 + \frac{2GM}{p_{\text{max}} v_\infty} \right]^{1/2},$$

(53)

such that the incoming hyperbola’s periapse radius is at most

$$p_{\text{max}} = a_p + d_{p,\text{max}} + R_{\text{Roche}},$$

(54)

With this choice all incoming trajectories that pass the planet at distances $d_p \leq d_{p,\text{max}}$ are sampled (the addition of $R_{\text{Roche}}$ accounts for deviations of the actual orbits from simple hyperbolae). The correct choice of the parameter $d_{p,\text{max}}$ is critical for the validity of our method as detailed in section 3.1.4.

Having drawn appropriate $b$ and $v_\infty$, the actual initial position and velocity for the numerical orbit integration are taken to be those of the incoming hyperbola when it first reaches the starting radius $r_0 > a_p$ (the choice of $r_0$ is discussed in section 3.1.4 below). This initial condition corresponds to a time $t = -T$, obtained from equation (C6), which we use to set the planet initial mean anomaly to $\ell_p = -\Omega_p T$ with $\Omega_p^2 = GM/a_p^3$ the orbital frequency of the planet.

3.1.2 Orbit integration

The orbits are numerically integrated with an integrator that constructs the trajectory from alternating Kepler orbits around star and planet, and hence treats close encounters correctly, see Appendix B for details. We set the accuracy parameter (see equation B7) to $2 \times 10^{-6}$, when a few hundred steps per orbit are required, and in the case of a circular planet orbit the local and global errors of the Jacobi integral $J = E - \Omega_p L_z$ are $10^{-9}$ and $10^{-8}$ times $GM/a_p$, respectively. Of course, more accurate integration is possible at the expense of higher computational costs, but has no benefit since our uncertainties are dominated by the shot noise of the Monte-Carlo approach.

We integrate each orbit either until time $t = T$ (when the incoming hyperbola reaches the starting radius $r_0$ again on its way back out), or until the orbit passes an apo-apse (a sign change of the radial velocity from $+\to -$) outside of the planet’s Roche sphere, or until a collision with star or planet, whatever occurs first. For each orbit we record the initial parameters, the total and rms local errors of the Jacobi integral (for circular planet orbits only), the times and distances of closest approaches to star and planet, and the barycentric osculating orbital elements at the end of integration.

3.1.3 Avoiding unnecessary integrations

The vast majority of initial conditions generated in our Monte-Carlo approach pass through the binary like ‘Oumuamua through the Solar system and do not result in capture, because they do not come close enough to the planet. Numerical integration of such interlopers is best avoided when calculating the capture cross section. Close encounters with the planet can be constructed by integrating initial conditions
Dehnen, Hands

Figure 5. Top: the numerically calculated cross-section $\sigma$, scaled by $(v_{\infty}/v_c)^2$, for capture by a planet on a circular orbit ($e_p = 0$) with semi-major axis $a_p$ and radius $R_p = 10^{-3} a_p$ is plotted against the dimensionless measure $X$ (equation 43) of the minimum energy change for various values of the planet-to-star mass ratio $q$ and the maximum semi-major axis $a$ for the initial captive orbit. Only values for $a$ with at least 100 simulated captures are included, such that the statistical error of the Monte-Carlo estimate for $\sigma$ is at most 10% (smaller than the symbol sizes), but often much less. The thin full curve is a fitting function (equation 60), which approaches the theoretical asymptotes at small and large $X$. The dotted lines are predictions for $q = 10^{-2}$ including the transfer factor $Y$.

Bottom: Ratio of the numerically calculated $\sigma$ to $\pi a_p^2 (v_c/v_{\infty})^2 f_m(X)$ for all data at $X \gtrsim q^{-1}$. close to the planet both backward and forward in time (Siraj & Loeb 2019). However, the probability for such events to arise from randomly incoming orbits cannot be obtained rigorously (only within the impulse approximation) and, hence, neither can be the capture cross-section with this method.

Instead, we only numerically integrate orbits for initial conditions whose incoming hyperbola actually comes closer to the planet than $d_{p,\max}$. This is a much more stringent condition than that it comes closer than $a_p + d_{p,\max}$ to the barycentre (satisfied by all initial conditions), especially for $d_{p,\max} < a_p$. Calculating the closest approach $d_{p,\text{hyp}}$ of the incoming hyperbola to the planet requires careful numerical minimisation (for some orbits there are two minima) but is still $\sim 10^2$-3 times faster than a full orbit integration, substantially cutting the overall computational costs, in particular for large $v_{\infty}$, when capture becomes ever less likely and requires very close encounters.

3.1.4 Tuning the numerical parameters

Apart from the accuracy parameter of the orbit integrator, our method has two more numerical parameters introduced in section 3.1.1: the initial radius $r_0$ of the numerical orbit integrations and the parameter $d_{p,\max}$.

The choice of the starting radius $r_0$. Starting the numerical integration not at infinity but at $r_0$ incurs an error that to good approximation is given by the effect of the binary’s quadrupole integrated from infinity to $r_0$. The amplitude of the quadrupole of the binary’s orbit-averaged potential at barycentric radius $r$,

$$\Phi_2(r) = \frac{\sqrt{3}}{8} \frac{a_p^2 q}{(1+q)^2} \frac{GM}{r^3}$$

(e.g. Aly et al. 2015, equation A9), is therefore an estimate for the energy error contracted by starting the integration at $r$. Demanding that this error is much smaller than $|\Delta E|$ required for capture gives the condition

$$r_0^3 \gtrsim \frac{3}{2} \frac{q a_p^2}{(1+q)^2} \left( \frac{GM}{v_{\infty}^2 + v_a^2} \right) = \frac{G m_p a_p^2}{v_{\infty}^2 + v_a^2}.$$

In practice we set

$$r_0 = 10 \left( \frac{G m_p a_p^2}{v_{\infty}^2} \right)^{1/3},$$

or $r_0 = 20a_p$, whichever is larger.

The choice of $d_{p,\max}$. The choice of $d_{p,\max}$ is critical for the validity of our method: if too small some capture events will be missed because the orbit is not integrated, and if too large many non-capture events will be integrated unnecessarily. Moreover, the most suitable value depends strongly on $v_{\infty}$. In practice, we leave a 10% safety margin of values for $d_p$ which are integrated but never result in
capture by ensuring that
\[ d_p \leq 0.9 d_{p,\text{max}}. \]  

(58)

where \( d_p \) and \( d_{p,\text{hyp}} \) denote closest-approach distances to the planet of the actual ISO orbit and the incoming hyperbola, respectively, while the maximum is over all initial conditions that have been integrated (i.e. for which \( d_{p,\text{hyp}} < d_{p,\text{max}} \)) and resulted in capture. In order to enforce this criterion, if \( d_{p,\text{max}} \) is ever found to violate (58) by a newly integrated orbit, it is increased appropriately (this does not require a complete re-start of the Monte-Carlo sampling as long as care is taken to adapt the previous sampling to the new value). This method works extremely well if started with slightly too small initial \( d_{p,\text{max}} \).

3.2 Results

We use these methods to simulate, for \( q = 10^{-2}, 10^{-3}, 10^{-4} \) and a grid of values for \( v_{\infty}, \) as many ISO orbits as necessary, but no fewer than \( 10^3 \), to generate at least \( 10^3 \) bare captures, unless the number of captures exceeds \( 10^5 \) (when we terminate the runs before \( 10^3 \) orbits are reached). Here, 'bare capture' refers to any bound ISO orbit, regardless of its semi-major axis, i.e. \( E_{\text{final}} < 0 \). We assume that planet and star have radii \( R_p = 10^{-4} a_p \) and \( R_s = 10^{-3} a_p \), when the case \( q = 10^{-3} \) approximately corresponds to the Sun-Jupiter system.

3.2.1 Capture cross-section

For each \( v_{\infty} \) considered, we estimate the cumulative cross-sections \( \sigma(v_{\infty}|v_a) \) for capture onto orbits with \( E_{\text{final}} < -\frac{1}{2} v_a^2 \), i.e. semi-major axis \( a < [v_c/v_a]^2 a_p \), if at least 100 captured orbits satisfy this condition.

For the situation of a circular planet orbit (\( e_p = 0 \)) and various values of the mass ratio \( q \), Figure 5 plots the resulting cross-sections, multiplied by \( (v_{\infty}/v_c)^2 \), against the dimensionless measure \( X \) (see equation 43) for the minimal energy change required to capture an ISO onto an orbit with semi-major axis \( \leq a \). Our theoretical considerations in Section 2 suggest that the cumulative capture cross-section follows the general form

\[ \sigma(v_{\infty}|v_a) = \pi a_p^2 \frac{v_{\infty}^2}{v_c^2} f(X) Y \left( \frac{v_{\infty}^2}{v_c^2} \frac{v_a^2}{v_c^2} \right). \]

(59)

Here, \( Y \) is the transfer function of equation (27), which obtains \( Y = 1 \) for \( v_{\infty}, v_c \ll v_a \), i.e. for \( X \leq q^{-1} \), and drops to zero at the maxima \( (30) \). At large \( X \), the impulse approximation predicts \( f = \frac{8}{7} X^{-2} \) (equation 29), while at small \( X \), perturbation theory suggests the functional form \( f = (s_{\text{max}}/a_p)^2 \sim \ln|X|^p \) (equation 46, see also Figure 4). A simple function that combines these asymptotic limits is (thin curve in Figure 5)

\[ f_{\text{fit}}(X) = \frac{8}{3X_0^2} \left[ \sinh^{-1}(X_0/X)^{2/p} \right]^p \]

(60)

where a fit to the data at \( X < q^{-1} \) obtains \( X_0 \approx 2.95 \) and \( p \approx 0.82 \).

The data also clearly show the drop of \( \sigma \) at \( X \approx q^{-1} \) below this model due to the geometrical transfer function \( Y \) and collisions with the planet (small symbols). The thin dotted lines in Figure 5 give the prediction for \( q = 10^{-2} \) from equation (59) for \( f = \frac{8}{7} X^{-2} \). They fit the data quite well, despite ignoring the finite size of the planet, i.e. collisions with the planet.
At \( X \leq 1 \), the numerical results follow the expectation (46) from perturbation theory if we set the geometrical factor \( (\xi) = \frac{1}{12} \). The transition between these two regimes occurs at \( X = X_0 \approx 3 \) and is remarkably sharp. In particular, the relation \( f(X) \approx \frac{2}{3} X^{-2} \) from the impulse approximation holds down to much smaller values for \( X \) than its formal range of validity \( X \geq 2q^{-1/3} \), as discussed in Section 2.2.3.

This may just be a coincidence in the sense that the capture process at \( 1 < X < 2q^{-1/3} \), which is not accessible by analytic approximation, follows the same scaling. Indeed, the small but systematic departures from \( f = \frac{2}{3} X^{-2} \) at \( 2 < X < 20 \) (clearly visible in the bottom panel of Figure 5) indicate that some other process (than impulsive deflection) is at play here.
The functional form (59) has a simple interpretation: \( \pi a_p^2 \) is the cross-section of the planetary orbit, which is enhanced by gravitational focusing accounted for by the factor \( v_c^2/v_{\infty}^2 \). The factor \( f(X) \) is proportional to the probability that an incoming object coming close to the planet orbit suffers an energy change \( \Delta E = -\frac{1}{2}qXv_c^2 \), while the factor \( Y \) accounts for geometrical limits.

Finally, Figure 6 shows the numerically estimated cross-section for different planetary eccentricities up to \( e_p = 0.4 \) but fixed \( q = 10^{-3} \). The dependence of \( \sigma \) on eccentricity is remarkably weak compared to its variation with \( v_\infty \) or \( v_c \) (i.e. \( X \)). In the regime of wide interactions (\( X < 1 \)), the capture by planets on eccentric orbits is somewhat enhanced compared to circular orbits, while in the intermediate regime \( 1 < X < 10 \) it is reduced. In the strong deflection limit (impulse approximation, \( X > 10 \), the eccentricity dependence is at most very weak and below the uncertainties of the simulation data.

### 3.2.2 Captured orbits

For a planet with mass ratio \( q = 10^{-3} \) on a circular orbit, we plot in Figure 7 the distributions over some characteristics of the orbits onto which the ISOs are captured for six of the 27 values for \( v_\infty \) that we sampled (each row in the figure corresponds to another \( v_\infty \)). In particular, we show the 2D distributions of semi-major axis \( a \) with the distance \( d_p \) of closest approach to the planet, periapsis radius and inclination, but also the 2D distribution between the latter two.

The first two values (\( v_\infty/v_c = 0.01 \) and 0.03) are in the regime where capture is dominated by wide interactions. The orbital distributions in this case appear rather smooth and featureless. The maximal periapsis radius \( r_{\text{peri}} \) is much larger than \( a_p \) and near-uniformly distributed below that. In the limit \( e \sim 1 \) applicable here, this translates to a distribution uniform in \( e^2 \), i.e. ergodic. The distribution in inclination is also remarkably smooth and close to uniform, somewhat unexpected from our analytical arguments in Section 2.3, which suggested a prevalence of pro-grade orbits.

The last two rows (for \( v_\infty/v_c = 0.2 \), 0.4 and 1) are firmly in the regime where capture requires close interactions with the planet. In this case, there is a preference for pro-grade orbits with \( r_{\text{peri}} \sim a_p \), except for the highest values (\( v_\infty \geq v_c \)), when the distribution returns to near uniform. The reason for this change is that the cross-section for capture depends correspondingly on the inclination of the incoming orbit (we have not considered such dependence in Section 2.2), but

Figure 7. continued
Similarly, the rate at which cometary ISOs (with density $0.6 \text{ g cm}^{-3}$) are tidally disrupted by close encounters is $\Gamma_{\text{tid}} = n_{\text{iso}} \Omega_{\text{tid}}$ with $\Omega_{\text{tid}}$ computed analogously with $\sigma_{\text{coll}}$ replaced by $\sigma_{\text{tid}}$ of equation (63).

$\Gamma_{\text{coll}} = n_{\text{iso}} Q_{\text{coll}}$ with the volume capture rate $Q_{\text{coll}}$ defined in equation (61).

Similarly, the rate at which cometary ISOs (with density $0.6 \text{ g cm}^{-3}$) are tidally disrupted by close encounters is $\Gamma_{\text{tid}} = n_{\text{iso}} \Omega_{\text{tid}}$ with $\Omega_{\text{tid}}$ computed analogously with $\sigma_{\text{coll}}$ replaced by $\sigma_{\text{tid}}$ of equation (63).

| planet/moon | $Q_{\text{coll}}$ $[\text{au}^3 \text{yr}^{-1}]$ | $Q_{\text{tid}}$ $[\text{au}^3 \text{yr}^{-1}]$ |
|-------------|------------------|------------------|
| Sun         | 0.1737           | 3.088            |
| Mercury     | $3.82 \times 10^{-3}$ | $2.62 \times 10^{-4}$ |
| Venus       | $1.53 \times 10^{-7}$ | $1.00 \times 10^{-4}$ |
| Earth       | $1.40 \times 10^{-7}$ | $9.42 \times 10^{-4}$ |
| Mars        | $3.09 \times 10^{-8}$ | $1.70 \times 10^{-5}$ |
| Jupiter     | $2.52 \times 10^{-5}$ | $5.73 \times 10^{-3}$ |
| Saturn      | $9.55 \times 10^{-6}$ | $8.95 \times 10^{-4}$ |
| Uranus      | $1.24 \times 10^{-6}$ | $2.55 \times 10^{-4}$ |
| Neptune     | $1.20 \times 10^{-6}$ | $2.78 \times 10^{-4}$ |
| Moon        | $1.94 \times 10^{-8}$ | $5.99 \times 10^{-6}$ |
| Io          | $1.57 \times 10^{-8}$ | $4.85 \times 10^{-6}$ |
| Europa      | $9.13 \times 10^{-9}$ | $2.81 \times 10^{-6}$ |
| Ganymede    | $2.03 \times 10^{-8}$ | $6.27 \times 10^{-6}$ |
| Callisto    | $1.11 \times 10^{-8}$ | $3.44 \times 10^{-6}$ |
| Titan       | $1.11 \times 10^{-8}$ | $3.41 \times 10^{-6}$ |
| Triton      | $2.82 \times 10^{-9}$ | $8.70 \times 10^{-7}$ |
| planets & moons | $3.77 \times 10^{-5}$ | $4.36 \times 10^{-3}$ |

Table 2. The rate at which major Solar-system bodies collide with ISOs is $\Gamma_{\text{coll}} = n_{\text{iso}} Q_{\text{coll}}$ with the volume capture rate $Q_{\text{coll}}$ defined in equation (61).

at very high $|\Delta E|$ a very close interaction is required in any case independent of inclination.

Most interesting is the intermediate regime of $q \lesssim (v_{\infty}/v_{\text{peri}})^2 \lesssim 10q$, where no analytic treatment was possible, and which is represented in Figure 7 by the values $v_{\infty}/v_{\text{peri}} = 0.064$ and 0.1. In this case, the distribution in $r_{\text{peri}}$ is bi-modal, while pro-grade orbits become ever more likely with increasing $v_{\infty}$.

4 COLLISION, TIDAL DISRUPTION, AND EJECTION

4.1 Collisions and Tidal Disruptions of ISOs

One byproduct of the analytical treatment of close encounters with the planets was the derivation of the cross-section for collisions of ISOs with planets or moons in equations (12) and (13), respectively. Integrating over the ISO velocity distribution, obtains the collision rate as $\Gamma_{\text{coll}} = n_{\text{iso}} Q_{\text{coll}}$ with the volume collision rate

$$Q_{\text{coll}} = \int_0^\infty dv_{\infty} v_{\infty} p(v_{\infty}) \sigma_{\text{coll}}(v_{\infty}),$$

where $p(v_{\infty})$ is the distribution of ISO asymptotic speeds. Assuming that $p(v_{\infty})$ is the same as the distribution observed for stars in the Solar neighbourhood from Gaia (see paper 2 for details) obtains the numbers reported in Table 2 for the Solar system planets. With $n_{\text{iso}} \approx 0.1 \text{ au}^{-3}$ we find that Earth is hit by an ISO only once every 70 Myr.

ISOs that just avoid collision may get tidally disrupted if their closest approach distance $d_p$ to the (centre of the) planet is smaller than their Roche limit

$$d_{\text{tid}} \approx R_p \left( \frac{2 P}{P_{\text{iso}}} \right)^{1/3}.$$

The conditions for tidal disruption are therefore that $\rho_{\text{iso}} < 2 \rho_p$ and $d_p < d_{\text{tid}}$. From the distribution of simulated captures over the closest distance $d_p$ to the planet in Figure 7, we see that only a few ISOs with incoming speeds $v_{\infty} \sim v_c$ reach $d_p \lesssim 1.4 \times 10^{-4} a_p$, which is the Roche limit for $\rho_{\text{iso}} = 0.5 \rho_p$, corresponding to comets passing Jupiter. Hence, tidal disruption of captured ISOs is extremely rare.

The cross-section $\sigma_{\text{tid}}$ for ISO’s to be tidally disrupted by a close encounter is hence that of having a closest approach to the planet satisfying $R_p < d_p < d_{\text{tid}}$. Using our results for the collision cross-section, this can be obtained as

$$\sigma_{\text{tid}}(v_{\infty}) = \max \{ 0, \sigma_{\text{coll}}(v_{\infty}) - \sigma_{\text{coll}}(v_{\infty}) \},$$

(63)

where the replacement $R_p \to d_{\text{tid}}$ includes the relation for the escape speed. Table 2 gives the corresponding volume rates $Q_{\text{tid}}$ in column three (again assuming that ISOs have the same speed distribution as nearby stars).

The distinction between tidal disruption events by planets or moons as opposed to the Sun is relevant inasmuch as slightly less than half of these occur during close encounters that capture the ISO or rather its fragments into the Solar system (while no such capture occurs for tidal disruption by the Sun). For cometary ISOs, $n_{\text{iso}} \approx 0.009 \text{ au}^{-3}$ (Siri& Loeb 2021) and we expect ~20 of them to be tidally disrupted and their fragments captured per Myr.

4.2 Sling-shot ejections of asteroids

Another byproduct of the treatment of close interactions was the maximum capturable speed $v_{\infty}$ and binding energy $GM/a = \frac{1}{2} v_{\infty}^2$ for the captured ISO as function of the planet radius $R_p$ through the Safronov number $\Theta = q a_p / R_p$. These limits also apply to the reverse process: ejection of a bound object by a single slingshot. In Figure 8 we plot the resulting minimum semi-major axis (corresponding to the maximum binding energy) of a bound object that a planet with given Safronov number $\Theta$ can just eject. For $\Theta < 1 + \sqrt{2} \approx 2.4$ the ability of a planet to eject orbit crossing objects is diminished. However, weakly bound orbits with semi-major axes twice that of the planet or larger can still be ejected via a single slingshot by a large planet with Safronov number as small as $\Theta = 0.1$, hundred times smaller than for Jupiter.

Figure 9 shows the Safronov numbers $\Theta$ for exoplanets with measured/inferred radius and mass. Obviously most of these have $\Theta \lesssim 0.1$, implying that they are incapable to eject most orbit crossing planetesimals in a single slingshot. However, this is of course largely owed to the selection inherent to the detection methods, which favour large planets with small semi-major axes.
Figure 9. Distribution of solar-system planets (blue) and exoplanets over semi-major axis $a_p$, mass $m_p$, and Safronov number $\Theta$ (clamped to $\Theta \leq 1000$), assuming circular orbits. Missing measurements for $R_p$ and $m_p$ were replaced by values inferred from $R_p(m_p)$ relations by Otegi et al. (2020) for $m_p < 124 M_{\oplus}$ and Bashi et al. (2017) for more massive planets (excluding $0.18 < R_p/R_{\text{sup}} < 0.27$ where these relations are not unique). Only compact planets with $\Theta > 2.414$ (dashed) can eject any orbit-crossing bound object via a single slingshot, while larger objects can only eject objects with ever greater semi-major axes, see also Figure 8.

Of course, these planets may still eject bound objects (rather than collide with them) via multiple wide encounters, slowly increasing the semi-major axis of the objects until ejection. This process may be slow, but planets on orbits $\sim 100$ times smaller than Jupiter’s have $\sim 1000$ times more orbital periods to act.

5 CONCLUSION

This study revisited the capture of initially unbound interstellar objects (ISOs) into bound states of a planet-star binary with semi-major axis $a_p$ in general. We first considered in Section 2 analytical arguments based on the impulse approximation for close encounters with the planet (extending previous studies) and on perturbation theory for wide encounters.

In Section 3 we performed numerical simulations, whereby substantially extending previous studies also to planets with eccentricity $e_p > 0$. These simulations confirmed the analytical results for the asymptotic cases when the energy change $|\Delta E|$ required for capture is much larger (close encounters) or much smaller (wide encounters) than $q v_c^2 = q G M / a_p$. The transition between these two well understood asymptotic regimes at $|\Delta E| \sim q v_c^2$ is remarkably sharp.

The general result of these investigations is that the capture cross-section $\sigma$ is a steeply declining function of both the incoming speed $v_{\infty}$ of the ISO and the energy change $|\Delta E|$ (equation 59). $\sigma$ depends on $|\Delta E|$ and the planet-to-star mass ratio $q$ only via their ratio $X = |2 \Delta E| / q v_c^2$, except that it drops to zero at $X \gtrsim q^{-1}$, corresponding to the closest encounters possible. This truncation is due to orbital geometry: the maximum captureable incoming speed is $v_{\infty} \approx 3 v_c$, even for point-like planets. In reality, the planet’s finite size limits the already tiny probability to capture objects with $v_{\infty} \gtrsim v_c$ further, since the corresponding slingshot approach the planet closer than its radius $R_p$. The effect of the planet size is most naturally expressed via its Safronov number $\Theta = q a_p / R_p$, which for Jupiter and Saturn is sufficiently large for their capture cross-sections to be largely unaffected by collisions.

The capture cross-section depends only weakly on the planet’s orbital eccentricity $e_p$, the most notable effect being an increase of $\sigma$ by a factor $\sim 1 + e_p^2$ near $X = 0.05$, when captures are dominated by wide encounters. The resulting capture rate is treated in an accompanying paper Dehnen et al. (2021) with particular emphasis on the Solar system, including the resulting steady-state population of captive ISOs.

ACKNOWLEDGEMENTS

We thank Douglas Heggie for discussions that lead to improving Sections 2 & 3, Ralph Schönrich for many stimulating conversations, Ravit Helled for helpful exchanges, and the reviewer, Simon Portegies Zwart, for useful comments. TH was supported by a University of Zürich Forschungskredit (grant K-76102-02-01). Part of this work has been carried out in the frame of the National Centre for Competence in Research ‘PlanetS’ supported by the Swiss National Science Foundation (SNSF) (grant F-76102-04-01). The simulations of Section 3 were performed using the DiRAC Data Intensive service at Leicester, operated by the University of Leicester IT Services, which forms part of the STFC DiRAC HPC Facility (www.dirac.ac.uk). The equipment was funded by BEIS capital funding via STFC capital grants ST/K000373/1 and ST/R002363/1 and STFC DiRAC Operations grant ST/R001014/1. DiRAC is part of the National e-Infrastructure.

DATA AVAILABILITY

The results of the numerical simulation of Section 3 are available on reasonable request to the corresponding author.

APPENDIX A: SLINGSHOT EJECTION

Here, we derive the ejection rate of captured ISOs via slingshots by the planet, which is needed in paper 2, but technically fits better here. The process is the reverse of the capture mechanism treated in Section 2.2 and the calculation of the flux proceeds analogously. However, the initial conditions are different: in Section 2.2 we considered the scattering of an incoming population of ISOs with singular (specific) energy \( E_v = v^2_p/2 \) onto bound orbits with a range of energies \( E \leq -v^2_p/2 \), while here we instead consider the scattering of a bound population with singular \( E = -v^2_p/2 \) onto unbound orbits in the range \( E \geq v^2_\infty/2 \).

A1 The flux of ejections

When the object enters and exits the planet Roche sphere, it has barycentric speeds

\[
v_1^2 = 2v^2_r - v^2_\infty, \quad v_2^2 = 2v^2_r + v^2_\infty, \tag{A1}
\]

and planetocentric speed \( w \) given by equation (5). Relations (17) also hold here, and the ejection condition is obtained by inserting \( v_2^2 - v_1^2 = v^2_\infty + v^2_\infty \):

\[
v^2_\infty + v_\infty^2 = -4Gm_pv_p w + \frac{Gm_p \cos \theta + b_p w^2 \sin \theta \cos \psi_p}{G^2 m_\infty^2 + b_p^2 w^4}, \tag{A2}
\]

which differs from the capture condition (19) only by the sign of the energy change. Combining equations (17a) and (A1) we find \(-2v_\infty w \cos \theta = D\) (as defined in equation 24) and can eliminate \( \theta \) from equation (A2) to obtain the ejection condition for \( w \), \( b_p \), and \( \psi_p \) at \( v_\infty \) and \( v_\infty \):

\[
v^2_\infty + v_\infty^2 = \frac{2G^2 m_\infty^2}{G^2 m_\infty^2 + b_p^2 w^4} \left[ D - \cos \psi_p \frac{b_p w^2}{Gm_p} \sqrt{4v^2_\infty w^2 - D^2} \right]. \tag{A3}
\]

The solution for \( b_p \) and \( \psi_p \) of this condition at \( v_\infty \) and \( v_\infty \) lies on a circle (22) in the impact plane with offset and radius

\[
b_0 = \frac{Gm_p}{(v^2_\infty + v^2_\infty)^{1/2}} \sqrt{4v^2_\infty w^2 - D^2}, \tag{A4a}
\]

\[
\rho = \frac{Gm_p}{(v^2_\infty + v^2_\infty)^{1/2}} \sqrt{4v^2_\infty w^2 - C^2}. \tag{A4b}
\]

Compared to the corresponding relations (23) for capture, \( b_0 \) and \( \rho \) have swapped, which is owed to the different initial conditions relating to \( v_\infty \) for capture and to \( v_\infty \) for ejection. In addition, the sign of \( b_0 \) is changed, because an energy increase (required for ejection) is favoured by orbits passing behind the planet, while for capture passing in front of the planet is better.

We proceed analogously to the treatment of capture and average the local flux \( F = n_1 w \rho^2 \) of objects scattered by the planet onto unbound orbits over all orientations \( \alpha \) of the incoming orbit using equation (8) with the limits (25). This gives

\[
\langle F \rangle_\alpha = \frac{8\pi}{3} n_1 G^2 m_\infty^2 \rho^2 w^2 v_1 \frac{1}{1 + \epsilon_p \cos \eta_p} \left( \frac{v^2_\infty}{v^2_p}, \frac{v^2_\infty}{v^2_p}, \frac{v^2_\infty}{v^2_p} \right), \tag{A5}
\]

with the transfer function

\[
Z(u, x, z) = \left[ \frac{3}{16} (2u - 1 + x)^2 + \frac{3y}{8} (2u + 1 + x) - \frac{y^3}{16} \right]_{y_-}, \tag{A6}
\]

where \( y_- \) and \( y_+ \) are the same as for the capture transfer function (27).

Equation (A5) for the averaged flux \( \langle F \rangle_\alpha \) differs from that for capture only by the transfer function. The transfer function \( Z \) for ejection has of course the same domain as the transfer function \( Y \) for capture but is everywhere larger (except at \( x, z = 0, 0 \) and on the edge of the domain), see also Figure A1.

Since here we are not interested in the asymptotic speed \( v_\infty \) of the ejected object, we set \( v_\infty = 0 \) in equation (A5) and also assume a circular planet orbit when the local cross-section for ejection becomes

\[
\sigma_\alpha(a) = 8\pi \frac{a^2 q^2}{3} \frac{C}{2 - \alpha_p/a} Z \left( 1, 0, \frac{a_p}{a} \right). \tag{A7}
\]

For most of the relevant range \( Z(1, 0, z) \approx 1 \), as shown in Figure A1, and we will in the following use this approximation.

A2 The retention time of captured ISOs

ISOs which have been captured by a slingshot with the planet will cross into radii \( r < a_p \) once per orbit and have the chance to suffer a slingshot with the planet. The probability to be ejected is therefore \( \sim \sigma_\alpha/a^2 \) per orbit. The typical time an ISO remains captive is then its orbital period divided by this probability

\[
T_{stay}(a) \approx \frac{3}{4q^2} \frac{a_p}{a} \frac{1 - \frac{a_p}{a}}{T_p}, \tag{A8}
\]

where \( T_p = 2\pi/\Omega_p \) is the orbital period of the planet.
Finally, we set $T = \sqrt{nE/m_p^2}$ with some reference energy $E$. A suitable value for $E$ is the Jacobi integral of a parabolic orbit with specific angular momentum comparable to that of the binary, i.e. $E = \Omega^2 a_p^2 = G(m_s + m_p)/a_p$, when

$$T^{-2} = \frac{1}{\eta m_s + m_p}\left[\frac{a_p}{r_{ep}^2 e_s^2} + \frac{a_p}{r_{sp}^2 e_s^2} + \frac{a_p}{r_{es}^2 e_s^2}\right].$$

### APPENDIX C: UNBOUND KEPLER ORBITS

Here, we summarise for our and the readers convenience some well-known relations for non-elliptic Kepler orbits (e.g. Battin 1987). Consider a test particle orbiting a mass $M$ at the origin. Let $\mu \equiv GM$ and $v \equiv r$, then $h = r \times v$ and $e = v \times (r \times v)/\mu - f$ is its angular momentum and eccentricity vector, respectively. These are orthogonal and conserved for all Kepler orbits, as is their cross product $\hat{k} \equiv h \times \hat{e}$. Semi-major axis and eccentricity are, respectively,

$$a = \frac{\mu}{2E} = \left[\frac{2}{r} - \frac{\mu}{r}\right]^{-1},$$

$$e = |e| = \sqrt{1 - h^2/\mu a},$$

where $E = \frac{1}{2}v^2 - \mu/r$ is the (specific) orbital energy.

#### C1 Hyperbolic orbits

For hyperbolic orbits $E > 0$ such that $a < 0$ and $e \geq 1$ with equality only for $h = 0$. The radius, position and velocity are

$$r = -\langle e \cosh \eta - 1 \rangle,$$

$$r = -\langle e - \cosh \eta \rangle \hat{e} - \hat{e} \hat{v} e^2 - 1 \sinh \eta \hat{k},$$

$$v = \frac{\sqrt{\mu r}}{e} \left(-\sinh \eta \hat{e} + e \hat{e} \hat{v} - 1 \cosh \eta \hat{k}\right),$$

$$\ell = \sinh \eta - e,$$

where $\ell = \Omega t$ and $\eta$ are the mean and eccentric anomaly, respectively, while $\Omega^2 = -\mu/a^3$. At $t \rightarrow \infty$, the orbit asymptotes the straight lines $r = b \pm tw$ with directions

$$\hat{w} = -\hat{e} / e, \quad \hat{b} = \left(\hat{e} - 1 \hat{e} \pm \hat{k}\right) / e$$

and amplitudes

$$w^2 = -\mu/a, \quad b = -\sqrt{e^2 - 1} a.$$  

From these relations, we may also express semi-major axis and eccentricity through the asymptotes as

$$a = -\mu/w^2, \quad e = \sqrt{1 + b^2 w^2}/\mu^2.$$  

The velocity change between the incoming and outgoing asymptotes is

$$\Delta v = -2(w/e)\hat{e},$$

which corresponds to a deflection by angle

$$\cos^{-1}(\hat{w} \cdot \hat{w}) = \cos^{-1}(1 - 2/e^2).$$

Hence, $e = \sqrt{2}$, corresponding to $b = -a$, gives a deflection by $90^\circ$. At closest approach $\eta = 0$ and

$$r_0 = -(e - 1)a \hat{e}, \quad v_0 = \frac{e + 1}{e - 1} w \hat{k}. $$

---

5. This is also the reason why a fourth-order version of the integrator, which simply integrates the error term $\dot{H}_{c,2}$ (Dehnen & Hernandez 2017), fails to obtain substantially better accuracy, as measured by the conservation of Jacobi’s integral for circular planet orbits.
C2 Parabolic orbits

For parabolic orbits $E = 0$ such that $a = \infty$ and $e = 1$, regardless of angular momentum $h$. Radius, position, and velocity are

\[
 r = \frac{h^2}{\mu} \frac{1}{1 + \cos \varphi}, \quad (C13)
\]
\[
 r = \frac{h^2}{\mu} \cos \varphi \hat{\varepsilon} + \sin \varphi \hat{k}, \quad (C14)
\]
\[
 v = \frac{h}{\mu} \left[ -\sin \varphi \hat{\varepsilon} + (1 + \cos \varphi) \hat{k} \right], \quad (C15)
\]

with $\varphi = 0$ (true anomaly) at periapse. From $r^2 \dot{\varphi} = h$,

\[
 \frac{dr}{d\varphi} = \frac{h^3}{\mu^2} \frac{d\varphi}{(1 + \cos \varphi)^2}, \quad (C16)
\]

which can be integrated to obtain Barker’s equation

\[
 \tan \frac{1}{2} \varphi + 3 \tan \frac{1}{2} \varphi = 2B \quad \text{with} \quad B \equiv 3 \frac{\mu^2}{h^3} (t - t_0) \quad (C17)
\]

and $t_0$ is the time of periapse. Unlike Kepler’s equation (C6) for hyperbolic orbits, Barker’s equation being cubic has a closed solution:

\[
 \tan \frac{1}{2} \varphi = \left( B + \sqrt{1 + B^2} \right)^{1/3} - \left( B + \sqrt{1 + B^2} \right)^{-1/3}. \quad (C18)
\]
