ABSTRACT
We develop a formalism for the identification and accurate estimation of the strength of structure formation shocks during cosmological smoothed particle hydrodynamics simulations. Shocks not only play a decisive role for the thermalization of gas in virialising structures but also for the acceleration of relativistic cosmic rays (CRs) through diffusive shock acceleration. Our formalism is applicable both to ordinary non-relativistic thermal gas, and to plasmas composed of CRs and thermal gas. To this end, we derive an analytical solution to the one-dimensional Riemann shock tube problem for a composite plasma of CRs and thermal gas. We apply our methods to study the properties of structure formation shocks in high-resolution hydrodynamic simulations of the Lambda cold dark matter (ΛCDM) model. We find that most of the energy is dissipated in weak internal shocks with Mach numbers $M \sim 2$ which are predominantly central flow shocks or merger shock waves traversing halo centres. Collapsed cosmological structures are surrounded by external shocks with much higher Mach numbers up to $M \sim 1000$, but they play only a minor role in the energy balance of thermalization. This is because of the higher pre-shock gas densities within non-linear structures, and the significant increase of the mean shock speed as the characteristic halo mass grows with cosmic time. We show that after the epoch of cosmic reionisation the Mach number distribution is significantly modified by an efficient suppression of strong external shock waves due to the associated increase of the sound speed of the diffuse gas. Invoking a model for CR acceleration in shock waves, we find that the average strength of shock waves responsible for CR energy injection is higher than that for shocks that dominate the thermalization of the gas. This implies that the dynamical importance of shock-injected CRs is comparatively large in the low-density, peripheral halo regions, but is less important for the weaker flow shocks occurring in central high-density regions of haloes. When combined with radiative dissipation and star formation, our formalism can also be used to study CR injection by supernova shocks, or to construct models for shock-induced star formation in the interstellar medium.

Key words: Shock waves – intergalactic medium – galaxies: clusters: general – cosmology: large-scale structure of universe – cosmic rays – methods: numerical

1 INTRODUCTION
1.1 Structure formation shock waves
Cosmological shock waves form abundantly in the course of structure formation, both due to infalling pristine cosmic plasma which accretes onto filaments, sheets and haloes, as well as due to supersonic flows associated with merging substructures (Quilis et al. 1998; Miniati et al. 2000; Ryu et al. 2003; Gabici & Blasi 2003; Pavlidou & Fields 2005). Additionally, shock waves occur due to non-gravitational physics in the interstellar and intracluster medium, e.g. as a result of supernova explosions. Structure formation shock waves propagate through the cosmic tenuous plasma, which is compressed at the transition layer of the shock while a part of the kinetic energy of the incoming plasma is dissipated into internal energy of the post-shock gas. Because of the large collisional mean free path, the energy transfer proceeds through collective electromagnetic viscosity which is provided by ubiquitous magnetic irregularities (Wentzel 1974; Kennel et al. 1985).

Cosmologically, shocks are important in several respects. (1) Shock waves dissipate gravitational energy associated with hierarchical clustering into thermal energy of the gas contained in dark matter haloes, thus supplying the intrahalo medium with entropy and thermal pressure support. Radiative cooling is then required to compress the gas further to densities that will allow star forma-
tion. (2) Shocks also occur around moderately overdense filaments, which leads to a heating of the intracluster medium. Sheets and filaments are predicted to host a warm-hot intergalactic medium with temperatures in the range $10^2 \, K < T < 10^5 \, K$ whose evolution is primarily driven by shock heating from gravitational perturbations breaking on mildly nonlinear, non-equilibrium structures (Hellsten et al. 1998; Cen & Ostriker 1999; Davé et al. 2001; Furlanetto & Loeb 2004; Kang et al. 2005). Thus, the shock-dissipated energy traces the large scale structure and contains information about its dynamical history. (3) Besides thermalization, collisionless shocks are also able to accelerate ions of the high-energy tail of the Maxwellian through diffusive shock acceleration (DSA) (for reviews see Drury 1983; Blandford & Eichler 1987; Malkov & O’C Drury 2001). These energetic ions are reflected at magnetic irregularities through magnetic resonances between the gyro-motion and waves in the magnetised plasma and are able to gain energy in moving back and forth through the shock front. This acceleration process typically yields a cosmic ray (CR) population with a power-law distribution of the particle momenta. Nonlinear studies of DSA have shown that a considerable part of the kinetic energy flux passing through shocks can be channelled into non-thermal populations, up to about one-half of the initial kinetic energy of the shock (Berezhko et al. 1995; Ellison et al. 1996; Malkov 1998, 1999; Kang et al. 2002). Note that CRs have sufficient momentum not to resonate with the electromagnetic turbulence in the shock front itself. They hence experience the shock as a discontinuity, i.e. the CR population is adiabatically compressed by the shock (e.g., Drury 1983).

Indeed, CR electrons have been observed in the intra-cluster medium (ICM) of galaxy clusters through their diffuse synchrotron emission (Kim et al. 1989; Giovannini et al. 1993; Deiss et al. 1997). In addition to these extended radio haloes which show a similar morphology compared to the thermal X-ray emission, there have been extended radio relics observed in the cluster periphery (e.g., Röttgering et al. 1997) which might well coincide with merger shock waves as proposed by Enßlin et al. (1998). Some clusters have also been reported to exhibit an excess of hard X-ray emission compared to the expected thermal bremsstrahlung of the hot ICM, most probably produced by inverse Compton up-scattering of cosmic microwave background photons by relativistic electrons (Fusco-Femiano et al. 1999; Sanders et al. 2005). It has been proposed that a fraction of the diffuse cosmological γ-ray background radiation originates from the same processes (Loeb & Waxman 2000; Miniati 2002; Reimer et al. 2003; Berrington & Dermer 2003; Kuo et al. 2005).

To date, there are two different scenarios explaining these non-thermal emission processes. (1) Reacceleration processes of ‘mildly’ relativistic electrons ($\gamma \approx 100 \ldots 300$) being injected over cosmological timescales into the ICM by sources like radio galaxies, supernova remnants, merger shocks, or galactic winds, which all can provide an efficient supply of highly-energetic CR electrons. Owing to their long lifetimes of a few times $10^9$ years these ‘mildly’ relativistic electrons can accumulate within the ICM (Sarazin 2002), until they experience continuous in-situ acceleration either via shock acceleration or resonant pitch angle scattering on turbulent Alfvén waves (Jaffe 1977; Schlickeiser et al. 1987; Brunetti et al. 2001; Ohno et al. 2002; Brunetti et al. 2004). (2) In the ICM, the CR protons have lifetimes of the order of the Hubble time (Völk et al. 1996), which is long enough to diffuse away from the production site and to maintain a space-filling distribution over the cluster volume. These CR protons can interact hadronically with the thermal ambient gas producing secondary electrons, neutrons, and γ-rays in inelastic collisions throughout the cluster volume, generating radio haloes through synchrotron emission (Dennison 1980; Vestrand 1982; Blasi & Colafrancesco 1999; Dolag & Enßlin 2000; Pfrommer & Enßlin 2003, 2004a,b). Cosmological simulations support the possibility of a hadronic origin of cluster radio haloes (Miniati et al. 2001).

### 1.2 Hydrodynamical simulations

Hydrodynamical solvers of cosmological codes are generally classified into two main categories: (1) Lagrangian methods like smoothed particle hydrodynamics (SPH) which discretise the mass of the fluid, and (2) Eulerian codes, which discretise the fluid volume. SPH methods were first proposed by Gingold & Monaghan (1977) and Lucy (1977) and approximate continuous fluid quantities by means of kernel interpolation over a set of tracer particles. Over the years, SPH techniques have been steadily improved and found widespread applications in cosmological problems (Evrard 1988; Hernquist & Katz 1989; Navarro & White 1993; Springel & Hernquist 2002).

In contrast, Eulerian methods discretise space and represent continuous fields on a mesh. Originally, Eulerian codes employed a mesh which is fixed in space (Cen & Ostriker 1993; Yepes et al. 1995) or adaptively moving (Pen 1998), while more recently, adaptive mesh refinement (AMR) algorithms have been developed for cosmological applications (Berger & Colella 1989; Bryan & Norman 1997; Norman & Bryan 1999; Abel et al. 2002; Kravtsov et al. 2002; Refregier & Teyssier 2002), which can adapt to regions of interest in a flexible way.

Grid-based techniques offer superior capabilities for capturing hydrodynamical shocks. In some algorithms, this can be done even without the aid of artificial viscosity, thanks to the use of Riemann solvers at the cell-level, so that a very low residual numerical viscosity is achieved. However, codes employing static meshes still lack the resolution and flexibility necessary to tackle structure formation problems in a hierarchically clustering universe, which is characterised by a very large dynamic range and a hierarchy of substructure at all stages of the evolution. For example, techniques based on a fixed mesh are seriously limited when one tries to study the formation of individual galaxies in a cosmological volume, simply because the internal galactic structure such as disk and bulge components can then in general not be sufficiently well resolved. A new generation of AMR codes which begin to be applied in cosmology may in principle resolve this problem. However, a number of grid-based problems remain even here, for example the dynamics is not Galilean-invariant, and there can be spurious advection and mixing errors, especially for large bulk velocities across the mesh.

These problems can be avoided in SPH, which thanks to its Lagrangian nature and its accurate treatment of self-gravity is particularly well suited for structure formation problems. SPH adaptively and automatically increases the resolution in dense regions such as galactic haloes or centres of galaxy clusters, which are the regions of primary interest in cosmology. One drawback of SPH is the dependence on the artificial viscosity which has to deliver the necessary entropy injection in shocks. While the parametrization of the artificial viscosity can be motivated in analogy with the Riemann problem (Monaghan 1997), the shocks themselves are broadened over the SPH smoothing scale and not resolved as discontinuities, but post-shock quantities are calculated very accurately. However, to date it has not been possible to identify and measure the shock strengths instantaneously with an SPH simulation.
Being interested in dynamical implications of CRs on structure formation and galaxy evolution, one faces not only the problem of the interplay of gravity and hydrodynamics of a plasma composed of CRs and thermal particles but in addition radiative processes such as cooling and supernova feedback. To date, AMR codes have not yet matured to the point that they can address all these requirements throughout a cosmological volume, although there are recent efforts along these lines (e.g. Kang & Jones 2005; Jones & Kang 2005). It would therefore be ideal if SPH codes for structure formation could acquire the ability to detect shocks reliably during simulations. Previous work on shock detection in SPH simulations (Keshet et al. 2003) was restricted to a posteriori analysis of two subsequent simulation time-slices, which can then be used to approximately detect a certain range of shocks as entropy jumps.

1.3 Motivation and structure

This article seeks to close this gap in order to allow studies of the following questions. (1) The cosmic evolution of shock strengths provides rich information about the thermal history of the baryonic component of the Universe: where and when is the gas heated to its present temperatures, and which shocks are mainly responsible for it? Does the missing baryonic component in the present-day universe reside in a warm-hot intergalactic medium? (2) CRs are accelerated at structure formation shocks through diffusive shock acceleration: what are the cosmological implications of such a CR component? (3) Shock waves are modified by nonlinear back-reaction of the accelerated CRs and their spatial diffusion into the pre-shock regime: does this change the cosmic thermal history or give rise to other effects? (4) Simulating realistic CR profiles within galaxy clusters can provide detailed predictions for the expected radio synchrotron and γ-ray emission. What are the observational signatures of this radiation that is predicted to be observed with the upcoming new generation of γ-ray instruments (imaging atmospheric Čerenkov telescopes and the GLAST satellite and radio telescopes (LOFAR and extended Very Large Array)?

The purpose of this paper is to study the properties of structure formation shock waves in cosmological simulations, allowing us to explore their role for the thermalization of the pristine plasma, as well as for the acceleration of relativistic CRs through DSA. In particular, we develop a framework for quantifying the importance of CRs during cosmological structure formation, including an accounting of the effects of adiabatic compressions and rarefactions of CR populations, as well as of numerous non-adiabatic processes. Besides CR injection by structure formation shocks, the latter include CR shock injection of supernova remnants, in-situ re-acceleration of CRs, spatial diffusion of CRs, CR energy losses due to Coulomb interactions, Bremsstrahlung, and hadronic interactions with the background gas, and the associated γ-ray and radio emission due to subsequent pion decay. A full description of these CR processes and their formulation for cosmological applications is described in Enßlin et al. (2006), while the numerical implementation within the SPH formalism is given by Jubelgas et al. (2006). In this work we provide a crucial input for this modelling: a formalism for identifying and accurately estimating the strength of structure formation shocks on-the-fly during cosmological SPH simulations.

The paper is structured as follows. The basic cosmic ray variables are introduced in Section 2. The formalism for identifying and measuring the Mach number of shock waves instantaneously within an SPH simulation is described in Section 3 for a purely thermal gas as well as for a composite plasma of CRs and thermal gas. The numerical implementation of the algorithm is discussed in Section 4. In Section 5, we compare shock tube simulations to analytic solutions of the Riemann problem which are presented in Appendices A and B. Finally, in Section 6, we perform cosmological non-radiative simulations to study CR energy injection at shocks, and the influence of reionisation on the Mach number distribution. A summary in Section 7 concludes the paper.

2 BASIC COSMIC RAY VARIABLES

Since we only consider CR protons, which are at least in our Galaxy the dominant CR species, it is convenient to introduce the dimensionless momentum $p = P_{\gamma}/(m_e c_{\text{q}0})$. CR electrons with $\gamma < 100$ experience efficient Coulomb losses such that their energy density is significantly diminished compared to the CR energy density (Sarazin 2002). The differential particle momentum spectrum per volume element is assumed to be a single power-law above the minimum momentum $q$:

$$f(p) = \frac{dN}{dp} = C p^{-\alpha} \theta(p-q).$$  \hfill (1)

$\theta(x)$ denotes the Heaviside step function. Note that we use an effective one-dimensional distribution function $f(p) = 4\pi p^2 f^{3D}(p)$. The CR population can hydrodynamically be described by an isotropic pressure component as long as the CRs are coupled to the thermal gas by small scale chaotic magnetic fields. The differential CR spectrum can vary spatially and temporally (although for brevity we suppress this in our notation) through the spatial dependence of the normalisation $C = C(r,t)$ and the cutoff $q = q(r,t)$.

Adiabatic compression or expansion leaves the phase-space density of the CR population unchanged, leading to a momentum shift according to $p \to p' = (\rho_0/\rho)^{3/2} p$ for a change in gas density from $\rho_0$ to $\rho$. Since this is fully reversible, it is useful to introduce the invariant cutoff and normalisation $q_0$ and $C_0$, which describe the CR population via equation (1) if the inter-stellar medium (ISM) or ICM is adiabatically compressed or expanded to the reference density $\rho_0$. The actual parameters are then given by

$$q(p) = \left(\frac{\rho}{\rho_0}\right)^{1/3} q_0 \quad \text{and} \quad C(p) = \left(\frac{\rho}{\rho_0}\right)^{(3+2)/3} C_0.$$  \hfill (2)

These adiabatically invariant variables are a suitable choice to be used in a Lagrangian description of the CR population.

The CR number density is

$$n_{\text{CR}} = \int_0^\infty dp f(p) = \frac{C q^\alpha}{\alpha-1}.$$  \hfill (3)

$^3$ α-particles carry a significant fraction of the total CR energy. Nevertheless, the assumption of considering only CR protons is a reasonable approximation, since the energy density of α-particles can be absorbed into the proton spectrum. A GeV energy α-particle can be approximated as an ensemble of four individual nucleons travelling together due to the relatively weak MeV nuclear binding energies compared to the kinetic energy of relativistic protons.
provided, that \( \alpha > 1 \). The kinetic energy density of the CR population is

\[
\varepsilon_{\text{CR}} = \int_0^\infty dp f(p) T(p) = \frac{C m_p c_{\text{light}}^2}{\alpha - 1} \times \left[ \frac{1}{2} B_a \left( \frac{\alpha - 2}{2}, \frac{3 - \alpha}{2} \right) + q^{\alpha - 1} \left( \sqrt{1 + q^2} - 1 \right) \right],
\]

(4)

where \( T(p) = (\sqrt{1 + p^2} - 1) m_p c_{\text{light}} \) is the kinetic energy of a proton with momentum \( p \), and \( B_a(a, b) \) denotes the incomplete Beta-function which is defined by \( B_a(a, b) \equiv \int_0^1 p^{a-1}(1 - p)^{b-1} \text{d} p \). The integral of equation (4) is well-defined if we assume \( \alpha > 2 \). The CR pressure is

\[
P_{\text{CR}} = \frac{m_p c_{\text{light}}^2}{3} \int_0^\infty dp f(p) \beta p \rho = \frac{C m_p c_{\text{light}}^2}{6} B_a \left( \frac{\alpha - 2}{2}, \frac{3 - \alpha}{2} \right),
\]

(5)

where \( \beta \equiv u/c_{\text{light}} = p/\sqrt{1 + p^2} \) is the dimensionless velocity of the CR particle. Note that for \( 2 < \alpha < 3 \) the kinetic energy density and pressure of the CR populations are well defined for the limit \( q \to 0 \), although the total CR number density diverges.

The adiabatic exponent of the CR population is defined by

\[
\gamma_{\text{CR}} \equiv \frac{d \log P_{\text{CR}}}{d \log \rho}|_{\text{i}},
\]

while the derivative has to be taken at constant entropy \( S \). Using equations (2) and (5), we obtain for the CR adiabatic exponent

\[
\gamma_{\text{CR}} = \frac{\rho}{P_{\text{CR}}} \left( \frac{\partial P_{\text{CR}}}{\partial C} \frac{\partial C}{\partial \rho} + \frac{\partial P_{\text{CR}}}{\partial q} \frac{\partial q}{\partial \rho} \right) = \frac{\alpha + 2}{3} - \frac{2}{3} q^{-\alpha} \beta(q) B_a \left( \frac{\alpha - 2}{2}, \frac{3 - \alpha}{2} \right)^{-1} \beta \left( \frac{\alpha - 2}{2}, \frac{3 - \alpha}{2} \right)^{-1}.
\]

(7)

Note that in contrast to the usual adiabatic exponent, the CR adiabatic exponent is time dependent due to its dependence on the lower cutoff of the CR population, \( q \). The ultra-relativistic limit \( (q \to \infty) \) of the adiabatic exponent, where \( \gamma_{\text{CR}} \to 4/3 \), can easily be obtained by taking the integral representation of the incomplete Beta-function and applying a Taylor expansion to the integrand. In the non-relativistic limit \( (q \ll 1 \text{ and } \alpha > 3) \), the adiabatic exponent approaches \( \gamma_{\text{CR}} \to 5/3 \). This can be seen by evaluating the CR pressure in this limit, \( P_{\text{CR}} = \frac{m_p c_{\text{light}}^2}{3} C q^{-\alpha} \) and applying the definition of \( \gamma_{\text{CR}} \) in equation (6). Considering a composite of thermal and CR gas, it is appropriate to define an effective adiabatic index by

\[
\gamma_{\text{eff}} = \frac{d \log (P_{\text{th}} + P_{\text{CR}})}{d \log \rho}|_{\text{i}} = \frac{\gamma_{\text{CR}} P_{\text{CR}}}{P_{\text{th}} + P_{\text{CR}}},
\]

(8)

3 MACH NUMBERS WITHIN THE SPH FORMALISM

The shock surface separates two regions: the upstream regime (pre-shock regime) defines the region in front of the shock whereas the downstream regime (post-shock regime) defines the wake of the shock wave. The shock front itself is the region in which the mean plasma velocity changes rapidly on small scales given by plasma physical processes. All calculations in this section are done in the rest frame of the shock which we assume to be non-relativistic. This assumption is justified in the case of cosmological structure formation shock waves for which typical shock velocities are of the order of \( 10^3 \text{ km s}^{-1} \).

Particles are impinging on the shock surface at a rate per unit shock surface, \( j \), while conserving their mass:

\[
\rho_1 v_1 = \rho_2 v_2 = j.
\]

(9)

Here \( v_1 \) and \( v_2 \) indicate the plasma velocities (relative to the shock’s rest frame) in the upstream and downstream regime of the shock, respectively. The mass densities in the respective shock regime are denoted by \( \rho_1 \) and \( \rho_2 \). Momentum conservation implies

\[
P_1 + \rho_1 v_1^2 = P_2 + \rho_2 v_2^2,
\]

(10)

where \( P_i \) denotes the pressure in the respective regime \( i \in \{1, 2\} \).

The energy conservation law at the shock surface reads

\[
(e_1 + P_1) \rho_1^{-1} + \frac{v_1^2}{2} = (e_2 + P_2) \rho_2^{-1} + \frac{v_2^2}{2}.
\]

(11)

\( e_i \) denotes the internal energy density in the regime \( i \in \{1, 2\} \). Combining solely these three equations without using any additional information about the equation of state, we arrive at the following system of two equations:

\[
\gamma^2 = \frac{P_2}{P_1} \frac{\rho_1^{\gamma - 1} \rho_2^{\gamma - 1}}{\rho_1^{\gamma - 1} \rho_2^{\gamma - 1}}
\]

(12)

\[
P_2 = \frac{2\gamma_2 + P_1 + P_2}{2\gamma_1 + P_1 + P_2}.
\]

(13)

Here we introduced the Mach number in the upstream regime, \( M_i = v_i/c_i \), which is the plasma velocity in units of the local sound speed \( c_i = \sqrt{\gamma P_1/\rho_1} \).

3.1 Polytopic gas

Non-radiative polytropic gas in the regime \( i \in \{1, 2\} \) is characterised by its particular equation of state,

\[
e_i = \frac{1}{\gamma - 1} P_i \text{ or equivalently } P_i = P_0 \left( \frac{\rho_i}{\rho_0} \right)^\gamma,
\]

(14)

where \( \gamma \) denotes the adiabatic index. This allows us to derive the well-known Rankine-Hugoniot conditions which relate quantities from the upstream to the downstream regime solely as a function of \( M_i \):

\[
\frac{P_2}{P_1} = \frac{(\gamma + 1) M_i^2}{(\gamma - 1) M_i^2 + 2},
\]

(15)

\[
P_2 = \frac{2\gamma M_i^2 - (\gamma - 1)}{\gamma + 1},
\]

(16)

\[
T_2 = \frac{[2\gamma M_i^2 - (\gamma - 1)] [(\gamma - 1) M_i^2 + 2]}{(\gamma + 1)^2 M_i^2}.
\]

(17)

In cosmological simulations using a Lagrangian description of hydrodynamics such as SPH, it is infeasible to identify the rest frame of each shock and thus \( M_i \) unambiguously, especially in the presence of multiple oblique structure formation shocks. As an approximative solution, we rather propose the following procedure, which takes advantage of the entropy-conserving formulation of SPH (Springel & Hernquist 2002). For one particle, the instantaneous injection rate of the entropy function due to shocks is computed, i.e. \( \text{d} A / \text{d} t \), where \( A \) denotes the entropic function \( A(x) \) defined by

\[
P = A(s)^\gamma,
\]

(18)

Note, that the symbol \( c \) (sometimes with subscript) denotes the sound velocity.
and $\varepsilon$ gives the specific entropy. Suppose further that the shock is broadened to a scale of order the SPH smoothing length $f_h$, where $f_h \sim 2$ denotes a factor which has to be calibrated against shock-tubes. We can roughly estimate the time it takes the particle to pass through the broadened shock front as $\Delta t = f_h/\nu$, where one may approximate $\nu$ with the pre-shock velocity $v_1$. Assuming that the present particle temperature is a good approximation for the pre-shock temperature, we can also replace $v_1$ with $M_1 c_s$.

Based on these assumptions and using $\Delta A_1 \approx \Delta A_1/dt$, one can estimate the jump of the entropic function the particle will receive while passing through the shock:

$$A_2/A_1 = 1 + f_h \frac{dA_1}{c_s A_1} \frac{dA_1}{dt}, \quad (19)$$

where

$$A_1 = \frac{P_2}{P_1} \frac{P_1^\gamma}{P_2^\gamma} = f_s(M_1), \quad (20)$$

using equations (15) and (16). Combining equations (19) and (20), we arrive at the final equation which is a function of Mach number only:

$$[f_s(M_1) - 1]M_1 = f_h \frac{dA_1}{c_s A_1} \frac{dA_1}{dt}. \quad (22)$$

The right-hand side can be estimated individually for each particle, and the left-hand side depends only on $M_1$. Determining the root of the equation hence allows one to estimate a Mach number for each particle.

### 3.2 Composite of cosmic rays and thermal gas

In the presence of a gas composed of cosmic rays and thermal components, equations (9) to (13) are still applicable if one identifies the energy density $\varepsilon_i$ and the pressure $P_i$ with the sum of the individual components in the regime $i \in \{1, 2\}$,

$$\varepsilon_i = \varepsilon_{CRi} + \varepsilon_{th}, \quad (23)$$

$$P_i = P_{CRi} + P_{th}. \quad (24)$$

The sound speed of such a composite gas is $c_s = \sqrt{\gamma \varepsilon_{CR} P_{th}/P_{CR}}$, where $\gamma_{eff}$ is given by equation (8). Note that in contrast to the single-component fluid, for the general case there is no equivalent to the equation of state (equation 14) in terms of the total energy density $\varepsilon_i$, because of the additivity of both pressure and energy density. For later convenience, we introduce the shock compression ratio $\Delta$ and the thermal pressure ratio $\gamma_{eff}$,

$$\frac{\Delta}{\rho_1} = \frac{P_2}{P_1} \quad \text{and} \quad \gamma_{eff} = \frac{\varepsilon_2}{\varepsilon_1} = \frac{\rho_2}{\rho_1}. \quad (25)$$

While taking the equation of state (equation 14) for the thermal gas component, we assume adiabatic compression of the CRs at the shock$^5$,

$$P_{CR} = P_{CR1} \frac{\varepsilon_{CR}}{\varepsilon_1} \quad \text{and} \quad e_{CR2} = \varepsilon_{CR1} \frac{\varepsilon_{CR}}{\varepsilon_1}. \quad (26)$$

Here we assume a constant CR spectral index over the shock which holds only approximately owing to the weak dependence of the CR lower momentum cutoff $\rho$ on the density (equation 2).

For the composite of thermal and CR gas, it is convenient to define the effective entropic function $A_{eff}$ and its time derivative,

$$\frac{dA_{eff}}{dt} = \frac{P_2 + P_{CR}}{P_{th}} \frac{P_{th}}{P_{CR}} A_{eff} \quad (20)$$

$$\frac{dA_{eff}}{dt} = \frac{dA_{th}}{dt} \frac{P_{th}}{P_{eff}} A_{eff}. \quad (28)$$

The expression for the time derivative of the effective adiabatic function uses the approximation of adiabatic compression of the CRs at the shock. Using the same assumptions like in the non-radiative case, we estimate the jump of the entropic function for the particle on passing through the shock made of composite gas:

$$A_{eff} = \frac{P_{CR2} + P_{th2}}{P_{CR1} + P_{th1}} \frac{P_{th2}}{P_{CR2}} - 1 = \frac{dA_{th}}{dt} \frac{P_{th}}{P_{eff}} A_{eff}. \quad (29)$$

Combining equations (12), (13), (26), and (29), we arrive at the following system of equations,

$$f_1(x_1, y_1) = x_1 P_{CR1}(x_1, y_1) - P_{th1}$$

$$\times \left\{ P_{CR1}(x_1, y_1) \varepsilon_{CR1} (x_1, y_1) - P_{th1} \varepsilon_{th1} \right\} ^\gamma_{eff} = 0, \quad (30)$$

$$f_2(x_1, y_1) = 2 \varepsilon_{CR1}(x_1, y_1) + P_{th1} + P_{CR1}(x_1, y_1) - x_1 \left[ \varepsilon_{CR1} + P_{th1} \right] = 0. \quad (31)$$

The effective adiabatic index in the post-shock regime is given by

$$\gamma_{eff} = \frac{\varepsilon_{CR} P_{CR2} + \varepsilon_{th} P_{th2}}{\varepsilon_{CR2} P_{th1}}. \quad (32)$$

Given all the quantities in the pre-shock regime, we can solve for the roots $x_1$ and $y_1$ of this system of two non-linear equations. This system of equations turns out to be nearly degenerate for plausible values of pre-shock quantities such that it might be convenient to apply the following coordinate transformation:

$$(x_1, y_1) \rightarrow (x_2, z_2) \quad \text{with} \quad z_2 = \frac{y_1 - x_1}{4}. \quad (33)$$

The Mach number $M_1$ and the jump of internal specific energies can then be obtained by

$$M_1 = \sqrt{\frac{P_{th1} (x_2, z_2)}{\rho_1 (x_2, z_2)}} \quad \text{and} \quad \gamma_{eff} = \frac{\rho_2 (x_2, z_2)}{\rho_1 (x_2, z_2)}. \quad (34)$$

$$\frac{u_2}{u_1} = \frac{y_1}{x_1} \quad \text{where} \quad u = \frac{P_{th1} (x_2, z_2)}{(\gamma_{eff} - 1) \rho_1 (x_2, z_2)}. \quad (35)$$

### 4 NUMERICAL IMPLEMENTATION

#### 4.1 Polytropic gas

Applying the algorithm of inferring the shock strength within the SPH formalism in a straightforward manner will lead to systematically underestimated values of the Mach number for SPH particles which are located within the SPH broadened shock surface: the proposed algorithm of Section 3 assumes that the present particle quantities such as entropy, sound velocity, and smoothing length are good representations of the hydrodynamical state in the pre-shock regime, which is not longer the case for particles within the SPH broadened shock surface. To overcome this problem, we...
define a decay time interval \( \Delta \text{dec} = \min[f_s h/(M_1 c), \Delta \text{max}] \), during which the Mach number is set to the maximum value that is estimated during the transition from the pre-shock regime to the shock surface. At this maximum, the corresponding particle quantities are good approximations of the hydrodynamical values in the pre-shock regime. We thus have a finite temporal resolution for detecting shocks, which is of order the transit time through the broadened shock front. Note that \( \Delta \text{max} \) is just introduced as a safeguard against too long decay times for very weak shocks. In the case of cosmological simulations, which are conveniently carried out in a computational domain that is convolving with the cosmological expansion, we redefine the decay time \( \Delta (\ln a)_{\text{dec}} = \min[H(a)f_s h/(M_1 c), \Delta (\ln a)_{\text{max}}] \) where \( a \) denotes the cosmic scale factor and \( H(a) = \dot{a}/a \) is the Hubble function. An appropriate choice for the safeguard parameter is \( \Delta (\ln a)_{\text{max}} = 0.0025 \).

Secondly, there is no universal value \( f_s \) which measures the SPH shock broadening accurately irrespective of the Mach number of the shock, especially in the regime of strong shocks. We therefore use the original algorithm (with \( f_s = 2 \)) only for estimated Mach numbers with \( M_{\text{esc}} < 3 \), while for stronger shocks, we apply an empirically determined formula (calibrated against shock-tubes) which corrects for the additional broadening of strong shocks and smoothly joins into the weak shock regime:

\[
M_{\text{est}} = \left( a_M M_{\text{esc}}^{3/2} + c_M \exp^{-M_{\text{esc}}/3} \right) M_{\text{est}},
\]

(36)

where \( a_M = 0.09 \), \( b_M = 1.34 \), and \( c_M = 1.66 \). These numbers may depend on the viscosity scheme of the SPH implementation.

4.2 Composite of cosmic rays and thermal gas

Our formalism of inferring the jump conditions for a composite of cosmic rays and thermal gas yields the density jump, \( \rho_x = \rho_2/\rho_1 \), and the thermal pressure jump at the shock, \( \rho_y = P_{\text{th}2}/P_{\text{th}1} \) (Section 3.2). As described in the previous section (Section 4.1), the values for the estimated jump conditions are systematically underestimated in the regime of strong shocks (\( M_{\text{esc}} \geq 5 \)) implying an additional broadening of the shock surface. Thus, we proceed the same way as above: using the value of the density jump \( \rho_x \), we derive the Mach number of the shock through equation (34) and recalibrate it for strong shocks. In addition, we use the decay time \( \Delta \text{dec} \) as before in the thermal case to obtain reliable Mach number estimates. The post-shock density is then obtained by multiplying the stored pre-shock density with the density jump \( \rho_x \).

In the case of a thermal pressure jump at the shock \( \rho_y \), we decided not to derive another empirical formula but rather exploit CR physics at non-relativistic shocks. Since the CR population is adiabatically compressed at the shock in the limit of strong shocks, the total pressure jump is nearly solely determined by the jump of the thermal pressure in the post-shock regime, i.e. we can safely neglect the contribution of CRs to the pressure jump. This assumption is justified as long as the CR pressure is not dominated by sub-relativistic CRs of low energy which is on the other hand a very short lived population owing to Coulomb interactions in the ICM. Thus, the thermal post-shock pressure for \( M_{\text{est}} \geq 5 \) is estimated as

\[
P_{\text{th}2} \approx \frac{2\gamma_0 M_2^2}{\gamma_0 + 1} \rho_1 P_1,
\]

(37)

where \( M_2 \) is obtained by equation (36), and \( P_1 \) denotes the stored total pre-shock pressure.

5 SHOCK TUBES

To assess the reliability of our formalism and the validity of our numerical implementation, we perform a sequence of shock-tube simulations with Mach numbers ranging from \( M = 1.4 \) up to \( M = 100 \). We use a three-dimensional problem setup which is more demanding and more realistic than carrying out the computation in one dimension. Here and in the following, we drop the subscript ‘1’ of the pre-shock Mach number for convenience. By comparing with known analytic solutions, we are able to demonstrate the validity of our implemented formalism.

There exists an analytic solution of the Riemann shock-tube problem in the case of a fluid described by a polytropic equation of state, \( e = P/(\gamma - 1) \) (cf. Appendix A). Unfortunately, a composite of thermal gas and CRs does not obey this relation. Thus, we derive an analytic solution to the Riemann shock-tube problem for the composite of CRs and thermal gas in Appendix B. This analytic solution assumes the CR adiabatic index (equation 6) to be constant over the shock-tube and neglects CR diffusion such that the problem remains analytically treatable.

5.1 Polytropic thermal gas

We consider eight standard shock-tube tests (Sod 1978) which provide a validation of both the code’s solution to hydrodynamic problems and our Mach number formalism. We consider first an ideal gas with \( \gamma = 5/3 \), initially at rest. The left-half space (\( x < 250 \)) is filled with gas at unit density, \( \rho_2 = 1 \), and \( P_2 = (\gamma - 1)\rho_2^\gamma \), while \( x > 250 \) is filled with low density gas \( \rho_1 = 0.2 \) at low pressure. The exact value of the low pressure gas has been chosen such that the resulting solutions yield the Mach numbers \( M = (1, 2, 3, 6, 10, 30, 60, 100) \) (cf. Appendix A). We set up the initial conditions in 3D using an irregular glass-like distribution of a total of \( 3 \times 10^6 \) particles of equal mass in hydrostatic equilibrium. They are contained in a periodic box which is longer in \( x \)-direction than in the other two dimensions, \( y \) and \( z \).

In the left-hand panel of Fig. 1, we show the result for the case of the Mach number \( M = 10 \) obtained with the GADGET-2 code (Springel 2005; Springel et al. 2001) at time \( t = 0.5 \). Shown are the volume averaged hydrodynamical quantities \( \langle \rho(x) \rangle \), \( \langle P(x) \rangle \), \( \langle u_{\perp}(x) \rangle \), and \( \langle M(x) \rangle \) within bins with a spacing equal to the inter-particle separation of the denser medium and represented by solid black lines. One can clearly distinguish five regions of gas with different hydrodynamical states. These regions are separated by the head and the tail of the leftwards propagating rarefaction wave, and the rightwards propagating contact discontinuity and the shock wave. The overall agreement with the analytic solution is good, while the discontinuities are resolved within 2 – 3 SPH smoothing lengths. Despite the shock broadening, the post-shock quantities are calculated very accurately. Our formalism is clearly able to detect the shock and precisely measure its strength, i.e. the Mach number \( M \). The pressure quantity drawn is not the hydrodynamically acting pressure of the SPH dynamics but \( P = (\gamma - 1)\mu \rho_2 \), a product of two fields that are calculated each using SPH interpolation. Thus, the observed characteristic pressure blip at the contact discontinuity has no real analogue either in the averaged \( x \)-component of the velocity \( \langle u_{\parallel}(x) \rangle \) or in the averaged Mach number \( \langle M(x) \rangle \). The \( x \)-component of the velocity \( \langle u_{\parallel}(x) \rangle \) shows tiny post-shock oscillations which might be damped with higher values of the artificial viscosity in the expense of a broader shock surface. The leftwards propagating rarefaction wave seems to exhibit a slightly faster signal velocity compared to the sound velocity. This might be
**Figure 1.** Shock-tube test carried out in a periodic three-dimensional box which is longer in x-direction than in the other two dimensions where a shock with the Mach number $M = 10$ develops. The numerical result of the volume averaged hydrodynamical quantities $\langle \rho(x) \rangle$, $\langle P(x) \rangle$, $\langle v_x(x) \rangle$, and $\langle M(x) \rangle$ within bins with a spacing equal to the interparticle separation of the denser medium is shown in black and compared with the analytic result in colour. *Left-hand panels:* Shock-tubes are filled with pure thermal gas ($\gamma = 5/3$). *Right-hand panels:* Shock-tubes are filled with a composite of cosmic rays and thermal gas. Initially, the relative CR pressure is $X_{CR} = P_{CR}/P_{th} = 2$ in the left-half space ($x < 250$), while we assume pressure equilibrium between CRs and thermal gas for $x > 250$. The bottom panel of Fig. 2, we show the Mach number distributions weighted by the change of dissipated energy per time interval, $\langle d\dot{u}_{th}(d \log M) \rangle$ for our eight shock-tubes. The sharp peaks of these distributions around their expected values $\log M$ are apparent. This demonstrates the reliability of our formalism to precisely measure shock strengths instantaneously during SPH simulations. The bottom panel shows their integral, i.e. the change of dissipated energy per time interval, $\langle \dot{u}_{th} \rangle$. The rising dissipated energy with growing Mach number reflects the larger amount of available kinetic energy for dissipation.

We additionally calculate the shock-injected CR energy using our formalism of diffusive shock acceleration described in Enßlin et al. (2006). However, the injected CR energy $\langle \dot{u}_{CR,inj} \rangle$ was only monitored and not dynamically tracked. For comparison, we also show the theoretically expected injected CR energy $\langle \dot{u}_{CR,\text{theo}} \rangle = \zeta_{inj} \langle \dot{u}_{th} \rangle$, where $\zeta_{inj}$ is the energy efficiency due to diffusive shock acceleration (cf. Enßlin et al. 2006, for details). The good comparison of the simulated and theoretically expected shock-injected CR energy demonstrates that our formalism is reliably able to describe the on-the-fly acceleration of CRs during the simulation.
5.2 Composite of cosmic rays and thermal gas

Again, we consider eight shock-tube simulations containing a composite of cosmic rays and thermal gas, providing a useful validation of our CR implementation in solving basic hydrodynamic problems as well as our Mach number formalism in the presence of CRs. In these simulations, we neither inject shock-accelerated CRs nor consider CR diffusion: these processes would lead to CR modified shock structures and shall be the subject of a companion paper.

To characterise this composite fluid, we define the relative CR pressure $X_{\text{CR}} = P_{\text{CR}}/P_{\text{th}}$. Our composite gas is initially at rest, while the left-half space ($x < 250$) is filled with gas at unit density, $\rho_1 = 1$, $X_{\text{CR}2} = 2$, and $P_{\text{th}2} = (\gamma - 1)10^5$, while $x > 250$ is filled with low density gas $\rho_1 = 0.2$, $X_{\text{CR}1} = 1$, at low pressure. The exact value of the low pressure gas has again been chosen such that the resulting solutions yield the Mach numbers $M = \{1.4, 2.3, 6, 10, 30, 60, 100\}$ (cf. Appendix B). Otherwise, we use the same initial setup as in Section 5.1. This CR load represents a rather extreme case and can be taken as the limiting case for our Mach number formalism in the presence of CRs. Cosmologically, it may find application in galaxy mergers where the outer regions might be composed of an adiabatically expanded composite gas containing a high CR component.

In the right-hand panel of Fig. 2, we show the Mach number distributions weighted by the change of dissipated energy per time interval, $\langle d\delta M/d\log M \rangle$ for our eight shock-tubes. While our formalism is able to measure the shock strength with a Mach number accuracy better than 10%, the distributions are sharply peaked. This demonstrates the reliability of our formalism to measure shock strengths for the composite gas instantaneously during SPH simulations.

The bottom panel shows the change of dissipated energy per...
time interval, \( \langle \dot{u}_{\text{th}} \rangle \) together with the shock-injected CR energy \( \langle \dot{E}_{\text{sh}} \rangle \). Concerning the amount of injected CR energy, we neglected cooling processes such as Coulomb interactions with thermal particles: this would effectively result in a density dependent recalibration of the maximum CR energy efficiency \( E_{\text{max}} \) of the otherwise arbitrary absolute value of our fiducial density. In the case of high Mach numbers, there is a good agreement between the simulated and theoretically expected shock-injected CR energy while there are discrepancies at low Mach numbers: our formalism estimates volume averaged Mach numbers with an accuracy better than 10%; this uncertainty translates to estimates of the density jump \( \chi \) and the thermal pressure jump \( \gamma \) with a scatter among different SPH particles. In the regime of weak shocks, the CR energy efficiency due to diffusive shock acceleration \( \zeta_{\text{sh}} \) is extremely sensitive to these two quantities, leading to larger uncertainties for the shock-injected CR energy in the case of a high CR load. However, the overall trend for the shock-injected CR energy can still be matched in such an extreme physical environment.

6 NON-RADIATIVE COSMOLOGICAL SIMULATIONS

6.1 Simulation setup

As a first application of our formalism, we are here interested in studying the spatial distribution of cosmological structure formation shocks in combination with Mach number statistics. We focus on the “concordance” (i.e.) cosmological cold dark matter model with a cosmological constant (ΛCDM). The cosmological parameters of our model are: \( \Omega_m = \Omega_{\text{dm}} + \Omega_\Lambda = 0.3 \), \( \Omega_\Lambda = 0.7 \), \( h = 0.7 \), \( n = 1 \), and \( \sigma_8 = 0.9 \). Here, \( \Omega_m \) denotes the total matter density in units of the critical density for geometrical closure, \( \rho_{\text{crit}} = 3H_0^2/(8\pi G) \), \( \Omega_\Lambda \) and \( \Omega_\Lambda \) denote the densities of baryons and the cosmological constant at the present day. The Hubble constant at the present day is parametrized as \( H_0 = 100h \text{ km s}^{-1}\text{Mpc}^{-1} \), while \( n \) denotes the spectral index of the primordial power-spectrum, and \( \sigma_8 \) is the rms linear mass fluctuation within a sphere of radius \( 8h^{-1}\text{Mpc} \) extrapolated to \( z = 0 \). This model yields a reasonable fit to current cosmological constraints and provides a good framework for investigating cosmological shocks.

Our simulations were carried out with an updated and extended version of the distributed-memory parallel TreeSPH code GADGET-2 (Springel 2005; Springel et al. 2001) including now self-consistent cosmic ray physics (Enßlin et al. 2006; Jubelgas et al. 2006). Our reference simulation employed \( 2 \times 256^3 \) particles which were simulated within a periodic box of comoving size \( 100h^{-1}\text{Mpc} \), so the dark matter particles had masses of \( 4.3 \times 10^7 h^{-1} \text{M}_\odot \) and the SPH particles \( 6.6 \times 10^6 h^{-1} \text{M}_\odot \). The SPH densities were computed from 32 neighbours which leads to our minimum gas temperature of \( 57 \text{ K} \). This reflects the fact that the baryons are thermally coupled to the CMB photons via Compton interactions with the residual free electrons after the universe became transparent until it eventually decoupled at \( 1 + z_{\text{dec}} = 100(\Omega_\Lambda h^2/0.0125)^{1/2} \). In all our simulations, we stored the full particle data at 100 output times, equally spaced in \( \ln(1+z) \) between \( z = 40 \) and \( z = 0 \).

In order to investigate the effects of reionisation on the Mach number statistics, we additionally perform two similar simulations which contain a simple reionisation model where we impose a minimum gas temperature of \( T = 10^5 \text{ K} \) at a redshift of \( z = 10 \) to all SPH particles. We decided to adopt this simplified model to study its effect on the Mach number statistics rather than a more complicated reionisation history. A more realistic scenario might be to add energy only to gas within haloes above a certain density in combination with energy input from QSO activity, and to describe the merging of the reionisation fronts and their evolution into the lower density regions (e.g., Ciardi et al. 2003).

The simulation reported here follow only non-radiative gas physics. We neglected several physical processes, such as radiative cooling, galaxy/star formation, and feedback from galaxies and stars including cosmic ray pressure. Our primary focus are shocks that are mostly outside the cluster core regions. Thus, the conclusions drawn in this work should not be significantly weakened by the exclusion of these additional radiative processes.

In contrast to the idealised shock-tube experiment where all particles that are shocked experience the same shock strength, in cosmological simulations there might be a effect Mach numbers for a given region of space because of curvature effects, multiple shocks, etc. Thus the Mach number estimation in shock tubes involves averaging over many particles all of which are experiencing a shock of a given Mach number, whereas in the cosmological simulations the averaging has to be done over Mach number also. This might introduce a scatter to the Mach number estimation of a single particle in cosmological simulations which is difficult to quantify. We are confident that this effect has only a minor impact on our results because they agree well with results of similar studies that used Eulerian structure formation simulations (Ryu et al. 2003).

6.2 Visualisation of the Mach number

In the SPH formalism, continuous fields \( A(x) \) such as the hydrodynamical quantities are represented by the values \( A_i \) at discrete particle positions \( r_i = (x_i, y_i, z_i) \) with a local spatial resolution given by the SPH smoothing length \( h \). To visualise a scalar quantity in two dimensions we employ the mass conserving \( \text{scatter} \) approach for the projection, where the particle’s smoothing kernel is distributed onto cells of a Cartesian grid which is characterised by its physical mesh size \( g \). The line-of-sight integration of any quantity \( A(x) \) at the pixel at position \( r = (x, y, z) \) is determined as the average of integration of all lines of sight passing through the pixel,

\[
\langle a(x_1) \rangle_{\text{los}} = g^{-2} \sum_i h_i^{-3} \int_{-g/2}^{+g/2} dx_i \int_{-g/2}^{+g/2} dy_i \int_{-h_i}^{h_i} dz_i \mathcal{K} \left( \frac{r - h_i}{h_i} \right) A_i,
\]

with \( r = \sqrt{(x_i - x)^2 + (y_i - y)^2 + z_i^2} \), and where the summation is extended over all particles in the desired slice of projection. The function \( \mathcal{K} \) is the dimensionless spherically symmetric cubic spline kernel suggested by Monaghan & Lattanzio (1985).
The left-hand side of Fig. 3 shows the time evolution of the density contrast \( \delta \) averaged over the line-of-sight with a comoving projection length \( L_{\text{proj}} = 10 \, h^{-1} \) Mpc:

\[
\langle 1 + \delta_{\text{gas}}(x) \rangle_{\text{los}} = \frac{\langle \Sigma(x) \rangle_{\text{los}}}{L_{\text{proj}}^{\text{crit}} \Omega_b},
\]

where \( \Sigma \) denotes the surface mass density. The fine-spun cosmic web at high redshift evolves into a much more pronounced, knotty

![Figure 3. Visualisation of a non-radiative cosmological simulation at redshift \( z = 2 \) (top panels) and \( z = 0 \) (bottom panels). Shown are the overdensity of the gas (left-hand side) and the density weighed gas temperature (right-hand side). These pictures have a comoving side length of \( 100 \, h^{-1} \) Mpc while the projection length along the line-of-sight amounts to \( 10 \, h^{-1} \) Mpc.](image-url)
Figure 4. Mach number visualisation of a non-radiative cosmological simulation at redshift $z = 2$ (top panels) and $z = 0$ (bottom panels). The colour hue of the maps on the left-hand side encodes the spatial Mach number distribution weighted by the rate of energy dissipation at the shocks, normalised to the simulation volume. The maps on the right-hand side show instead the Mach number distribution weighted by the rate of CR energy injection above $q = 0.8$, the threshold of hadronic interactions. The brightness of each pixel is determined by the respective weights, i.e., by the energy production density. These pictures have a comoving length of $100\, h^{-1}\, \text{Mpc}$ on a side. Most of the energy is dissipated in weak shocks which are situated in the internal regions of groups or clusters, while collapsed cosmological structures are surrounded by strong external shocks (shown in blue).
and filamentary structure at late times, as a result of the hierarchical structure formation process driven by gravity.

The right-hand side of Fig. 3 shows the time evolution of the density weighted temperature averaged over the line-of-sight. Again, the growth of galaxy clusters visible as large bright regions with temperatures around $10^7\,K$ is clearly visible. Through dissipation, the shock waves convert part of the gravitational energy associated with cosmological structure formation into internal energy of the gas, apart from the additional contribution due to adiabatic compression caused by the material that falls in at later times and itself is compressed at these shock waves. The large black regions show voids which cool down during cosmic evolution due to two effects: while the universe expands, non-relativistic gas is adiabatically expanded and cools according to $T \propto V^{1/2} \propto a^{-2}$ for $\gamma = 5/3$ when shock heating is still absent. Secondly, matter is flowing towards filaments during structure formation, hence the voids get depleted, providing an additional adiabatic expansion of the remaining material.

Fig. 4 shows a visualisation of the responsible structure formation shocks and their corresponding strengths. The colour scaling represents the spatial Mach number distribution weighted by the rate of energy dissipation at the shocks, and normalised to the simulation volume (left-hand side). The Mach number distribution weighted by the rate of CR energy injection is shown in the right-hand side, again normalised to the simulation volume. The brightness of these pixels scales with the respective weights, i.e. by the rates of energy dissipation or injection, respectively. The spatial Mach number distribution impressively reflects the nonlinear structures and voids of the density and temperature maps of Fig. 3. It is apparent that most of the energy is dissipated in weak shocks which are situated in the internal regions of groups or clusters while collapsed cosmological structures are surrounded by external strong shocks (shown in blue). These external shocks are often referred to as ‘first shocks’, because here the compressed gas has been processed for the first time in its cosmic history through shock waves.

Following Ryu et al. (2003), we classify structure formation shocks into two broad populations which are labelled as internal and external shocks, depending on whether or not the associated pre-shock gas was previously shocked. Rather than using a thermodynamical criterion such as the temperature, we prefer a criterion such as the overdensity $\delta$ in order not to confuse the shock definition once we will follow radiatively cooling gas in galaxies (in practice, we use the criterion of a critical pre-shock overdensity $\delta > 10$ for the classification of an internal shock). External shocks surround filaments, sheets, and haloes while internal shocks are located within the regions bound by external shocks and are created by flow motions accompanying hierarchical structure formation. For more detailed studies, internal shocks can be further divided into three types of shock waves: (1) accretion shocks caused by infalling gas from sheets to filaments or haloes while the mean shock speed and pre-shock gas densities are significantly larger for internal shocks. (2) Merger shocks occurring from merging haloes, and (3) supersonic chaotic flow shocks inside nonlinear structures which are produced in the course of hierarchical clustering.

In contrast to the present time, the comoving surface area of external shock waves surpasses that of internal shocks at high redshift, due to the small fraction of mass bound in large haloes and the simultaneous existence of an all pervading fine-spun cosmic web with large surface area. Also, there the thermal gas has a low sound velocity $c = \sqrt{\gamma P/\rho} = \sqrt{\gamma (\gamma - 1)u}$ owing to the low temperature, so once the diffuse gas breaks on mildly nonlinear structures, strong shock waves develop that are characterised by high Mach numbers $M = u/c$. Nevertheless, the energy dissipation rate in internal shocks is always higher compared to external shocks because the mean shock speed and pre-shock gas densities are significantly larger for internal shocks.

We use the same colour and brightness scale for the Mach number distribution weighted by the injected CR energy rate normalised to the simulation volume (right-hand side of Fig. 4). We emphasize two important points which have fundamental implications for the CR population in galaxy clusters. (1) There is an absence of weak shocks (shown in yellow) when the Mach number distribution is weighted by the injected CR energy. This reflects the Mach number dependent energy injection efficiency: the CR injection is saturated for strong shocks which leads to similar spatial distribution of both weightings, by dissipated thermal as well as injected CR energy. In contrast, most of the dissipated energy is thermalized in weak shocks and only small parts are used for the acceleration of relativistic particles (compare Fig. 5). (2) The mechanism of energy dissipation at shocks is very density dependent, implying a tight correlation of weak internal shocks and the amount of dissipated energy. This can be seen by the strongly peaked brightness distribution of the dissipated energy rate towards the cluster centres. For the CR-weighted case, this correlation is counteracted by the CR energy injection efficiency leading to a smoother brightness distribution of the CR energy injection. This has the important implication that the ratio of CR injected energy to dissipated thermal energy is increasing as the density declines. Relative to the thermal non-relativistic energy density, the CR energy density is dynamically more important at the outer cluster regions and dynamically less important at the cluster centres.

### 6.3 Mach number statistics

#### 6.3.1 Influence of reionisation

To quantify previous considerations, we compute the differential Mach number distribution weighted by the dissipated energy nor-
nalised to the simulation volume $d^3 e_{\text{diss}}(a, M)/(d \log a \ d \log M)$ at different redshifts. The top left-hand panel of Fig. 6 shows this Mach number distribution for our reference simulation with reionisation (showing a resolution of $2 \times 256^3$), while the top right-hand panel shows this distribution for the simulation without reionisation. The lower left-hand panel shows both distributions integrated over the scale factor, $d e_{\text{diss}}(M)/(d \log M)$, in addition to the Mach number distribution weighted by the injected CR energy normalised to the simulation volume, $d e_{\text{CR}}(M)/(d \log M)$ (see Section 6.3.2). Internal shocks are shown with dotted lines and external shocks with dashed lines. The lower right-hand panel shows the evolution of the dissipated energy due to shock waves with scale factor, $d e_{\text{diss}}(a)/(d \log a)$, for the models with and without reionisation.

Several important points are apparent. (1) The median of the Mach number distribution weighted by the dissipated energy decreases as cosmic time evolves, i.e. the average shock becomes weaker at later times. (2) There is an increasing amount of energy dissipated at shock waves as the universe evolves because the mean shock speed is significantly growing when the characteristic mass becomes larger with time. This trend starts to level off at redshift $z \approx 1$ although the median Mach number in shocks continuous to decrease. (3) Reionisation influences the Mach number distribution predominantly at early times (however after reionation took place) and suppresses strong external shock waves efficiently. The reason is that reionisation of the thermal gas increases its sound speed $c = \sqrt{n m T/p}$ dramatically, so that weaker shocks are produced for the same shock velocities. (4) The time integrated Mach number distribution weighted by the dissipated energy peaks at Mach numbers $1 \leq M \leq 3$. The main contribution in terms of energy dissipation originates from internal shocks because of enhanced pre-shock densities and mean shock speeds. (5) External shocks dominate the Mach number distribution at early times while internal shocks take over at $z \approx 9$ (depending somewhat on the resolution of the simulation). Their amount of dissipated energy surpasses that in external shocks by over an order of magnitude at the present time. Internal shocks play a more important role than external shocks in dissipating energy associated with structure formation.

The total shock-dissipated energy in our simulation box amounts to $E_{\text{diss}} = 2.27 \times 10^{66}$ erg. This translates to a mean energy deposition per particle of $E_{\text{diss}}/\mu(\rho_{\text{diss}} \Delta V) = 0.63$ keV, where $\mu = 4m_p/(3 + 5\Sigma H)$ is the mean particle weight assuming full ionisation and $\Sigma H = 0.76$ is the primordial hydrogen mass fraction. Our results agree well with those of Ryu et al. (2003) in the case of internal shocks while our external shocks tend to be weaker. This can be attributed to our differing definition of internal/external shocks as we prefer a density criterion and use the critical pre-shock overdensity $\delta > 10$ for the classification of an internal shock.

6.3.2 Cosmic ray acceleration

In our non-radiative cosmological simulations we additionally calculate the expected shock-injected CR energy using our formalism of diffusive shock acceleration described in Enßlin et al. (2006). This formalism follows a model based on plasma physics for the leakage of thermal ions into the CR population. However, in the present analysis, the injected CR energy $d n_{\text{CR,inj}}/(d \log a)$ was only monitored and not dynamically tracked. In our model, the CR population is described by single power-law distribution which is uniquely determined by the dimensionless momentum cutoff $q$, the normalisation $C$, and the spectral index $\alpha$. Considering shock injected CRs only, the spectral index is determined by $\alpha = (x_1 + 2)/(x_2 - 1)$, where $x_1$ denotes the density jump at the shock.

Our simplified model for the diffusive shock acceleration fails in the limit of weak shocks and over-predicts the injection efficiency. Especially in this regime, Coulomb losses have to be taken into account which remove the low-energetic part of the injected CR spectrum efficiently on a short timescale giving rise to an effective CR energy efficiency. Thus, the instantaneous injected CR energy $d n_{\text{CR,inj}}/(d \log a)$ depends on the simulation timestep and the resolution. To provide a resolution independent statement about the injected CR energy, we decided to rethermalise the injected CR energy below the cutoff $q_{\text{threshold}} = 0.83$. This cutoff has the desired property, that it coincides with the kinematic threshold of the hadronic CR p-p interaction to produce pions which decay into secondary electrons (and neutrinos) and $\gamma$-rays:

$$\pi^+ \rightarrow \mu^+ + \nu_\mu / \bar{\nu}_\mu \rightarrow e^+ + \nu_e / \bar{\nu}_e + \nu_\mu / \bar{\nu}_\mu$$

$$\pi^0 \rightarrow 2\gamma.$$  

Only CR protons above this kinematic threshold are therefore visible through their decay products in both the $\gamma$-ray and radio bands via radiative processes, making them directly observationally detectable.

The lower left-hand panel of Fig. 6 shows the Mach number distribution weighted by the injected CR energy rate and normalised to the simulation volume, $d e_{\text{CR}}(M)/(d \log M)$ (solid green). The effect of the CR injection efficiency $\xi_{\text{inj}} = e_{\text{CR}}/e_{\text{diss}}$ can easily be seen: while the CR injection is saturated for strong shocks to $\xi_{\text{max}} = 0.5$, in weak shocks most of the dissipated energy is thermalized and only small parts are used for the acceleration of relativistic particles. Effectively, this shifts the maximum and the mean value of the Mach number distribution weighted by the shock-dissipated energy towards higher values in the case of the distribution weighted by the injected CR energy. This effect is even stronger when considering only CRs with a lower cutoff $q = 10, 30$ which are responsible for radio haloes observed at frequencies above $100$ MHz, assuming typical magnetic field strengths of $B = 10, 1 \mu G$, respectively. This follows from the mono-energetic approximation of the hadronic electron production and synchrotron formula,

$$\nu_e = \frac{3eB}{2\pi m_e c} \gamma_e^2,$$

where $\gamma_e \approx \frac{q}{m_0} \frac{10}{6 m_e}$ and $e$ denotes the elementary charge.

As the regime of strong shocks is dominated by external shocks where the CR injection is saturated, CRs are dynamically more important in dilute regions and dynamically less important at the cluster centres compared to the thermal non-relativistic gas. As weak shocks are mainly internal shocks we have to distinguish between their different appearance: strong internal shocks are probably accretion shocks produced by infalling gas from sheets or filaments towards clusters, or peripheral merger shocks which steepen as they propagate outwards in the shallow cluster potential, highlighting the importance of CR injection in the outer cluster regions relative to thermally dissipated gas at shocks. In contrast, CR injection is dynamically less important in the case of flow shocks at the cluster centres or merging shock waves traversing the cluster centre. From these considerations we again draw the important conclusion that the ratio of CR injected energy to dissipated thermal energy at shocks is an increasing function of decreasing density. Such a CR distribution is required within galaxy clusters to explain the diffuse radio synchrotron emission of galaxy clusters (so-
Figure 6. Influence of reionisation on the Mach number statistics of non-radiative cosmological simulations. The top left-hand panel shows the differential Mach number distribution $d^2 \varepsilon_{\text{diss}}(a, M) / (\log a \, d \log M)$ for our reference simulation with reionisation while the top right-hand panel shows this distribution for the simulation without reionisation. The lower left-hand panel shows both distributions integrated over the scale factor, $d \varepsilon_{\text{diss}}(M) / (d \log M)$ in addition to the Mach number distribution weighted by the injected CR energy rate normalised to the simulation volume, $d \varepsilon_{\text{CR}}(M) / (d \log M)$ (green). Internal shocks are shown with dotted lines and external shocks with dashed lines. The lower right-hand panel shows the evolution of the dissipated energy due to shock waves with scale factor, $d \varepsilon_{\text{diss}}(a) / (d \log a)$. The models with and without reionisation lie on top of each other.

6.3.3 Resolution study

To study numerical convergence we perform two additional simulations with a resolution of $2 \times 128^3$, respectively, for our models with and without reionisation. Fig. 7 shows this resolution study for non-radiative cosmological simulations with a reionisation epoch at $z = 10$. The lower right-hand panel of Fig. 7 shows the evolution of the density-weighted temperature with redshift, $(1 + \delta)\langle T \rangle_v (z)$. Shown are different resolutions in our models with and without reionisation. The two differently resolved simulations ($2 \times 256^3$ and $2 \times 128^3$) have converged well at redshifts $z \leq 4$. In our reference simulation, the adiabatic decay of the mean temperature is halted at slightly higher redshift: because of the better mass resolution of this

called radio haloes) within the hadronic model of secondary electrons. For that, we assume a stationary CR electron spectrum which balances hadronic injection of secondaries and synchrotron and inverse Compton cooling processes (Brunetti 2002; Pfrommer & Enßlin 2004a,b). However, to make more precise statements about the origin of cluster radio haloes, more work is needed which studies the effect of the CR dynamics including CR diffusion and other CR injection processes such as supernovae driven galactic winds.
simulation, nonlinear structures of smaller mass can be resolved earlier while converting part of their gravitational binding energy into internal energy through structure formation shock waves. In the simulation with reionisation, the temperature increases discontinuously at \(z = 10\), declines again with the adiabatic expansion, until shock heating takes over at \(z \sim 7\). After the plasma has been shock-heated, relaxation processes in the course of virialisation let the plasma expand adiabatically on average. Secondly, mildly non-linear structures characterised by a shallow gravitational potential are partly effected by the Hubble flow which forces them to adiabatically expand.

The top left-hand panel shows the differential Mach number distribution \(d^2E_{\text{diss}}(a, M) / (d \log a \, d \log M)\) for our reference simulation with a resolution of \(2 \times 256^3\) while the top right-hand panel shows this distribution for the simulation with a resolution of \(2 \times 128^3\). The lower left-hand panel shows both distributions integrated over the scale factor, \(dE_{\text{diss}}(M) / (d \log M)\). Internal shocks are shown with dotted lines and external shocks with dashed lines. The lower right-hand panel shows the evolution of the density-weighted temperature with redshift. Shown are different resolutions in our models with and without reionisation.
solved collapsing earlier in higher resolution simulations. Accordingly, the differential Mach number distribution is not well converged at redshifts \( z \gtrsim 6 \) while the distribution is well converged for \( z \lesssim 3 \). Since most of the energy is dissipated at late times, where our differential Mach number distribution is well converged, the integrated distribution \( d\Phi_{\text{diss}}(M)/d\log M \) shows only marginal differences among the differently resolved simulations. In particular, our statements about CR injection at structure formation shocks are robust with respect to resolution issues.

7 SUMMARY AND CONCLUSIONS

We provide a formalism for identifying and estimating the strength of structure formation shocks in cosmological SPH simulations on-the-fly, both for non-relativistic thermal gas as well as for a plasma composed of a mixture of cosmic rays (CRs) and thermal gas. In addition, we derive an analytical solution to the one-dimensional Riemann shock tube problem for the composite plasma of CRs and thermal gas (Appendix B). In the case of non-relativistic thermal gas, shock-tube simulations within a periodic three-dimensional box that is longer in \( x \)-direction than in the other two dimensions show that our formalism is able to unambiguously detect and accurately measure the Mach numbers of shocks, while in the case of plasma composed of cosmic rays (CRs) and thermal gas, the Mach numbers of shocks are estimated with an accuracy better than 10%. In both cases, we find a very good agreement of the averaged simulated hydrodynamical quantities (such as density, pressure, and velocity) and the analytical solutions. Using our formalism for diffusive shock acceleration, we additionally calculate and monitor the shock-injected CR energy, but without dynamically tracking this CR energy component; the latter will be studied in forthcoming work. The good agreement between the simulated and theoretically expected shock-injected CR energy demonstrates that our formalism is reliably able to accelerate CRs instantaneously during the simulation.

Subsequently, we identified and studied structure formation shock waves using cosmological N-body/hydrodynamical SPH simulations for a concordance ΛCDM universe in a periodic cubic box of comoving size \( 100 \, h^{-1} \text{Mpc} \). We performed simulations with and without a reionisation epoch at \( z = 10 \) in order to investigate the effects of reionisation on the Mach number distribution. Our sets of simulations follow only non-relativistic gas physics where we neglected additional physical processes, such as radiative cooling, star formation, and feedback from galaxies and stars including cosmic ray pressure. Since we are mainly interested in shock waves situated mostly outside the cluster core regions, the conclusions drawn in this article should not be significantly weakened by the exclusion of those radiative processes. Furthermore, these simplifications align our work with the mesh-based simulations of Ryu et al. (2003) and enable a direct comparison and verification of our results. We classify cosmological shock waves as internal and external shocks, depending on whether or not the associated pre-shock gas was previously shocked (cf. Ryu et al. 2003). Rather than using a thermodynamical criterion such as the temperature, we prefer a density criterion such as the over-density \( \delta \) in order not to confuse the shock definition once we will follow radiatively cooling gas in galaxies. External shocks surround filaments, sheets, and haloes where the pristine adiabatically cooling gas is shocked for the first time. Internal shocks on the other hand are located within the regions bound by external shocks and are created by flow motions accompanying hierarchical structure formation. Their population includes accretion shocks produced by infalling material along the filaments into clusters, merger shocks resulting from infalling haloes, and flow shocks inside nonlinear structures which are excited by supersonic motions of subclumps.

The Mach number distribution weighted by the dissipated energy shows in detail that most of the energy is dissipated in weak shocks which are situated in the internal regions of groups or clusters while collapsed cosmological structures are surrounded by external strong shocks which have a minor impact on the energy balance. The evolution of the Mach number distribution shows that the average shock strength becomes weaker at later times while there is an increasing amount of energy dissipated at shock waves as cosmic time evolves because the mean shock speed increases together with the characteristic mass of haloes forming during cosmic structure formation. For the same reason, internal shocks play a more important role than external shocks in dissipating energy associated with structure formation, especially at small redshift. The energy input through reionisation processes influences the Mach number distribution primarily during a period following the reionisation era and suppresses strong external shock waves efficiently because of the significant increase of the sound speed of the intergalactic medium.

Weighting the Mach number distribution by the injected CR energy shows the potential dynamical implications of CR populations in galaxy clusters and haloes: the maximum and the mean value of the Mach number distribution, weighted by the shock-dissipated energy, is effectively shifted towards higher values of the Mach number when the distribution is weighted by the injected CR energy. In other words, the average shock wave responsible for CR energy injection is stronger compared to the average shock which thermalizes the plasma. The fundamental reason for this lies in the theory of diffusive shock acceleration at collisionless shock waves and can be phenomenologically described by a CR injection efficiency: while the CR injection is saturated to an almost equipartition value between injected CR energy and dissipated thermal energy for strong shocks, in weak shocks most of the dissipated energy is thermalized and only small parts are used for the acceleration of relativistic particles. Relative to the thermal non-relativistic energy density, the shock-injected CR energy density is dynamically more important at the outer dilute cluster regions and less important at the cluster centres since weak shock waves predominantly occur in high-density regions. This has the crucial consequence that the ratio of CR injected energy to dissipated thermal energy is an increasing function as the density declines. Such a CR distribution within galaxy cluster is required to explain the diffuse radio synchrotron emission of galaxy clusters (so-called radio haloes) within the hadronic model of secondary electrons. In order to draw thorough conclusions about the origin of cluster radio haloes, more work is needed which studies the effect of the CR dynamics comprising of CR injection and cooling processes as well as CR diffusion mechanisms.

We note that our new formalism for shock-detection in SPH simulations should have a range of interesting applications in simulations of galaxy formation. For example, when combined with radiative dissipation and star formation, our method can be used to study CR injection by supernova shocks, or to construct models for shock-induced star formation in the interstellar medium (e.g. Barnes 2004). It should also be useful to improve the accuracy of predictions for the production of \( \gamma \)-rays by intergalactic shocks (e.g. Keshet et al. 2003).

APPENDIX A: RIEMANN SHOCK-TUBE PROBLEM

The Riemann shock-tube calculation of Sod (1978) has become a generally accepted test of numerical hydrodynamical codes. As a baseline for later extension, we present in the section the quasi-analytical solution for the Riemann problem in the standard case of a polytropic gas. Then, in Appendix B we derive the quasi-analytic solution in the case of a gas composed of CRs and thermal gas, where the effective adiabatic index depends on the different equations of state and changes across the shock-tube.

In the following, we summarise the key considerations which lead to the solution of the Riemann problem, for completeness (see e.g. Courant & Friedrichs 1948; Toro 1997; Rasio & Shapiro 1991, for a compact representation). For the initial state, we assume a state with higher pressure in the left-half space without loss of generality. At any time $\Gamma\rho$ gas. Then, in Appendix B we derive the quasi-analytic solution in the case of a gas composed of CRs and thermal gas, where the Courant & Friedrichs 1948; Toro 1997; Rasio & Shapiro 1991, for a compact representation). For the initial state, we assume a state with higher pressure in the left-half space without loss of generality.

For the initial state, we assume a state with higher pressure in the left-half space without loss of generality. At any time $\Gamma\rho$ gas. Then, in Appendix B we derive the quasi-analytic solution in the case of a gas composed of CRs and thermal gas, where the Courant & Friedrichs 1948; Toro 1997; Rasio & Shapiro 1991, for a compact representation). For the initial state, we assume a state with higher pressure in the left-half space without loss of generality.

Here $\nu_0$ denotes the speed of the discontinuity under consideration with respect to our coordinate system and we introduced the abbreviation $[F] = F_1 - F_\Gamma$ for the jump of some quantity $F$ across the discontinuity. Within the leftwards propagating rarefaction wave, the generalised Riemann invariants yield an isentropic change of state, $ds = 0$, and conserve the quantity $\Gamma^+$:

$$\Gamma^+ = \nu + \int_0^\nu \frac{c'(\rho')}{\rho'} d\rho' = \nu + \frac{2 c(\rho)}{\gamma - 1} = \text{const.}$$  \hspace{1cm} (A2)

For the last step, we assumed a polytropic equation of state $P = \rho^\gamma$. Appropriately combining these equations, the solution can be expressed as follows:

$$\rho(x, t) = \begin{cases} 
\rho_5, & x \leq -c_5t, \\
\rho_5 - \rho_5^2 \frac{x}{c_5t} + (1 - \mu^2)^{2/(y-1)}, & -c_5t < x \leq -v_5t, \\
\rho_3, & -v_5t < x \leq v_5t, \\
\rho_2, & v_5t < x \leq v_5t, \\
\rho_1, & x > v_5t, \end{cases}$$  \hspace{1cm} (A3)

$$P(x, t) = \begin{cases} 
P_5, & x \leq -c_5t, \\
P_5 - P_5^2 \frac{x}{c_5t} + (1 - \mu^2)^{2y/(y-1)}, & -c_5t < x \leq -v_5t, \\
P_2 - P_5, & -v_5t < x \leq v_5t, \\
P_1, & x > v_5t, \end{cases}$$  \hspace{1cm} (A4)

$$\nu(x, t) = \begin{cases} 
0, & x \leq -c_5t, \\
(1 - \mu^2) \left(\frac{x}{t} + c_5\right), & -c_5t < x \leq -v_5t, \\
v_2 \equiv v_5, & -v_5t < x \leq v_5t, \\
0, & x > v_5t, \end{cases}$$  \hspace{1cm} (A5)

Here $\mu^2 = (y - 1)/(y + 1)$, $c_1 = \sqrt{\gamma P_1/\rho_1}$, and $c_5 = \sqrt{\gamma P_5/\rho_5}$ are the speeds of sound, $v_5$ is the speed of propagation of the rarefaction wave’s tail, and $c_5$ is the shock speed. The post-shock pressure is obtained by solving (numerically) the non-linear equation, which is derived from the Rankine-Hugoniot conditions over the shock while ensuring the conservation of the two Riemann invariants of equation (A2):

$$\left(\frac{P_2}{P_1} - 1\right) \sqrt{\frac{1 - \mu^2}{\gamma (P_2/P_1 + \mu^2)}} - 2 c_5 \left[\frac{1 - (P_2/(P_1))^{(y-1)/(2y)}}{c_1}\right] = 0.$$  \hspace{1cm} (A6)

The density on the left-hand side of the contact discontinuity is $\rho_3 = \rho_5 (P_2/P_5)^{1/\gamma}$, since the gas is adiabatically connected to the left-hand side. The post-shock density $\rho_2$ is also derived from the Rankine-Hugoniot conditions,

$$\rho_2 = \rho_1 \left(\frac{P_2 + \mu^2 \rho_1}{P_1 + \mu^2 \rho_2}\right).$$  \hspace{1cm} (A7)

The post-shock gas velocity $v_2$ is obtained from the rarefaction wave equation, $s/t = \nu - c$, and usage of the Riemann invariant $\Gamma^+$:

$$v_2 = \frac{2 c_5}{(y - 1)} \left[1 - \left(P_2/(P_5)\right)^{(y-1)/(2y)}\right].$$  \hspace{1cm} (A8)

and from equation (A5) we derive the speed of propagation of the rarefaction wave’s tail $v_1 = c_5 - v_2/(1 - \mu^2)$. Finally, mass conservation across the shock yields

$$\nu = \frac{v_2}{1 - \rho_1/\rho_2}.$$  \hspace{1cm} (A9)
APPENDIX B: RIEMANN SHOCK-TUBE PROBLEM FOR A COMPOSITE OF COSMIC RAYS AND THERMAL GAS

B1 Derivation

In contrast to the previous case, the composite of CRs and thermal gas does not obey a polytropic equation of state. In this section, we present an analytical derivation of the Riemann shock-tube problem for the composite of polytropic gas and a component that is adiabatically compressed at the shock such as relativistic gas or a homogeneous magnetic field which is parallel to the shock front. For the analytical derivation, we adopt the following two approximations: (i) we assume the CR adiabatic index (equation 6) to be constant over the shock-tube, and (ii) we neglect CR diffusion. The first assumption is justified as long as the CR pressure is not dominated by trans-relativistic CRs of low energy while the second assumption is a strong simplification with respect to simulating realistic shocks including CRs (Kang & Jones 2005). However, including CR diffusion complicates the problem significantly such that it is not any more analytically tractable.

For the initial state, we again assume a state with higher pressure in the left-half space. At any time $t > 0$, five regions of gas with different hydrodynamical states coexist, and are numbered in ascending order from the right-hand side. We use the notation $P_i = P_{i\text{CR}} + P_{i\text{th}}$ and $\varepsilon_i = \varepsilon_{i\text{CR}} + \varepsilon_{i\text{th}}$, for the composite quantities in region $i$. The full solution of the initial value problem consists of determining 12 unknown quantities in regions $(2)$ and $(3)$: $\rho_2$, $\varepsilon_2$, $P_{\text{CR2}}$, $P_{\text{th2}}$, $\varepsilon_{\text{CR2}}$, $\varepsilon_{\text{th2}}$, and $\rho_3$, $\varepsilon_3$, $P_{\text{CR3}}$, $P_{\text{th3}}$, $\varepsilon_{\text{CR3}}$, $\varepsilon_{\text{th3}}$. The thermal gas obeys a polytropic equation of state, $\varepsilon = P_{\text{th}}/\rho^{\gamma_{\text{th}}}$ for $\gamma_{\text{th}} = 1 - 1/\gamma_{\text{th}} = 1$ for $i \in [2, 3]$ and the regions $(2)$ and $(3)$ are separated by a contact discontinuity, implying vanishing mass flux through it and thus, $\rho_2 = \rho_3$ and $P_2 = P_3$. This reduces the dimensionality of our problem to 8 unknowns. In our approximation, the CRs are adiabatically expanded over the rarefaction wave and adiabatically compressed at the shock while obeying a polytropic equation of state:

\[
P_{\text{CR3}} = \left(\frac{\rho_{\text{CR3}}}{\rho_{\text{CR1}}}\right)^{\gamma_{\text{CR1}}}, \quad \varepsilon_{\text{CR3}} = \varepsilon_{\text{CR1}} \left(\frac{\rho_{\text{CR3}}}{\rho_{\text{CR1}}}\right)^{\gamma_{\text{CR1}}}, \quad P_{\text{CR2}} = \left(\frac{\rho_{\text{CR2}}}{\rho_{\text{CR1}}}\right)^{\gamma_{\text{CR1}}}, \quad \varepsilon_{\text{CR2}} = \varepsilon_{\text{CR1}} \left(\frac{\rho_{\text{CR2}}}{\rho_{\text{CR1}}}\right)^{\gamma_{\text{CR1}}},
\]

which further reduces the dimensionality by 4 unknowns. Moreover, the thermal gas is also adiabatically expanded over the rarefaction wave yielding $P_{\text{th5}} = P_{\text{th2}}(\rho_{\text{CR2}}/\rho_{\text{CR3}})^{\gamma_{\text{CR3}}}$. Hence, we need 3 more linearly independent equations for the solution: 2 are obtained by considering the Rankine-Hugoniot conditions (equation A1) in a stationary system of reference with $\nu_0 = \nu_3$. The last equation is given by the Riemann invariant $\Gamma^+$, where the effective speed of sound is given by $c = \sqrt{\gamma_{\text{th}} P/\rho}$:

\[
\Gamma^+ = \nu + \int_0^\nu \frac{c(\rho')}{\rho'} d\rho' = \nu + I(\rho)\quad \text{with} \quad I(\rho) = \int_0^\rho \sqrt{A_{\text{CR}\rho^\gamma_{\text{CR}}}} - \sqrt{A_{\rho^\gamma_{\text{th}}}} d\rho.
\]

Here, we use the abbreviations $\tilde{A}_i = \gamma_i A_i$ where $i \in \{\text{th}, \text{CR}\}$ and $A_i = P_i/\rho_i^{\gamma_i}$ denotes the invariant adiabatic factor over the rarefaction wave. Introducing the difference of the adiabatic indices of the two populations, $\Delta \gamma = \gamma_{\text{th}} - \gamma_{\text{CR}}$, the solution to the integral $I(\rho)$ is given by

\[
I(\rho) = \sqrt{\frac{\Delta \gamma}{A_{\text{CR}}}} \left(\frac{\tilde{A}_{\text{CR}}}{\tilde{A}_{\rho^\gamma_{\text{th}}}}\right)^{\frac{1}{2}} B_{\rho,\gamma}(\frac{\rho^\gamma_{\text{CR}} - 1}{2\Delta \gamma}, \frac{1 - \gamma_{\text{th}}}{2\Delta \gamma}) \quad \text{with} \quad x(\rho) = \sqrt{\frac{\tilde{A}_{\rho^\gamma_{\text{th}}}}{A_{\text{CR}^\rho^\gamma_{\text{th}}} + \tilde{A}_{\rho^\gamma_{\text{th}}}}}
\]

Although the second argument of the incomplete Beta-function is always negative, $I(\rho)$ is well defined as long as we consider a non-zero CR pressure which is characterised by $\tilde{A}_{\text{CR}} > 0$, and $\gamma_{\text{CR}}$ sufficiently far from $\gamma_{\text{th}}$, i.e. $\Delta \gamma > 0$. For $\tilde{A}_{\text{CR}} = 0$, the integral can be solved in closed form, yielding $I(\rho) = 2x(\rho)/(\gamma_{\text{th}} - 1)$.

B2 Solution of the Riemann problem

The densities leftwards and rightwards of the contact discontinuity, $\rho_3$ and $\rho_2$, are obtained by solving (numerically) the following non-linear system of equations. It is derived from matching the possible post-shock states (pressure and density) with the possible post-rarefaction wave states while simultaneously ensuring the conservation laws over the rarefaction wave and the shock:

\[
f_1(x_i, x_j) = [P_2(x_i) - P_1] (x_j - 1) - P_1 x_i [I(\rho_3) - I(x_3 \rho_3)]^2 = 0,
\]

\[
f_2(x_i, x_j) = [P_2(x_i) + P_1] (x_j - 1) + 2[x_i x_j - \varepsilon_2(x_i, x_j)] = 0.
\]

Here we introduced the shock compression ratio $x_i \equiv \rho_2/\rho_1$ and the rarefaction ratio $x_i \equiv \rho_3/\rho_2$. Furthermore, the implicit dependences on $x_i$ and $x_j$ can explicitly be expressed as follows,

\[
P_2(x_i) = P_3(x_i) = P_{\text{CR3}} x_i^{\gamma_{\text{CR}}}, \quad P_{\text{CR2}}(x_i) = P_{\text{CR3}} x_i^{\gamma_{\text{CR}}},
\]

\[
\varepsilon_2(x_i, x_j) = \varepsilon_{\text{CR2}} x_i^{\gamma_{\text{CR}}} + \frac{1}{\gamma_{\text{th}} - 1} [P_2(x_i) - P_{\text{CR2}}(x_i)].
\]

The roots of the non-linear system of equations (equation B4) immediately yield the post-shock pressure of the fluid via equation (B5). The post-shock velocity $\nu_2 = \nu_3$ and the shock speed $\nu_s$ are then obtained from the Rankine-Hugoniot relations:

\[
\nu_2 = \sqrt{\frac{[P_2(x_i) - P_1] \rho_2^2 - \rho_1}{\rho_2^2 - \rho_1}},
\]

\[
\nu_s = \frac{\rho_2 \nu_2}{\rho_2 - \rho_1}.
\]

© 2005 RAS, MNRAS 000, 1–20
Using the previous results, we can construct the solution to the generalised Riemann problem for CRs and thermal gas as follows:

\[ \rho(x, t) = \begin{cases} 
\rho_5, & x \leq -c_5 t, \\
\rho(x, t), & -c_5 t < x \leq -v_t, \\
\rho_3, & -v_t < x \leq v_2 t, \\
\rho_2, & v_2 t < x \leq v_1 t, \\
\rho_1, & x > v_1 t. 
\end{cases} \]  

(B10)

\[ P(x, t) = \begin{cases} 
P_5, & x \leq -c_5 t, \\
A_{CR} \rho(x, t)^{\gamma_{CR}} + A_{th} \rho(x, t)^{\gamma_{th}}, & -c_5 t < x \leq -v_t, \\
P_3, & -v_t < x \leq v_2 t, \\
P_1, & x > v_1 t. 
\end{cases} \]  

(B11)

\[ \nu(x, t) = \begin{cases} 
0, & x \leq -c_5 t, \\
\frac{\nu_2 - \nu_3}{t} + \sqrt{A_{CR} \rho(x, t)^{\gamma_{CR}} - A_{th} \rho(x, t)^{\gamma_{th}}} - 1, & -c_5 t < x \leq -v_t, \\
\nu_2 - \nu_3, & -v_t < x \leq v_2 t, \\
0, & x > v_1 t. 
\end{cases} \]  

(B12)

Here \( c_5 = \sqrt{\gamma_{eff} P_5/\rho_5} \) is the effective speed of sound, \( v_t \) is the speed of propagation of the rarefaction wave’s tail, and \( v_s \) is the shock speed. Matching the rarefaction wave equation to the density of the post-contact discontinuity yields \( v_t \):

\[ v_t = I(\rho_3) - I(\rho_5) + \sqrt{A_{CR} P_3^{\gamma_{CR}} - A_{th} P_3^{\gamma_{th}}}. \]  

(B13)

The density within the rarefaction regime is obtained by solving (numerically) the non-linear equation for a given \((x, t)\), which is derived from the rarefaction wave equation,

\[ I[\rho(x, t)] - I(\rho_5) + \frac{x}{t} + \sqrt{A_{CR} \rho(x, t)^{\gamma_{CR}} - A_{th} \rho(x, t)^{\gamma_{th}}} = 0. \]
