ABSTRACT Scribble (Scrib), Discs-large (Dlg), and Lethal giant larvae (Lgl) are basolateral regulators of epithelial polarity and tumor suppressors whose molecular mechanisms of action remain unclear. We used proximity biotinylation to identify proteins localized near Dlg in the Drosophila wing imaginal disc epithelium. In addition to expected membrane- and cytoskeleton-associated protein classes, nuclear proteins were prevalent in the resulting mass spectrometry dataset, including all four members of the nucleosome remodeling factor (NURF) chromatin remodeling complex. Subcellular fractionation demonstrated a nuclear pool of Dlg and proximity ligation confirmed its position near the NURF complex. Genetic analysis showed that NURF activity is also required for the overgrowth of dlg tumors, and this growth suppression correlated with a reduction in Hippo pathway gene expression. Together, these data suggest a nuclear role for Dlg in regulating chromatin and transcription through a more direct mechanism than previously thought.

INTRODUCTION Discs-large (Dlg), Scribble (Scrib), and Lethal giant larvae (Lgl) are evolutionarily conserved polarity-regulating proteins found at the basolateral membranes of epithelial cells, where they restrict the localization of the aPKC and Par complexes to the apical region of the cell (Elsum et al., 2012; Rodriguez-Boulan and Macara, 2014; Campanale et al., 2017). They can also regulate the formation and maintenance of cell junctions, the division axis of epithelial cells, and the asymmetric division of stem cells (Woods et al., 1996; Tepass et al., 2001; Albertson and Doe, 2003; Bilder et al., 2003; Johnston et al., 2009; Bergstralh et al., 2013; Rodriguez-Boulan and Macara, 2014; Campanale et al., 2017; Nakajima et al., 2019). In Drosophila epithelia, loss of any one of these three proteins causes not only loss of polarity but also neoplastic transformation and tumors, and this overgrowth is mediated by a nuclear role for Dlg in regulating chromatin and transcription through a more direct mechanism than previously thought.

Despite the importance of Scrib, Dlg, and Lgl for development, homeostasis, and disease, we still have a limited understanding of these vertebrate proteins have been implicated in regulation of tumor growth, with changes detected in a variety of human cancers (Halaoui and McCaffrey, 2015). They are also involved in apicobasal polarity and formation of both adherens and occluding tight junctions in epithelial cells (Su et al., 2012; Choi et al., 2019) and have a similar role in endothelial cells (Elsum et al., 2012; Lizama and Zovein, 2013; Worzfeld and Schwaninger, 2016). Further, Dlg homologues regulate the migration of epithelial cells during development. Mutations in these genes can result in cleft palate (Caruana and Bernstein, 2001), hydrocephalus (Nechiporuk et al., 2007), and defects in renal and urogenital systems (Iizuka-Kogo et al., 2007; Nechiporuk et al., 2007; Elsum et al., 2012).

their molecular functions and the mechanisms by which they regulate cell biology and gene expression. Scrib and Dlg are multivalent “scaffolding” proteins containing a variety of protein–protein interaction domains and motifs. Scrib contains four PSD95-Dlg-1-ZO-1 (PDZ) domains and a leucine-rich repeat (LRR) domain, while Dlg contains three PDZ domains, one Src homology 3 (SH3) domain, and a catalytically dead guanylate kinase (GUK) domain (Tepass and Tanentzapf, 2001; Elsum et al., 2012; Su et al., 2012; Campanale et al., 2017). Understanding the function of these scaffolds will require defining the proteins with which they interact as well as how those interactions change and are regulated over space and time within cells. However, PDZ and other domains are thought to facilitate weak and transient interactions, often involving plasma membrane (PM)-embedded receptors, making it difficult to define the full complement of proteins with which they interact using traditional biochemical methods (Amacher et al., 2020). Numerous prior efforts have used coimmunoprecipitation with mass spectrometry (IP-MS) to identify binding partners for Dlg, Scrib, and Lgl (Audebert et al., 2004; Van Campenhout et al., 2011; Anastasia et al., 2012; Belotti et al., 2013; Michaelis et al., 2013; Nagasaka et al., 2013; Ivasson et al., 2014; Waaijers et al., 2016; Drew et al., 2017; Dash et al., 2018; Portela et al., 2018; Nakajima et al., 2019) (reviewed in Stephens et al., 2018). However, such experiments have yielded largely nonoverlapping lists of binding partners and relatively few mechanistic insights. The limited utility of some IP-MS approaches may additionally derive from the use of nonepithelial cell lines in which functionally important interactions may not exist.

We sought a different approach that could be carried out in intact epithelial cells and that would not rely on strong, stable interactions between proteins. We therefore turned to proximity-based biotin labeling using the enhanced ascorbate peroxidase 2 (APEX2) enzyme. APEX2 is an ascorbate-peroxidase derived from the pea plant that, in the presence of hydrogen peroxide, catalyzes the conversion of phenol into a phenoxyl radical. In cells supplied with biotin-phenol as a substrate, APEX2 catalyzes the conversion of phenol into a phenoxyl radical. In cells supplied with biotin-phenol as a substrate, APEX2 covalently labels proteins within a 20-nm radius of the enzyme (Figure 1A). By leveraging the strength and specificity of streptavidin-biotin binding, labeled proteins can then be efficiently and cleanly isolated and identified by MS (Martell et al., 2012; Rhee et al., 2013; Hung et al., 2014, 2016; Lam et al., 2014; Chen et al., 2015). Proximity-based biotinylation has been used in a variety of experimental systems to identify catalog of proteins associated with a particular organelle or localized to a particular subcellular region. Importantly, this method can also capture protein–protein interactions that cannot be isolated by more conventional methods (Rhee et al., 2013; Van Itallie et al., 2013; Hung et al., 2014; Chen et al., 2015; Gingras et al., 2019; Mannix et al., 2019; Trinkle-Mulcahy, 2019; Bagci et al., 2020; Tan et al., 2020).

As an entry point into understanding Scrib module function, we used an APEX2-tagged Drosophila Dlg to identify nearby proteins in an epithelium in vivo. In addition to previously proposed Dlg binding partners and other cortical proteins, there was a surprising enrichment of nuclear proteins, including the nucleosome remodeling factor (NURF) complex of chromatin regulators. We demonstrate that a nuclear pool of Dlg exists in proximity to NURF members and provide evidence that NURF facilitates the growth of Dlg tumors by activating neoplastic transcriptional programs. Our results further demonstrate the utility of proximity-based proteomics for the elucidation of the localization and function of individual proteins, particularly for multivalent scaffolding proteins.

RESULTS

An APEX2-Dlg transgene for proteomics

To identify proteins enriched near Dlg in the cells of an intact epithelial sheet, we used APEX2-based in vivo proximity labeling. We drove an N-terminally tagged UAS-3xMyc-APEX2-Dlg (APEX2-Dlg) construct using a broadly but moderately expressed GAL4 driver (D174-GAL4) in a dlg null background. In these animals, APEX2-Dlg was the only Dlg protein present. APEX2-Dlg restored the morphology of dlg mutant discs (Figure 1, B, E, and H), and adult flies were rescued to viability and fertility (Figure 1, C, D, F, G, I, and J), demonstrating that this transgenic protein is fully functional. Because proximity-based proteomics labels not only direct binding partners but also all proteins within a 20-nm radius of the enzyme (Martell et al., 2012) (Figure 1A), it is critical that APEX2-tagged constructs localize comparably to their wild-type counterparts. Comparison to endogenously tagged Dlg::EGFP revealed that APEX2-Dlg displayed similar localization along the basolateral membranes of wing disc epithelial cells (Figure 1, K and L). We tested the enzymatic function of APEX2-Dlg by treating both control and experimental discs with hydrogen peroxide and comparing the amount of biotinylation by Western blot. As expected, increased biotinylation was seen in lysate from discs expressing APEX2-Dlg as compared with control (Figure 1M), and we successfully isolated the biotinylated proteins using streptavidin beads from both control and experimental samples (Figure 1M and Supplemental Figure S1A). Finally, we assessed whether APEX2-Dlg would biotinylate proteins known to be in close proximity to endogenous Dlg. Indeed, Western blotting revealed that Scrib was present in the streptavidin-bead eluate from experimental but not control samples, verifying that APEX2-Dlg was functioning as designed (Figure 1N; Supplemental Figure S1B).

Proximity biotin labeling and MS analysis

We next collected samples from APEX2-Dlg epithelia for MS. Larvae were dissected to isolate the wing, haltere, and leg imaginal discs that are found together in the thorax. Samples were collected in batches, subjected to biotin labeling, and a small fraction of each postlabeling reaction lysate was reserved to verify consistent sample quality (Supplemental Figure S1, C and D). Batches were then pooled into three biological replicates for both the experimental and the control genotype, each containing the thoracic discs of 400 larvae. Samples were tandem mass tag (TMT) labeled and then pooled for LC-MS3 (see Methods for details).

The MS results yielded a list of 485 proteins with a p value below the statistical threshold and a log2 fold change of at least 2 between experimental and control samples (Supplemental Table S1). This list included many translation initiation and elongation factors as well as ribosomal proteins. It is possible that these proteins were labeled because APEX2-Dlg is translated from a UAS construct that is being continually produced. We therefore excluded them from further analysis, leaving a final dataset of 413 proteins (Supplemental Table S2).

We then performed cellular component Gene Ontology (GO) analysis on this dataset. Gratifyingly, enriched terms included “basolateral membrane” and “septate junction” (Figure 2, A and B). The proteins that led to these terms included both Scrib and Lgl, which are junctional components (Audebert et al., 2004; Oshima and Feigon, 2011; Izumi and Furuse, 2014; Lee et al., 2020). The dataset also included proteins previously identified as direct physical interactors of Drosophila Dlg (Kinesin heavy chain, Calmodulin Kinase II, 14-3-3 zeta and epsilon) (Koh et al., 1999;...
Siegrist and Doe, 2005; Nakajima et al., 2019). Other hits include the coassociated RNA binding proteins Caprin and Fmr1, the latter of which interacts with Lgl (Zarnescu et al., 2005; Baumgartner et al., 2013). Interestingly, “Proton-transporting V-type ATPase, V1 domain” is another enriched term in the GO analysis (Figure 2A and Supplemental Table S3), and a recent study identified an indirect physical interaction between the V-ATPase proton pump and the Lgl in cultured Drosophila cells (Portela et al., 2018). Altogether, these results support the hypothesis that proximity-based proteomics can capture a snapshot of Dlg biology in living epithelia (Figure 2A and Supplemental Table S3).

Nuclear localization of Dlg
The GO analysis also highlighted some unexpected results. Proteins annotated to the term “nucleus” were enriched in the dataset (Figure 2A and Supplemental Table S3), and a recent study identified an indirect physical interaction between the V-ATPase proton pump and the Lgl in cultured Drosophila cells (Portela et al., 2018). Altogether, these results support the hypothesis that proximity-based proteomics can capture a snapshot of Dlg biology in living epithelia (Figure 2A and Supplemental Table S3).

Nuclear localization of Dlg
The GO analysis also highlighted some unexpected results. Proteins annotated to the term “nucleus” were enriched in the dataset (Figure 2A and Supplemental Table S3), and a recent study identified an indirect physical interaction between the V-ATPase proton pump and the Lgl in cultured Drosophila cells (Portela et al., 2018). Altogether, these results support the hypothesis that proximity-based proteomics can capture a snapshot of Dlg biology in living epithelia (Figure 2A and Supplemental Table S3).

FIGURE 1: A fully functional APEX2-Dlg efficiently labels proteins with biotin. (A) In the presence of H₂O₂, APEX2 catalyzes the conversion of biotin-phenol into a phenoxyl radical that can then covalently label proteins with biotin within a 20 nm radius of the enzyme. (B–D) Control D174GAL4 3rd instar larval wing disc (B), larva (C), and adult (D) fly with normal size and morphology. Scale bar = 100 µM. (E–G) dlg, D174GAL4 wing discs (E) form neoplastic tumors. Larvae (F) are overgrown and no adult flies eclose (G) because animals die as giant larvae. Scale bar = 100 µM. (H–J) dlg mutant phenotypes were rescued by UAS-3xMyc-APEX2-Dlg (APEX2-Dlg). Wing discs (H) have normal size and morphology, larvae are normal in size (I), and adult viability (J) and fertility are restored. Scale bar = 100 µM. (K) Endogenously tagged Dlg::EGFP reflects Dlg localization along the epithelial basolateral membrane of wing disc cells. Localization is excluded from the apical domain labeled by α-aPKC staining. Scale bar = 10 µM. (L) APEX2-Dlg (α-myc) localization recapitulated normal Dlg localization along the basolateral domain of wing disc cells and is excluded from the apical domain. Scale bar = 10 µM. (M) APEX2-Dlg efficiently labeled cellular proteins with biotin as seen by increased Streptavidin-HRP signal in experimental disc lysate (L, lane 1) compared with lysate from control discs (L, lane 5). Some biotinylated protein remained unbound to beads (U, lanes 2 and 6), but most was serially eluted off streptavidin–conjugated beads (eluate [E] 1 and 2, lanes 3, 4, 7, and 8). Biotinylation catalyzed by APEX2 was particularly apparent in these eluates. (N) Both experimental (lane 1) and control (lane 5) lysates (L) contained Scrib, but only experimental lysate contained APEX2-Dlg (α-myc). While some Scrib and APEX2-Dlg remained unbound (and possibly unlabeled) (U, lanes 2 and 5), both were detected in the experimental but not control streptavidin-bead eluate (E1, E2, lanes 3 and 4 and 7 and 8) showing that both proteins were labeled with biotin only in the presence of the APEX2 tag.
we infer that the amount of nuclear Dlg is small compared with that found in the cytoplasm. Because Dlg, Scrib, and Lgl colocalize at the cortex and work together in many biological contexts, we asked if either Scrib or Lgl were also found in the nuclear fraction. Western blotting of fractions showed a nuclear population of Scrib (Figure 2C), but not Lgl (Figure 2D). In dlg null flies, this nuclear population of Scrib was lost (Figure 2E). However, in scrib null flies, Dlg was still found in both the nuclear and cytoplasmic fractions of scrib null samples, but in dlg null samples, Scrib is detected only in the cytoplasmic fraction (E). We note that in different experimental replicates, the relative cytoplasmic:nuclear ratio of Scrib protein is variable.

FIGURE 2: Existence of a nuclear pool of Dlg. (A) Hierarchical map of selected enriched cellular component GO terms from APEX2-Dlg proximity biotinylation. Size of circles indicates the number of genes associated with a given term. Color of the circle indicates the p value of enrichment for that term as indicated by the provided scale. Enriched terms include the proteasome; membrane-associated terms including regions of the cell, types of membrane associated proteins, and types of vesicles; cytoskeleton-related terms including actin and microtubule cytoskeletons; and nuclear terms. Map was pruned for viewability. Full list of enriched terms and their associated p values is found in Supplementary Table 3. (B) Selected enriched GO terms with their associated FDR-corrected p values, and examples of genes from the dataset associated with each term. “Basolateral PM” and “septate junction” were expected terms, while “nuclear pore,” “chromatin remodeling complex,” and “NURF complex” were unexpected. (C–E) Western blots of fractionated disc extracts, probed with Tubulin (α-tub) to mark the cytoplasmic fraction and Lamin (α-lam) to mark the nuclear fraction. Percentage of fraction loaded into each lane is given below; higher percent of less concentrated nuclear fractions were loaded to equalize total protein per lane. Native Scrib and Dlg are found in both cytoplasmic and nuclear fractions of disc cells (C), but endogenously GFP-tagged Lgl is detected only in cytoplasmic and not nuclear fraction (D). Dlg is still found in both the nuclear and cytoplasmic fractions of scrib null samples, but in dlg null samples, Scrib is detected only in the cytoplasmic fraction (E). We note that in different experimental replicates, the relative cytoplasmic:nuclear ratio of Scrib protein is variable.
the proteins at the cell cortex (Bilder et al., 2000; Albertson and Doe, 2003; Khoury and Bilder, 2020; Ventura et al., 2020).

Nuclear Dlg is in close proximity to the NURF complex

Having identified the existence of a small nuclear pool of Dlg, we considered what its function could be. In addition to “nucleus” and “nuclear pore,” proteins associated with the term “chromatin remodeling complex” were also enriched in the APEX2-Dlg proteomic dataset (Figure 2, A and B). While several chromatin remodeling complexes were overrepresented in the proteomics dataset, for only one were all members of the complex present: the NURF complex (Figure 2, A and B; Supplemental Table S3).

The NURF complex is a conserved molecular machine that catalyzes, through an ATP-dependent mechanism, the sliding of nucleosomes along DNA to regulate gene expression (Badenhorst et al., 2002; Bouazoune and Brehm, 2006; Alkhatib and Landry, 2011). E(bx) serves as a scaffold for the NURF complex (Figure 2, A and B). As a final control, we performed PLA on wing discs expressing the NURF complex member E(bx) endogenously tagged with GFP. We further expressed dlg RNAi in the posterior compartment of the E(bx)::GFP wing discs (Figure 3F) as an internal negative control for specificity. A positive PLA signal was detected in epithelial cells from the control side of wing discs (Figure 3B) that was significantly greater than single antibody background (Figure 3D) and also significantly greater than signal from the eps::GFP-only background signal (Figure 3E). 

The APEX2 proteomic data suggest that Dlg is found within 20 nm of the NURF complex. To verify this, we turned to a proximity ligation assay (PLA) which creates a punctate fluorescent signal when two target proteins are less than 40 nm apart (Söderberg et al., 2006). We performed PLA using α-Dlg and α-GFP antibodies on wing discs expressing the NURF complex member E(bx) endogenously tagged with GFP. We further expressed dlg RNAi in the posterior compartment of the E(bx)::GFP wing discs (Figure 3F) and also significantly greater than signal from the eps::GFP-only background signal (Figure 3E). A final control, we performed PLA on wing discs expressing Polybromo endogenously tagged with GFP. Polybromo is a member of the PBAP complex, one of two SWI/SNF chromatin remodeling complexes in Drosophila (Bouazoune and Brehm, 2006). We detected other SWI/SNF complex members in our MS data (Supplemental Tables S2 and S3) including Brm and Bap60 (Figure 2B), but not Polybromo. We therefore reasoned that Polybromo::GFP would be a stringent negative control. We did not detect PLA signal significantly above single antibody background between Dlg and Polybromo::GFP (Figure 3F).
An advantage of PLA in this context is its sensitivity, which allows small numbers of protein molecules to be visualized via microscopy with good spatial resolution. The PLA signal detected between Dlg and E(bx)::GFP appeared in the nuclei of epithelial cells (Figure 3B). Because Dlg has a well-established role in regulating spindle orientation during cell division (Albertson and Doe, 2003; Johnston et al., 2009; Bergstralh et al., 2013; Nakajima et al., 2019), we considered that the nuclear Dlg signal from both MS and cell fractionation could derive exclusively from dividing cells. However, the PLA signal was even across cells and not limited to those undergoing mitosis. Thus, in addition to confirming a population of Dlg near the NURF complex, this method also enabled the detection of endogenous Dlg in the nuclei of intact cells, for the first time to our knowledge. These data corroborate the evidence from MS and subcellular fractionation that a nuclear pool of Dlg exists and lies specifically near the NURF complex.

The NURF complex is required for overgrowth of dlg tumors

We next sought to determine if there was a functional connection between Dlg and the NURF complex. Depleting dlg with RNAi from the boundary between anterior and posterior compartments of the wing disc using a conditionally active ptc<sup>ts</sup> GAL4 (see Methods) can cause neoplastic overgrowth in the hinge regions both proximal and distal to the pouch; within the pouch, dlg-depleted cells undergo apoptosis likely due to cell competition (Figure 4D). Depleting the NURF complex components E(bx) or iswi in otherwise WT discs using ptc<sup>ts</sup> GAL4 has no effect on hinge cells and only minor effects, inducing limited apoptosis, in the pouch (Figure 4, A–C). Strikingly, coexpressing RNAi against either NURF complex component along with dlg RNAi rescued the overgrowth of dlg-depleted cells (Figure 4, E and F). Examination of cell death revealed that dlg-depleted cells coexpressing NURF complex RNAi did not have...
significantly increased levels of apoptosis cells in either the hinge or the pouch compared with dlg RNAi alone (Supplemental Figure S2, A–G), demonstrating that rescue of dlg RNAi by NURF complex depletion is not due to synthetic lethality. A similar reduction of tumor size by RNAi against NURF components was seen when dlg was depleted in the posterior compartment of wing discs induced using hhGAL4 (Supplemental Figure S3, D–F). Again with this driver, expressing either NURF RNAi alone had little effect on tissue size, although these animals showed a small developmental delay (Supplemental Figure S3, A–C). We noticed that NURF RNAi restores the architecture of cells depleted of dlg using ptcGAL4 but not using hhGAL4. The latter tumors overgrow more than the former, and previous work has shown that mitotic cells are particularly challenged by polarity remodeling (Bergstrahl et al., 2013; Ragkousi et al., 2017; Moreira et al., 2019; Osswald and Morais-de-Sá, 2019); moreover, increased cell divisions may dilute the store of Dlg protein translated prior to the onset of RNAi. Finally, we found that heterozygosity for a null allele of E(bx), E(bx);NURF301-4, partially suppressed the frequency of the pouch fold (55.2%, compared with 96.3% for dlg RNAi alone) and hinge overgrowth phenotypes (15.8%, compared with 55.2% for dlg RNAi alone) in dlg RNAi wing discs using the ptcGAL4 model (Supplemental Figure S4, A–E).

We tested the specificity of the requirement of NURF complex for tumor growth. Coexpression of a control RNAi construct targetting RFP did not rescue dlg RNAi phenotypes, suggesting that the suppression we observed is not due to titration of GAL4 by multiple UAS transgenes (Supplemental Figure S5, A–C). A constitutively active form of Yki (S168A) induces strong hyperplastic overgrowth when expressed in the ptcGAL4 stripe (Figure 4J), but this growth was not rescued by E(bx) or iswi RNAi (Figure 4, K and L). Even though there is also a nuclear pool of Scrib (Figure 2, C and E), overgrowth in scrib RNAi tumors was also not rescued by RNAi against either NURF component, and we did not observe altered levels of apoptosis in the pouch or hinge of scrib RNAi cells codepleted for NURF components (Figure 4, G–I; Supplemental Figure S2, G–J). These results suggest that the reduction of tumor size by NURF RNAi is not a general characteristic of all tumors and the rescue we observe is specific to dlg.

**NURF complex promotes Yki target-gene expression in dlg tumors**

Transcriptional changes that drive neoplastic tumor growth in *Drosophila* are regulated by a signaling network involving JNK-mediated regulation of the Fos transcription factor and aPKC-mediated regulation of Yki (Kulshammer et al., 2015; Atkins et al., 2016). Because the NURF complex, via its interaction with Trl, participates in activation of Yki target genes (Oh et al., 2013), we asked if this might account for NURF complex role in promoting dlg tumor growth. NURF RNAi-mediated suppression of dlg-depleted tumor growth did not rescue epithelial architecture, but it caused significant suppression of a reporter for Yki activity, ex-LacZ (McCartney et al., 2000; Hamaratoglu et al., 2006). While NURF RNAi alone had no effect on expression of ex-LacZ in otherwise WT tissue (Figure 5, A–C), ex-LacZ expression was reduced to normal levels in dlg RNAi tissue coexpressing either NURF RNAi (Figure 5, D–F). However, in scrib RNAi tumors, where overgrowth is not suppressed, ex-LacZ levels are unchanged by NURF RNAi (Figure 5, G–I). Thus, the ability of NURF RNAi to limit tumor overgrowth correlates with the extent to which it limits Yki target gene activation in that tumor type. The failure of NURF RNAi to reduce the overgrowth caused by Yki(168A) (Figure 4, J–L) suggests that the NURF complex is not absolutely required for Yki to drive proliferation, and that strong, constitutive activation of Yki can overcome an unfavorable chromatin environment to drive gene expression. Altogether, these data support a model where nuclear Dlg negatively regulates the NURF complex to limit Yki driven growth.

**Nuclear localization of Dlg involves sequences outside of consensus nuclear localization signals (NLSs)**

To explore a function for nuclear Dlg, we investigated potential NLSs. Prediction algorithms consistently identified two regions enriched in basic amino acids that are characteristic of recognized NLSs (Figure 6A). The first lies at the C-terminus of PDZ1, while the second is in the so-called E-F region at the N-terminus of the HOOK domain, which itself lies between the SH3 and GUK domains. Both are conserved in the human homolog hDlg1, and for the latter, experimental evidence consistent with an NLS has been demonstrated (McLaughlin et al., 2002; Roberts et al., 2007). Transgenic constructs have previously deleted either the E-F or the entire HOOK domain; each results in mutant Dlg proteins that show strongly increased nuclear localization visible by immunohistochemistry (Hough et al., 1997; Lu et al., 2021). Since these data indicate that the E-F region cannot constitute the sole NLS of Dlg, we mutated basic residues within the predicted NLSs in both the E-F region and the PDZ1 to alanine (Dlg2xNLS-A; Figure 6A).

When overexpressed in dlg mutant discs or follicle cells, Dlg2xNLS-A had no detectable rescuing activity compared with expression of WT Dlg (Figure 6, B and C; Supplemental Figure S6, H–J). Both Dlg2xNLS-A and matched WT Dlg transgenic proteins exhibited membrane and cytoplasmic localization in disc and follicle cells (Figure 6, D and E; Supplemental Figure S6, A–D). Quantitation of membrane localization in follicle cells showed that, while Dlg2xNLS-A was enriched at the membrane (PM Index >1), its localization was reduced compared with WT Dlg (Supplemental Figure S6, A–D, Q). We considered whether this might be due to disruption of electrostatic membrane binding, since the mutated residues in NLS2 of Dlg2xNLS-A partially overlap with a recently described membrane binding polybasic region (Figure 6A) (Lu et al., 2021). However, localization was further reduced in scrib-depleted cells (Supplemental Figure S6, E–Q), while Dlg constructs that lack electrostatic membrane binding are insensitive to scrib depletion (Lu et al., 2021). Most importantly, to determine if mutation of both predicted NLS altered Dlg's ability to enter the nucleus, we carried out subcellular fractionation studies on protein extracted from imaginal discs. Dlg2xNLS-A protein could still be detected in the nuclear fraction, similarly to the matched overexpressed WT Dlg (Figure 6F). We conclude that nuclear entry of Dlg can involve sequences outside of the two predicted NLSs.

**DISCUSSION**

Here we report the use of an in vivo proximity-based biotin labeling approach to investigate new biological functions of the polarity-regulating tumor suppressor Dlg. Our strategy used transgenic replacement of Dlg by an APEX2-tagged version, coupled with MS of subsequently tagged proteins; critically, we carried this out in native epithelial tissue. The resultant MS data led to the discovery of a nuclear pool of native Dlg that is not apparent by microscopy but that nevertheless lies near the NURF chromatin remodeling complex. We further found that NURF is required for the overgrowth of epithelia lacking Dlg and suggest that this may be due to the role of NURF in activating pro-proliferative yki target genes.

To our knowledge, our data provide the first demonstration of endogenous *Drosophila* Dlg in the nucleus. Dlg is a member of the membrane-associated guanylate kinase (MAGUK) family of...
proteins that are generally found at cell–cell junctions, but nuclear localization of many MAGUKs has also been observed including hDlg1 (Mantovani and Banks, 2003; Roberts et al., 2007; Narayan et al., 2009) as well as ZO-1 (Gottardi et al., 1996; González-Mariscal et al., 1999), ZO-2 (Islas et al., 2000), CASK1 (Hsueh et al., 2000), MAGI-2 (Dobrosotskaya et al., 1997), and Nagie Oko (Bit-Avragim et al., 2008). Due to their size, movement of MAGUKs into and out of the nucleus must involve active transport via NLS and nuclear export signals (NES) respectively, consistent with the presence of several importin proteins as well as the nuclear import regulator Ran in our Dlg proximity biotinylation dataset (Supplemental Tables S1 and S2). The predicted NLS in the Dlg E-F/HOOK region is conserved in hDlg1. The SH3-HOOK-GUK region undergoes an intramolecular interaction that regulates exposure of sequences that can mediate several Dlg functions (Nix et al., 2000; McGee et al., 2001; Qian and Prehoda, 2006; Marcette et al., 2009; Newman and Prehoda, 2009; Zeng et al., 2017; Rademacher et al., 2019; Lu et al., 2021); the increased nuclear localization of transgenic Dlg or hDlg1 deleted for the GUK domain raises the possibility that nuclear entry could be one of these (Thomas et al., 2000; Kohu et al., 2002; Lu et al., 2021). The predicted NLS in Dlg PDZ1 is conserved not only in hDlg1 but also in other MAGUK homologs: Polychaetoid, ZO-1, ZO-2, and their Drosophila homologs Polychaetoid. We were unable to predict an NES, although such sequences have been detected in vertebrate ZO-1 (Islas et al., 2002), ZO-2 (Islas et al., 2002; Jaramillo et al., 2004; González-Mariscal et al., 2006), Nagie Oko (Bit-Avragim et al., 2008). However, various transgenically expressed truncations of Dlg localize strongly to nuclei (Hough et al., 1997; Thomas et al., 2000; Bachmann et al., 2004; Lu et al., 2021), including one that deletes the E-F region itself. Additionally, coding exons that are alternatively spliced in a neural-specific isoform of Dlg are sufficient to drive nuclear localization; these protein sequences are conserved with hDlg1 (Bachmann et al., 2004). Clearly, MAGUKs have evolved and maintained multiple mechanisms of nuclear entry and exit; our data demonstrate that this may be true even for proteins where a nuclear pool is not visible by microscopy.

We attempted to test the nuclear function of Drosophila Dlg by mutating two conserved and predicted NLSs; however, this failed to abolish nuclear entry. This result agrees with a recently published Dlg transgene that deletes the three PDZ domains while also mutating 15 basic residues in and adjacent to the predicted E-F region NLS to glutamine; nuclear localization of the mutant protein is visible, again emphasizing that an additional NLS must reside outside of the consensus sequences (Lu et al., 2021). Interestingly, Dlg\textsuperscript{NLS-A} provided no rescuing activity, consistent with the deleterious effects of mutations in the HOOK domain (Hough et al., 1997; Lu et al., 2021).

**FIGURE 5:** NURF RNAi rescues Yki target gene expression in dlg tumors. (A–C) ex-LacZ expression (α-β-gal) in control wing discs (A) was unaffected by either E(bx) (B) or iswi (C) RNAi. (D–F) ex-LacZ levels were elevated in neoplastically overgrown regions of dlg RNAi discs. (D, arrows). E(bx) (E) or iswi (F) RNAi coexpression rescued both overgrowth and ex-LacZ levels. (G–I) ex-LacZ levels were also elevated in neoplastically overgrown areas of scrib RNAi discs (G). Neither overgrowth nor ex-LacZ levels were rescued with coexpression of E(bx) (H) or iswi (I) RNAi. The phenotype here was made less severe than in Figure 4, G–I by reducing ptc\textsuperscript{GAL4} activity time, to facilitate comparison of normal to tumorous tissue. Scale bar = 100 µM.
Previous work shows that PDZ and GUK domains are not absolutely required for Dlg function, while the SH3 and HOOK domains are (Hough et al., 1997; Thomas et al., 2000; Khoury and Bilder, 2020; Lu et al., 2021). Our results hint at a critical role for the eight basic amino acids in the E-F region within HOOK that is independent of electrostatic membrane binding; these can be the subject of future experiments.

Nakajima and Gibson recently used coimmunoprecipitation (Co-IP) to isolate Dlg-associated proteins from embryos. Their dataset identified several proteins involved in nuclear pore traffic (Ran, CRM1, NUP358) but not NURF components (Nakajima et al., 2019). Similarly, we were unable to Co-IP Dlg and NURF complex member E(bx) (data not shown). It is possible that Dlg and E(bx) associate through an interaction that is not stable enough to pull down or that Dlg may interact with another member of the NURF complex (for which reagents for co-IP were not available) or through an intermediary protein. Any of these possibilities would highlight the utility of APEX2 fusion proteins to facilitate the in vivo detection of weak and/or transient interactions that are hard to discover by other methods. In the case of the Scrib module, they could provide a path forward to identifying relevant interactors, which has been a major obstacle in understanding the biology of these key polarity-regulating tumor suppressors.

It has long been observed that Scrib, Dlg, and Lgl are required to maintain the proper transcriptional state of epithelial tissues (Hariharan and Bilder, 2006; Grzeschik et al., 2010; Zhu et al., 2010; Doggett et al., 2011; Sun and Irvine, 2011; Bunker et al., 2015). Our observations that Dlg is near the NURF complex in the nucleus and that the NURF complex is required for Yki-driven overgrowth of dlg tumors suggest that Dlg may regulate transcription through a much more direct mechanism than previously thought. Several other MAGUKs physically interact with transcription factors, including ZO-2.
with Jun, Fos, C/EBP (Betanzos et al., 2004), Myc (Huerta et al., 2007), YAP (Oka et al., 2010) (the vertebrate homolog of Yki), and TEAD (Gallego-Gutiérrez et al., 2021), while CASK1 can form a trimeric complex in the nucleus with the T-box transcription factor Tbr-1 and CINAP, a nucleosome assembly protein that facilitates chromatin remodeling (Hsueh et al., 2000; Wang et al., 2004).

While we found a functional role for the NURF complex in tumor overgrowth in dlg mutants, the same assays did not produce evidence for a functional connection between the NURF complex and the Scrib. This is intriguing, given the close relationship between Scrib and Dlg in epithelial polarity and our evidence here that Scrib is also detectable in the nucleus. However, it is clear that Scrib and Dlg do not have overlapping functions (Elsum et al., 2012; Stephens et al., 2018); recent work has demonstrated distinct roles for the two proteins, in part by showing that they cannot substitute for one another in epithelial polarity (Khoury and Bilder, 2020; Ventura et al., 2020). Independent roles have also been documented for the Caenorhabditis elegans Scrib and Dlg homologues (Legouis et al., 2000; Firestein and Rongo, 2001; McMahon et al., 2001), and recent proteomic studies in C. elegans as well as Drosophila uncover only modestly overlapping sets of Scrib- and Dlg-interacting proteins (Waaijers et al., 2016; Nakajima et al., 2019) (reviewed in Stephens et al., 2018). Of particular relevance here, transcriptome profiling of scrib and dlg mutant wing disc tumors also found only partially overlapping changes in gene expression (Bunker et al., 2015). It is therefore plausible that while Dlg may regulate transcription via the NURF complex, Scrib’s effects on gene expression may be exerted in a distinct manner. Whether these effects require nuclear entry of Scrib will await further study.

The association between nuclear Drosophila Dlg and the NURF complex extends data about other nuclear MAGUKs and supports the importance of this understudied aspect of these highly conserved proteins. Still, as we were unable to separately test the functions of cytoplasmic and nuclear Dlg pools, we cannot definitively conclude that the latter drives the observed growth phenotypes. We also do not know how Dlg proteins move through the pore; whether the nuclear population is a small, stable pool or a transient, dynamic one; or the signals or cellular states that cause their nuclear localization. Nonetheless, our data indicate that a comprehensive understanding of this critical protein may have to include its function not just at the PM but also in the nucleus.

**METHODS**

Request a protocol through Bio-protocol.

**Drosophila stocks and genetics**

Drosophila melanogaster stocks were raised on cornmeal molasses food. Experimental crosses were raised at 25°C unless otherwise noted. Fly lines used are listed in Supplemental Table S4; ptc-GAL4 denotes the use of ptcGAL4 in combination with temperature-sensitive GAL80 (GAL80ts) to allow conditional GAL4 expression on temperature shift. For experiments using ptc-GAL4, crosses were started at 25°C. Adults were removed after 48 h then after another 24 h, vials were shifted to 29°C to induce Gal4 expression. Wing discs were dissected from wandering third-instar larvae starting 72 h after temperature shift and continuing every 24 h thereafter for 1–3 additional days to track tumor development. For clonal GAL4 expression in follicle cells, larvae were heat-shocked for 13 min at 37°C 120 h after egg deposition (AED). For follicle cell MARCM experiments, larvae were heat-shocked for 1 h on 3 consecutive days starting at 120 h AED. Ovaries were dissected from adult females fed on yeast for 3 d after eclosion. The sequences for UAS-3xMyc-APEX2-Dlg, UAS-Dlg-3xHA, and UAS-Dlg\_3XNL5\_SVA-3xHA are presented in Supplemental Table S4. UAS-3xMyc-APEX2-Dlg contains the dlgA coding sequence with the dlg S97-specific exon using a cdNA provided by Ulrich Thomas; it was cloned into a Gateway N-terminal 3xMyc-APEX2 destination vector. UAS-Dlg-3xHA was cloned into the pUAST-attB vector and contains a C-terminal flexible linker followed by a 3xHA tag. UAS-Dlg\_3XNL5\_SVA-3xHA was cloned from UAS-Dlg-3xHA using Gibson assembly (NEB). All transgenes were inserted into the attP40 site. Primer sequences are given in Supplemental Table S4.

**Immunofluorescence and microscopy**

Wandering third-instar larval imaginal discs were dissected in phosphat-buffered saline (PBS) and fixed for 20 min in 4% paraformaldehyde (PFA). Samples were rinsed in PBS. Follicles were dissected in Schneider’s medium containing 15% fetal bovine serum (FBS) and fixed for 20 min in 4% PFA. Primary and secondary antibodies were diluted in PBST (0.1% Triton X-100) with 4% NGS (Life Technologies) and 1% bovine serum albumin (BSA; Life Technologies). Primary antibodies (Supplemental Table S4) were incubated with samples overnight at 4°C. Secondary fluorophore-conjugated antibodies (Molecular Probes) were diluted 1:400 and incubated for 2 h at room temperature. Phalloidin and DAPI incubated with samples for 20 min in PBS. Images were captured on a Zeiss LSM700 scanning confocal microscope or a Zeiss Axio Imager M2 with Apotome 2 with Plan Apochromat 20x/NA 0.8, LD C-Apochromat 40x/NA 1.1 W and Plan Apochromat 63x/NA 1.4 oil objectives at 1024 x 1024 pixels with 2 line averages.

For all imaginal disc experiments, at least 15 discs were examined per condition, except in Supplemental Figure S3, H and I, where 7 discs were analyzed per genotype. For follicle cell experiments, tissue from at least 5 females was analyzed and at least 10 ovarioles and at least 2 egg chambers per ovariole were examined. Images are representative of at least 2 independent biological replicates. Reported phenotypes were observed with at least 80% penetrance in all cases unless otherwise noted.

Dlg cortical enrichment was quantified as described in Lu et al. (2021). For single cells in en face conical sections, the fluorescent signal intensity of at the membrane and in the cytoplasm were quantified in Fiji (Schindelin et al., 2012) using rectangular ROIs of fixed 1.17 μM width, approximately the thickness of the cell cortex. The ratio of membrane:cytoplasmic intensity was calculated to give the “PM index.” Average PM indices were calculated for all cells per genotype.

Death caspase-1 enrichment was quantified by taking the mean fluorescence intensity in maximum intensity projected images of a 63.77 μM-wide rectangular ROI spanning the ptc\_GAL4-expressing stripe and an adjacent, equivalently sized control ROI outside the GAL4 domain and calculating the ratio of these two values per disc. Ratios were calculated separately for the wing pouch and the hinge.

**Western blots**

Protein concentrations in samples were measured by BCA protein assay (Pierce). Proteins were electrophoresed at 150 V for 1 h through 7.5% or 4–20% mini-PROTEAN TGX gels (Bio-Rad) and blotted to 300 mA for 1 h onto PVDF membranes. Membranes were blocked in 3% BSA in Tris-buffered saline (TBS)-T for 1 h. All antibodies were incubated with membrane in blocking solution. Primary antibodies were incubated overnight at 4°C. Streptavidin-HRP and HRP-conjugated secondary antibodies were incubated with the membrane for 2 h at room temperature. Blots were developed with standard ECL reagents (Advansa).
Sample preparation and biotin labeling for mass spectrometry

Larvae were reared at room temperature (21–23°C). Thoracic discs were dissected in chilled labeling media: Schneider’s medium (Life Technologies) containing 1% Pen/Strep (Caisson Labs), 10% FBS (Life Technologies), 500 µM biotin-pheno (aka biotinyl tyramide, AdipoGen Life Sciences), and 2 mM probenecid (Thermo). Samples were incubated at room temperature with nutation for 30 min. Labeling media was removed. Samples were incubated in 1 mM hydrogen peroxide for 1 min. Samples were then washed three times in quenching buffer (5 mM Trolox [Sigma], 10 mM sodium azide [Sigma], and 10 mM sodium ascorbate [Sigma] in PBS) and three times in PBS. Samples were lysed in RIPA buffer (50 mM Tris-HCl, pH 8.0, 150 mM NaCl, 1% NP-40, 0.5% sodium deoxycholate, 0.1% SDS, and protease inhibitors [Pierce mini-tablets]) using a pellet pestle motor and a polystyrene pestle. All solutions were pre-chilled on ice. Lysates were spun at 14,000 rpm in a tabletop microfuge for 10 min at 4°C to remove debris, and supernatants were saved as final sample lysate. A 5-µl lysate sample was reserved for Western blot analysis. The remainder was incubated with streptavidin-conjugated magnetic beads (Pierce) for 1 h at room temperature. Beads were washed twice in TBS with 0.1% Tween20, then three times with RIPA buffer. For Western blot analysis of pull down of biotinylated proteins, beads were boiled for 5 min in 60 µl SDS-PAGE sample buffer: NuPAGE LDS buffer (Thermo) with 20 mM DTT (Sigma) and 2 mM biotin (Thermo). Supernatant was saved as eluate 1 (E1). Beads were then boiled for 5 min in 40 µl sample buffer and supernatant was saved as eluate 2 (E2). For MS, labeled lysates were prepared in batches and stored at –80°C until all samples had been collected. Samples were then thawed and pooled into three replicates from 400 larvae each, and biotinylated proteins were isolated as described above. Protein-bound beads were kept in PBS at 4°C. MS, including remaining sample prep, was performed by the UC Davis Mass Spectrometry Facilities.

Proteins on beads were received and the buffer was exchanged with four washes of 50 mM TEAB (triethylammonium bicarbonate). The proteins were then digested off the beads overnight with trypsin at room temperature. The following day, the supernatant was removed, and the beads were washed with 50 mM TEAB and pooled with the supernatant. The peptides in all six sample were quantified using Pierce fluorescent peptide assay (Thermo Scientific).

TMT labeling

Based on the fluorescent peptide assay, the volume for 20 µg of the most concentrated sample was determined, and equal volumes of each sample were diluted with 50 mM TEAB to 25 µl per replicate. Each sample was labeled with TMT 6 Plex Mass Tag Labeling Kit (Thermo Scientific). Briefly, 20 µl of each TMT label (126-131) was added to each digested peptide sample and incubated for an hour. The reaction was quenched with 1 µl of 5% hydroxylamine and incubated for 15 min. All labeled samples were then mixed together and lyophilized to almost dryness. The TMT-labeled sample was reconstituted in 2% acetonitrile 0.1% TFA and desalted with a zip tip.

LC-MS3

LC separation was done on a Dionex nano Ultimate 3000 (Thermo Scientific) with a Thermo Easy-Spray source. The digested peptides were reconstituted in 2% acetonitrile/0.1% trifluoroacetic acid, and 5 µl of each sample was loaded onto a PepMap 100 Å 3U 75 µm × 20 mm reverse-phase trap where they were desalted online before being separated on a 100 Å 2U 50 µm × 150 mm PepMap EasySpray reverse-phase-column. Peptides were eluted using a 90-min gradient of 0.1% formic acid (A) and 80% acetonitrile (B) with a flow rate of 200 nL/min. The separation gradient was run with 2–5% B over 1 min, 5–10% B over 9 min, 10–20% B over 27 min, 20–35% B over 10 min, 35–99% B over 10 min, a 2-min hold at 99% B, and finally 99–2% B held at 2% B for 5 min.

MS3 synchronous precursor selection (SPS) workflow

Mass spectra were collected on a Fusion Lumos mass spectrometer (Thermo Fisher Scientific) in a data-dependent MS3 SPS method. MS1 spectra were acquired in the Orbitrap, 120 K resolution, 50 ms max inject time, 5 × 105 max inject time. MS2 spectra were acquired in the linear ion trap with a 0.7 Da isolation window, CID fragmentation energy of 35%, turbo scan speed, 50 ms max inject time, 1 × 104 AGC, and maximum parallelizable time turned on. MS2 ions were isolated in the ion trap and fragmented with an HCD energy of 65%. MS3 spectra were acquired in the orbitrap with a resolution of 50 K and a scan range of 100–500 Da, 105 ms max inject time, and 1 × 105 AGC.

MS3 SPS workflow

Database searching: tandem mass spectra were extracted by Proteome Discoverer 2.2. Charge state deconvolution and deisotoping were not performed. All MS/MS samples were analyzed using SequestHT (XCorr Only) (Thermo Fisher Scientific, San Jose, CA) in Proteome Discoverer 2.2.0.388. Sequest (XCorr Only) was set up to search uniprot-proteome-3AUP000000803.fasta (unknown version, 21,134 entries) and an equal number of decoy sequences, assuming the digestion enzyme trypsin. Sequest (XCorr Only) was searched with a fragment ion mass tolerance of 0.60 Da and a parent ion tolerance of 10.0 PPM. Carbamidomethyl of cysteine and TMT6plex of lysine were specified in SequestHT (XCorr Only) as variable modifications. Deamidated of asparagine, oxidation of methionine and acetyl of the n-terminus were specified in Sequest (XCorr Only) as variable modifications.

Criteria for protein identification: Scaffold (version Scaffold_4.8.4, Proteome Software, Portland, OR) was used to validate MS/MS-based peptide and protein identifications. Peptide identifications were accepted if they could be established at greater than 74.0% probability to achieve a false discovery rate (FDR) less than 1.0% by the Scaffold Local FDR algorithm. Protein identifications were accepted if they could be established at greater than 35.0% probability to achieve an FDR less than 1.0% and contained at least two identified peptides. This resulted in a peptide decay FDR of 0.31% and a Protein Decay FDR of 0.8%. Protein probabilities were assigned by the Protein Prophet algorithm (Nesvizhskii et al., 2003). Proteins that contained similar peptides and could not be differentiated based on MS/MS analysis alone were grouped to satisfy the principles of parsimony. Proteins sharing significant peptide evidence were grouped into clusters.

Quantitative data analysis: Scaffold Q+ (version Scaffold_4.8.4, Proteome Software, Portland, OR) was used to quantitate label-based quantitation (TMT) peptide and protein identifications. Peptide identifications were accepted if they could be established at greater than 74.0% probability to achieve an FDR less than 1.0% by the Scaffold Local FDR algorithm. Protein identifications were accepted if they could be established at greater than 35.0% probability to achieve an FDR less than 1.0% and contained at least two identified peptides. Protein probabilities were assigned by the Protein Prophet algorithm (Nesvizhskii et al., 2003). Proteins that contained similar peptides and could not be differentiated based on MS/MS analysis alone were grouped to satisfy the principles of
parsimony. Proteins sharing significant peptide evidence were grouped into clusters. Channels were corrected by correction factors supplied by the manufacturer in all samples according to the algorithm described in i-Tracker (Shadforth et al., 2005). Normalization was performed iteratively (across spectra) on intensities, as described in the statistical analysis of relative labeled mass spectrometry data from complex samples using anova (Oberg et al., 2008). Medians were used for averaging. Spectra data were log-transformed, pruned of those matched to multiple proteins, and weighted by an adaptive intensity weighting algorithm. Of 3635 spectra in the experiment at the given thresholds, 3247 (89%) were included in quantitation. Differentially expressed proteins were determined by applying the permutation test with unadjusted significance level \( p < 0.05 \) corrected by Benjamini-Hochberg.

Data availability
Raw data, mzML, and Scaffold results are available from the MassIVE proteomics repository (MSV000087186) and ProteomeXchange (PXD025378).

GO analysis
Cellular component GO analysis was performed using the BiNGO plug-in for Cytoscape using all genes in the \( D. \ melanogaster \) genome as a reference set. User selected settings were as follows: hypergeometric statistical test; Benjamini-Hochberg FDR used to correct \( P \) values; significance level set to 0.05.

Multiple sequence alignment
Multiple sequence alignment of Dlg NLS sequences was made with Clustal Omega (Madeira et al., 2019). Aligned sequences were visualized using SnapGene Viewer. The following protein sequences were used: \textit{Homo sapiens}, UniProt Q12959; \textit{Mus musculus}, UniProt Q811DO; \textit{Rattus norvegicus}, UniProt Q62696; \textit{Danio rerio}, UniProt E7FAT1; \textit{Xenopus tropicalis}, UniProt Q28CS5; \textit{D. melanogaster}, UniProt P31007.

Subcellular fractionation
Sixty to 70 wandering third-instar larvae were dissected in PBS. Cells were lysed using five strokes with the small pestle in a Dounce homogenizer. Sample was incubated on ice for 10 min and then spun at 3000 rpm for 10 min in a tabletop microfuge. Supernatant was spun at 14,000 × g for 10 min and supernatant was cytoplasmic fraction. Pellet from the first spin was rinsed in PBS. Pellet was then resuspended in 5 mM HEPES, pH 7.6, 1.5 mM MgCl\(_2\), 0.5 mM DTT, and 0.05% NP-40. After homogenization, samples were incubated on ice for 10 min and then spun at 24,000 × g for 20 min. Supernatant was nuclear fraction. All buffers were prechilled on ice and contained protease inhibitors (Pierce). All spins were conducted at 4°C.

PLA
PLA was performed using a Duolink In Situ Orange Mouse/Rabbit Kit (Sigma) according to the manufacturer's instructions with the following modifications. Samples were dissected and fixed as for immunofluorescence. Tissue was permeabilized in PBST, then washed 3x in PBS before proceeding. All subsequent steps were performed in recommended volumes in tubes with mounting of samples onto slides as the final step. Confocal images were taken on a Zeiss LSM 700 scanning microscope. For quantification, the total number of PLA puncta were counted in a maximum projection of a 101.61 × 101.61 × 24 μm vol from two regions of each disc: control and dgl RNAi. Presented images are a maximum projection of 5 μM depth. Images were processed and analyzed in Fiji. Statistics were done in Prism.

Statistical methods
Statistical significance was determined using two tailed t test or one-way ANOVA with Tukey’s multiple comparisons test. Analysis of mass spec data is described above in “MS3 SPS Workflow” and used Permutation Test with unadjusted significance level \( p < 0.05 \) corrected by Benjamini-Hochberg. GO analysis is described above and used hypergeometric test with Benjamini-Hochberg FDR to correct \( P \) values; significance level set to 0.05. In figures, n.s. is \( P > 0.05 \), *\( p < 0.05 \), **\( p < 0.01 \), ***\( p < 0.001 \), and ****\( p < 0.0001 \).

ACKNOWLEDGMENTS
We thank Laura Mathies for cloning \( Dlg \)\( ^{20NL-S} \) to Norbert Perrimon for key reagents, the UC Davis Core Proteomics facility for assistance, and the Bilder lab for helpful discussions.
