Abstract
Within the formulation of classical fields and branes in curved spacetime, we first discuss the Belinfante construction of an improved energy-momentum tensor density in curved backgrounds, in analogy to the case of flat spacetime. A novelty of our approach is the use of Noether identities for generally covariant theories as a guiding instrument. In this part of the paper, our basic results, which hold irrespective of the background being dynamical or fixed, agree with those previously obtained in Gamboa Saravi (2004 J. Phys. A: Math. Gen. 37 9573). We illustrate with the example of Maxwell theory the role played by the Belinfante tensor in the construction of the Noether conserved currents and symmetry generators associated with the Killing symmetries of the background, which become Noether symmetries for the matter Lagrangian. We also give some details on the existing obstructions to the realization of part of these symmetries in phase space. Next we study extended objects (\(p\)-branes) either in a dynamic or in a fixed background, and obtain the Noether identities associated both with target spacetime and world volume diffeomorphisms. We show that in field theory as well as with extended objects, the Killing symmetries of the background become ordinary rigid Noether symmetries of the theory in this fixed background.

Keywords: Noether symmetries, Killing symmetries, classical fields, branes, energy-momentum tensors

1. Introduction
This paper is devoted to the formulation of classical fields and branes in curved spacetime, with dynamics dictated by a variational principle. We discuss in particular whether some results holding for flat spacetime can be extended to curved backgrounds. In this sense this paper uses the methods set up in [1] for flat spacetime to get a generalization for curved
spacetime. In such flat spacetime theories it is well known that there are essentially two equivalent procedures to define a symmetric energy-momentum tensor. In one procedure, due to Belinfante [2], one starts with the canonical energy-momentum tensor obtainable from the Noether theorem [3] and applies to it an improvement in the form of a divergence. In the second method, due to Hilbert [4], one covariantizes the Lagrangian and defines the tensor as its Euler–Lagrange derivative with respect to the metric, and finally sets the metric to its original, Minkowski form. Rosenfeld [5] showed that both methods coincide on shell (in fact Belinfante tensor is—in general—only symmetric on shell).

One may ask whether there exists some analogous construction for curved spacetime. This issue has been addressed in several places, see for instance [6–9]. Of particular interest is the pioneering work by [6], which gives expressions for the relation between Belinfante and Hilbert tensors in curved spacetime. In our paper we show how these results can be obtained by direct use of the Noether identities for generally covariant theories. We consider matter Lagrangians with minimal couplings to gravity. An important difference with the Minkowski case is that the Riemann tensor appears now as a possible obstruction to the conservation of the would-be canonical energy-momentum tensor density (this point was already raised in [6]), whereas its ‘improvement’ à la Belinfante overcomes this obstruction and it is always conserved on shell. In fact Belinfante’s tensor density can be defined directly from the Hilbert tensor density with no restriction to minimal coupling cases. We stress also the crucial role of Belinfante tensor in the construction of the generators of the Noether symmetries -of a matter Lagrangian originated from the Killing symmetries of a fixed background.

We next apply the previous results to theories formulated in fixed backgrouds with Killing vectors. The generally covariant matter Lagrangian can be truncated to a fixed background and define a new Lagrangian for the matter field, which is no longer generally covariant. We show that the Killing symmetries of the fixed background become rigid Noether symmetries of the truncated Lagrangian. The associated conserved density current is just the contraction of the Belinfante energy-momentum tensor density with such Killing vector. A subtle point concerning the realization in phase space of these symmetries is that to construct their generator one must use Belinfante’s, not Hilbert’s, energy-momentumm tensor density. In this case, the off-shell difference between both tensor densities becomes crucial.

The second half of the paper is devoted to the classical dynamics of extended objects in a curved background, which can be either dynamical or fixed. Our focus will be the Nambu Goto (NG) brane. We will show the contents of the Noether identities associated both with the target spacetime diffeomorphisms and world volume diffeomorphism. Interestingly enough, we are able to obtain, just from the Noether analysis, the equations of motion (EOM) for the NG Lagrangian, that is, the vanishing of the trace of the extrinsic curvature, without doing any explicit computation of the Euler–Lagrange derivatives of the NG Lagrangian.

In the case of a fixed background we show that, in a way similar to the result obtained for field theories, the Killing symmetries of the background become rigid symmetries of the truncated theory. A simple geometric interpretation of the associated conserved currents is also given.

The paper is organized as follows. Afer some basic preliminaries, section 3 is devoted to the Noether identities in a general background and the connection between Hilbert, Belinfante energy-momentum tensors and what we call the canonical tensor. In section 4 we discuss the fate of the Killing symmetries in theories truncated to a fixed metric background. Next in section 5 we turn to branes in the different settings of fixed or dynamic backgrounds and we identify for the brane Lagrangian the symmetries associated with the Killing vectors. In section 6 the Noether identities associated with target spacetime and/or world volume diffeomorphisms are obtained. Conclusions are drawn in section 7. We finish with two appendices, the first, devoted to Maxwell theory in flat spacetime, to underline the relevance of Belinfante tensor in
the construction of the generator of the Noether symmetries, and the second, in order to make the paper more self-contained, with a review of basic results on the extrinsic curvature, useful for the sections on extended objects.

2. Preliminaries

Here we introduce some notation and basic observations.

2.1. Infinitesimal diffeomorphisms. Praise for the active view

Let us examine the transformation of the fields under reparametrizations of a manifold $P$, $x^\mu \rightarrow x'^\mu = x^\mu - \epsilon^\mu(x)$, with $\epsilon^\mu(x)$ an arbitrary infinitesimal function (though the infinitesimal parameter can always be factored out from $\epsilon^\mu(x)$).

Reparametrizations -that is, changes of coordinates- are the passive interpretation of diffeomorphisms. To discuss the active versus passive views of diffeomorphisms, consider for simplicity the case of a scalar field $\phi(x)$. According to the passive view, under an infinitesimal diffeomorphism, the coordinates undergo a change, $x^\mu \rightarrow x'^\mu(x)$, and the fields remain the same, the only change being in their mathematical description because we must write them -or their components- in the new coordinatization. For the scalar field this is given by $\phi'(x') = \phi(x)$. Instead, in the active view, the coordinates do not change but the fields undergo the change $\phi(x) \rightarrow \phi'(x)$, so that the functional variation of $\phi(x)$ is $\delta \phi = \phi'(x) - \phi(x) = \mathcal{L}_\epsilon \phi$, where the differential operator $\mathcal{L}_\epsilon$ is the Lie derivative under the vector field $\epsilon^\mu(x)$. In general, any vector, tensor, form, will experience an active variation given by its Lie derivative under $\epsilon^\mu(x)$.

Some praise is deserved for the active view of spacetime symmetries, in which we only consider the functional variation of the fields. First, it puts the spacetime symmetries on an equal footing with respect to the other, internal symmetries, that may eventually exist; second, the functional variation $\delta$ commutes with the partial derivative with respect to the coordinates, $[\delta, \partial_\mu] = 0$; third, the functional variation of an action does not modify the boundaries -because the coordinates are unchanged-, thus simplifying intermediate computations; fourth, if the variations are obtained in a canonical -phase space- formalism with a generator acting through the Poisson bracket, they are automatically functional variations, that is, of the active type. This is the case of conserved quantities acting as generators of symmetries according to Noether’s theorem.

When the dynamics of extended objects embedded in the manifold $P$ is considered, the same ideas apply. We must distinguish in this case target spacetime diffeomorphisms and world volume diffeomorphisms, but in both of them we will apply the active view. It is this active view of diffeomorphisms that we will adopt throughout the paper: move the structures -fields, branes-, not the coordinates.

2.2. Truncation to a fixed background

We consider theories formulated in manifolds endowed with a Lorentzian metric. With $g$ representing the metric field and $\phi$ the matter fields, we will consider a matter Lagrangian $\mathcal{L}[g, \phi]$ fully covariant, that is, behaving as a scalar density under diffeomorphisms. At any moment $\mathcal{L}$ can be truncated to $\mathcal{L}^{(0)}[\phi] := \mathcal{L}[g, \phi]|_{g \rightarrow g_0}$, where $g_0$ is a fixed background\(^1\). This type of

\(^1\) By fixed background we mean a non-dynamical metric field with no equations of motion for it.
truncation is not a gauge fixing nor it is a consistent truncation. It is not a gauge fixing because evidently there is no diffeomorphism connecting a generic metric configuration to $g_0$. As a truncation, it is not consistent because gravity universally couples with matter and therefore the backreaction must not be neglected. But it may be a useful approximation, as it is the case of field theory in flat spacetime.

Once the background is fixed (for instance to Minkowski spacetime) the gauge symmetry of diffeomorphisms is no longer there. In the Minkowski case the ‘residual’ (not exactly so, because fixing the background is not a gauge fixing) symmetry is rigid: Poincaré. It is the symmetry generated by the Killing vectors of the background. In the active interpretation one can still say that the spacetime configurations, before and after the action of a Poincaré symmetry, are physically indistinguishable (the language remains of gauge equivalent configurations) and in fact in the passive view we see that we are describing a unique physical configuration with different coordinates. But now the indeterminism with respect to the initial conditions, which is a characteristic feature of the gauge freedom, has disappeared.

3. Energy-momentum tensors and Noether identities in field theory

3.1. Noether identities

Consider a first order Lagrangian $L[\psi]$ with gauge freedom described by

$$\delta\psi^A = R^A_a e^a + Q^A_{\mu \nu} \partial_\mu e^\nu \Rightarrow \delta L = \partial_\mu F^\mu (\text{divergence})$$

(3.1)

where the index $A$ refers to fields or field components; $F^\mu$, $R^A_a$ and $Q^A_{\mu \nu}$ are functions of the fields and its derivatives; and $e^a$ are the infinitesimal arbitrary functions of the gauge symmetries (in a certain number given by the running of the index $a$). Notice that in view of the application of the formalism to generally covariant theories we have changed slightly the notion for the variation of the fields in (3.1) with respect to the one used in [1]. The associated Noether identities are easily obtained from (3.1) in two steps. First we integrate $\delta L$ over the spacetime but keeping $e^a$ with compact support, so the boundary terms associated with $F^\mu$ disappear. Still with compact support for $e^a$, we next eliminate more boundary terms to get

$$\int \delta L = \int [L,_{\mu}] \delta \psi^A = 0$$

(with the usual notation $[L,_{\mu}] = \frac{\delta L}{\delta \partial_\mu \psi}$. For arbitrary $e^a$ with compact support, thus implying the Noether identities

$$[L,_{\mu}] R^A_a - \partial_\mu ([L,_{\mu}] Q^A_{\mu \nu} e^\nu) = 0.$$ 

(3.2)

One can equivalently write, after saturating with the arbitrary functions $e^a$ (now we do not need the compact support condition),

$$[L,_{\mu}] \delta \psi^A - \partial_\mu ([L,_{\mu}] Q^A_{\mu \nu} e^\nu) = 0.$$ 

(3.3)

We are interested in a special type of gauge symmetries: spacetime diffeomorphisms. In view of that it is convenient to express these identities in covariant language. For notational convenience, let us distinguish, among the generic fields $\psi^A$, the metric field $g_{\mu \nu}$ and the matter fields $\phi^A$, which we consider bosonic (fermionic matter has to be formulated within the tetrad formalism). We assume that $L[g, \phi]$ depends at most on the first spacetime derivatives of the fields $\phi^A$.

---

2 The only connection we consider throughout the paper is the Levi Civita connection.
As usual in the framework of generally covariant theories, we consider that the matter Lagrangian $\mathcal{L}[g, \phi]$ behaves as a scalar density under diffeomorphisms. Thus diffeomorphisms are Noether gauge symmetries for the theory described by this Lagrangian. In the active view, diffeomorphism covariance is expressed infinitesimally with the transformations (Lie derivative)

$$
\delta g_{\mu\nu} = \nabla_\mu \epsilon_\nu + \nabla_\nu \epsilon_\mu, \quad \delta \phi^A = \epsilon^\nu \nabla_\nu \phi^A + Q^A_{\mu} \rho \nabla_\rho \epsilon^\sigma
$$

(3.4)

where now $\epsilon^\nu$ represent an infinitesimal diffeomorphism and we use the notation $Q^A_{\mu}$ for the previous objects $Q^A_{\mu\sigma}$. Indices $A$ for fields or field components may generically include space-time indices as well as internal indices. Equation (3.4) are just the Lie derivatives of the metric and the matter fields under an infinitesimal spacetime vector field $\epsilon^\mu$. These transformations (3.4) will induce the scalar density behaviour $\delta \mathcal{L} = \partial_\mu (\epsilon^\mu \mathcal{L})$. The Noether identities (3.3), now associated with diffeomorphism covariance, read (with $[\mathcal{L}]^{\mu\nu} = \frac{\delta \mathcal{L}}{\delta g_{\mu\nu}}$)

$$
[L]^{\mu\nu} \delta g_{\mu\nu} + [\mathcal{L}] \delta \phi^A - 2\nabla_\lambda ([\mathcal{L}] \lambda^\mu \epsilon_\mu) - \nabla_\lambda ([\mathcal{L}] \lambda^\mu Q^A_{\mu \rho} \epsilon^\rho) = 0,
$$

(3.5)

identically\(^3\).

### 3.2. Hilbert and Belinfante’s energy-momentum tensors

The Hilbert energy-momentum tensor density is defined as $T^{\mu\nu} := -2 \frac{\delta \mathcal{L}}{\delta g_{\mu\nu}}$, and so we can write

$$
-T^{\mu\nu} \nabla_\mu \epsilon_\nu + [\mathcal{L}] \delta \phi^A + \nabla_\lambda \left( (T^\lambda_{\mu} - [\mathcal{L}] \lambda^\mu Q^A_{\lambda \mu}) \epsilon^\mu \right) = 0,
$$

(3.6)

for arbitrary $\epsilon^\mu$. Comparing with the standard results in the Minkowski case (see details in [1]), it is reasonable to define the combination

$$
T^\lambda_{\mu \rho} := T^\lambda_{\mu} - [\mathcal{L}] \lambda^\mu Q^A_{\lambda \mu}
$$

(3.7)

as the Belinfante energy-momentum tensor density\(^4\), which will be connected later—see next subsection—with the canonical tensor.

Defining $Q^A_{\mu} = R^A_{\mu} - Q^{\lambda\rho}_{\mu} \Gamma^\rho_{\mu\nu}$, with $\Gamma^\rho_{\mu\nu}$ the Christoffel symbols, we may write (3.1) in a covariant form, $\delta \phi^A = Q^A_{\mu} \rho \nabla_\rho \epsilon^\sigma$. Then, integrating (3.6) with the arbitrary $\epsilon^\mu$ taken with compact support we can eliminate these arbitrary functions and obtain the covariant Noether identities

$$
\nabla_\mu T^{\mu\nu} + [\mathcal{L}] \delta \phi^A - \nabla_\lambda ([\mathcal{L}] \lambda^\mu Q^A_{\lambda \mu}) = 0.
$$

(3.8)

Notice that equation (3.8) can be understood as an identity satisfied by the matter Lagrangian in a fixed background. Clearly, since to compute its Hilbert tensor density one has to functionally derivate with respect to the components of the metric field, one must know the Lagrangian for metrics around the fixed configuration, which is possible in our case because our starting point was a fully covariant scalar density Lagrangian. We observe that the Hilbert tensor density—and Belinfante’s, according to (3.7)—is covariantly conserved as long as the EOM for

\(^3\)We have replaced the covariant derivative for the partial derivative because they coincide when defining the divergence of a vector density of weight one. This is also true for the divergence of an antisymmetric tensor density. This replacement will be made at convenience in the following sections with no further warning.

\(^4\)We underline, $\delta$, to distinguish the notation for the Belinfante tensor $T_{g}^\lambda$ from a tensorial index. We will do the same for the canonical tensor below.
the matter fields are satisfied, irrespective of being either in a fixed or in a dynamical metric background. More on dynamics on a fixed background in section 4.

3.3. Contact with the canonical tensor

To continue we will assume that the matter Lagrangian depends only up to the first spacetime derivatives of the metric. This means that we are excluding some non-minimal couplings that may use the Riemann tensor\(^5\).

In addition to Hilbert’s and Belinfante’s tensor densities, in Minkowski spacetime one defines the canonical energy-momentum tensor density, \( \frac{\partial L}{\partial \phi_{\alpha \beta}} \partial \mu \partial \phi^A - \delta^A_{\mu} L \). In this spirit we now define the canonical tensor density\(^6\) in curved spacetime

\[
T^\sigma_{\xi \rho} := \frac{\partial L}{\partial \nabla_\sigma \phi^A} \nabla_\rho \phi^A - \delta^A_{\rho} L. \tag{3.9}
\]

In the following we will connect this tensor density with Belinfante’s. To do so, we revisit the result \( \delta_{\xi} L = \partial_\rho (\epsilon^\rho L) \) for the Lie derivative of the Lagrangian under an arbitrary spacetime vector \( \epsilon^\rho \). It may be written\(^7\) as

\[
\delta_{\xi} L = \frac{\partial L}{\partial g_{\sigma \nu \rho}} \delta g_{\mu \nu} + \partial_{\alpha} \left( \frac{\partial L}{\partial g_{\mu \nu \sigma}} \delta g_{\mu \nu} \right) + [L]_{\alpha} \delta \phi^A + \nabla_{\mu} \left( \frac{\partial L}{\partial \nabla_\mu \phi^A} \delta \phi^A \right) = \nabla_{\mu} (\epsilon^\mu L). \tag{3.10}
\]

As consequence of our assumption, the dependence of \( L \) on the derivatives of the metric will be concealed within the covariant derivatives of the fields \( \phi^A \), so that

\[
\frac{\partial L}{\partial g_{\mu \nu \sigma}} = \frac{\partial L}{\partial (\nabla_\rho \phi^A)} \frac{\partial (\nabla_\rho \phi^A)}{\partial \nabla_\gamma \phi^A} \frac{\partial \nabla_\gamma \phi^A}{\partial g_{\mu \nu \sigma}} = \frac{1}{2} M^{\sigma \mu \nu},
\]

with \( M^{\sigma \mu \nu} = M^{\sigma (\mu \nu)} \) being a tensor density because the first factor \( \frac{\partial L}{\partial (\nabla_\rho \phi^A)} \) in the expression above is a tensor density whereas the other two are tensors. Thus we can write (3.10) as

\[
-T^{\mu \nu} \nabla_{\nu} \epsilon_{\mu} + \nabla_{\sigma} (M^{\sigma \mu \nu} \nabla_{\mu} \epsilon_{\nu}) + [L]_{\alpha} \delta \phi^A + \nabla_{\mu} \left( \frac{\partial L}{\partial \nabla_\mu \phi^A} \delta \phi^A - \epsilon^\mu L \right) = 0. \tag{3.11}
\]

Subtraction of (3.11) from (3.6) and the use of (3.4) together with definition (3.9) yields the -identical- conservation law

\[
\nabla_{\sigma} \left( (T^{\mu \nu} - [L]_{\alpha} Q^{\alpha \mu} \epsilon_{\mu}) \epsilon_{\nu} - M^{\mu \nu \rho} \nabla_{\nu} \epsilon_{\mu} - \frac{\partial L}{\partial \nabla_\sigma \phi^A} (\epsilon^{\nu} \nabla_\rho \phi^A + Q^{\nu \rho \lambda}) \nabla_{\nu} \epsilon_{\mu} + \epsilon^\sigma L \right)
\]

\[
= \nabla_{\sigma} \left( (T^{\sigma \mu} - T^{\mu \sigma}) \epsilon_{\mu} - (M^{\sigma \mu \nu} + \frac{\partial L}{\partial \nabla_\sigma \phi^A} Q^{\lambda \nu \mu}) \nabla_{\nu} \epsilon_{\mu} \right) = 0. \tag{3.12}
\]

We will get interesting information from the fact that this conservation law, consequence of general covariance, holds for any spacetime vector \( \epsilon^\mu \). Relation (3.12) has the form

\[\text{\footnotesize \textsuperscript{5} This restriction does not apply to the case of Killing symmetries, analyzed in the next section.}\]

\[\text{\footnotesize \textsuperscript{6} Denoting this tensor density the canonical energy-momentum tensor density would be misleading because, as we will see below, it is not covariantly conserved in general.}\]

\[\text{\footnotesize \textsuperscript{7} Notice that we take the Euler–Lagrange derivative \([L]_{\alpha} \) for \( L(\phi^A, \nabla_\mu \phi^A) \) as \([L]_{\alpha} = \frac{\partial L}{\partial \phi^A_{\alpha \beta}} - \nabla_\mu \frac{\partial L}{\partial \nabla_\mu \phi^A_{\alpha \beta}} \), so that both terms, \( \frac{\partial L}{\partial \phi^A_{\alpha \beta}} \) and \( \nabla_\mu \frac{\partial L}{\partial \nabla_\mu \phi^A_{\alpha \beta}} \), are geometric objects.}\]

\[\text{\footnotesize \textsuperscript{8} We use the standard notation for symmetrization \( N^{ab} = \frac{1}{2} (N_{ab} + N_{ba}) \) and antisymmetrization \( N^{[ab]} = \frac{1}{2} (N_{ab} - N_{ba}) \) and so on.}\]
\[ A^\mu \epsilon_\mu + B^{\nu \mu} \nabla_\nu \epsilon_\mu + C^{\sigma \nu \mu} \nabla_\sigma \nabla_\nu \epsilon_\mu = 0, \]

(3.13)

identically. Being \( \epsilon^\mu \) arbitrary, the coefficient of \( \partial_\sigma \partial_\nu \epsilon^\mu \) must vanish, which implies that \( C^{\sigma \nu \mu} \) is antisymmetric in its first two upper indices: \( C^{\sigma \nu \mu} = C^{[\sigma | \nu | \mu]} \), which in turn means that the last term in (3.13) is \[ \frac{1}{2} C^{[\sigma | \nu | \rho]} R_{\rho \sigma \nu \mu} \epsilon^\rho. \]

Thus the only term in (3.13) with derivatives of \( \epsilon^\mu \) is \( B^{\nu \mu} \partial_\nu \epsilon_\mu \), which implies that \( B^{\nu \mu} \) must vanish. So finally we obtain

\[ C^{\sigma \nu \mu} = C^{[\sigma \nu | \mu]}, \quad B^{\nu \mu} = 0, \quad A^\rho + \frac{1}{2} C^{[\sigma \nu | \rho]} R_{\rho \sigma \nu \mu} = 0, \]

which, translated to (3.12), becomes

\[ C^{[\sigma \nu | \mu]} = -M^{\sigma (\nu \mu)} - \frac{\partial L}{\partial \nabla_\sigma \phi^A} Q^{A \nu \lambda} \epsilon^\lambda \epsilon_\mu, \]

\[ 0 = T^\sigma_\mu - T^\sigma_\mu + \nabla_\lambda C^{[\lambda | \sigma | \mu]}, \]

\[ 0 = \nabla_\sigma (T^\sigma_\rho - T^\sigma_\rho) + \frac{1}{2} C^{[\sigma | \nu | \rho]} R_{\rho \sigma \nu \mu}. \]

(3.14)

The third equation in (3.14) is just a consistency check for the second. The second equation gives the relation

\[ T^\sigma_\mu = T^\sigma_\mu - \nabla_\lambda C^{[\lambda | \sigma | \mu]}. \]

(3.15)

The first equation is a statement on the decomposition of \( \frac{\partial L}{\partial \nabla_\sigma \phi^A} Q^{A \nu \lambda} \epsilon^\lambda \epsilon_\mu = C^{[\sigma | \nu | \mu]} + M^{\sigma (\nu \mu)}. \)

As a matter of fact it is well known that given an object with three indices, \( O^{\sigma \nu \mu} \), it has a unique decomposition of the form \( O^{\sigma \nu \mu} = O^{[\sigma | \nu | \mu]} + O^{(\nu \mu)} \). In particular, defining the antisymmetric combination

\[ S^A_B \phi^B := Q^{A \nu \lambda} \epsilon^\lambda \epsilon_\mu - Q^{A \mu \nu} \epsilon^\mu \epsilon_\nu, \]

(\( Q^{A \nu \lambda} \) is linear in the fields for the Lie derivative (3.4)) it turns out that

\[ C^{[\sigma \nu | \mu]} = \frac{1}{2} \left( \frac{\partial L}{\partial \nabla_\mu \phi^A} S^A_B \phi^B + \frac{\partial L}{\partial \nabla_\nu \phi^A} S^A_B \phi^B + \frac{\partial L}{\partial \nabla_\sigma \phi^A} S^A_B \phi^B \right). \]

(3.16)

Expressions (3.15) and (3.16) generalize to curved spacetime the classical formulas for obtaining Belinfante’s tensor density as an improvement of the canonical tensor density (see section 4.1 of [1]). With a caveat: in curved spacetime, since (3.8) and (3.7) imply that Belinfante’s tensor density is covariantly conserved on shell, we infer that the canonical tensor density is not conserved in general [6]. Indeed, from the third equation in (3.14) we obtain

\[ \nabla_\sigma T^\sigma_\mu \quad \text{(on shell)} \]

\[ = \frac{1}{2} C^{[\sigma | \nu | \rho]} R_{\rho \sigma \nu \mu}, \]

(3.17)

with \( R_{\rho \sigma \nu \mu} \) the Riemann tensor. Thus the construction of the Belinfante tensor density out of the canonical tensor density is not exactly an improvement but a procedure to obtain a conserved tensor density which coincides on shell with Hilbert tensor density (see (3.7)) and thus is symmetric on shell.

---

9 We use the conventions in [10].
Only for Minkowski spacetime -with vanishing Riemann tensor- or for theories with only scalar fields -for which \( Q^{\lambda \mu} \sigma \) in (3.4) vanishes-, the covariant conservation of the canonical tensor density can be generally asserted.

4. Fixed backgrounds with Killing vectors

Complementing what has been already said, we notice that the basic equations of the previous section, (3.6), (3.8), (3.11) and (3.12), can be understood as identities satisfied by the matter Lagrangian \( L^{(0)} \) truncated to a fixed background \( g_0 \). In this section we will interpret these equations in this sense. As identities, they are a gift from the former diffeomorphism covariance enjoyed by the theory before truncation.

An immediate consequence of identity (3.6) and definition (3.7) is that if \( \epsilon^\mu \) is a Killing (\( K \)) vector of the fixed background, that is,

\[
\delta g^{\mu \nu} = \nabla_\mu \epsilon_\nu + \nabla_\nu \epsilon_\mu = 0, \quad (\Leftrightarrow \epsilon^\mu \in K),
\]

then

\[
[L^{(0)}], \delta \phi^\lambda + \nabla_\lambda (T^\lambda_{\mu} \epsilon^\mu) = 0, \quad (\epsilon^\mu \in K), \tag{4.2}
\]

identically. Equation (4.2) neatly displays the result that the Killing symmetries of the background \( g_0 \) have morphed into rigid Noether symmetries for the truncated Lagrangian \( L^{(0)} \). Also this equation identifies the vector density

\[
J^\lambda := T^\lambda_{\mu} \epsilon^\mu, \quad (\epsilon^\mu \in K), \tag{4.3}
\]

as the Noether current for this rigid symmetry, \([L^{(0)}], \delta \phi^A + \partial_\lambda J^\lambda = 0\). We may say:

> In field theory, the conserved density current of a Noether symmetry generated by a Killing vector of the fixed background, is the contraction of the Belinfante energy-momentum tensor with such Killing vector.

One finds in the literature a trivial proof of the existence of an on shell conserved current \( T^\lambda_{\mu} \epsilon^\mu \) based on the Killing condition (4.1) and the fact that Hilbert tensor is -on shell- covariantly conserved, but the status of a Noether symmetry is more than that, and this conservation does not make the current \( T^\lambda_{\mu} \epsilon^\mu \) to be a Noether current -although both currents, \( T^\lambda_{\mu} \epsilon^\mu \) and \( T^\lambda_{\mu} \epsilon^\mu \), coincide on shell. The true Noether current associated with the Killing symmetries of a fixed background is (4.3), which uses the Belinfante -not Hilbert’s- tensor density. Switching to canonical variables, one would find as generator -under the Poisson bracket- of the symmetry the quantity \( G := \int d^3xJ^0 \), which, under suitable conditions at the spatial boundary, is a conserved charge.

In addition, if the matter theory is a gauge theory there may be obstructions [11] for this quantity \( G \) to generate the symmetry transformations in phase space. All these aspects are illustrated in the example we work out in appendix A, with details on the use of the Noether current in vacuum Maxwell theory in flat spacetime, and on the crucial role played by Belinfante tensor in constructing the internal gauge symmetry generators.

Notice that in the case of a fixed background with Killing vectors, as far as the rigid Noether symmetries generated by the Killing vectors are concerned, we do not need to restrict ourselves to the minimal coupling case leading to (3.10), because \( \delta g_{\mu \nu} \) vanishes. Thus we can write (3.10), with no restrictions on the coupling to gravity, as
\[ \delta L^{(0)} = [L^{(0)}]_A \delta \phi^A + \nabla_\mu \left( \frac{\partial L^{(0)}}{\partial \nabla_\mu \phi^A} \delta \phi^A \right) = \nabla_\mu (\epsilon^\mu L^{(0)}), \quad (\epsilon^\mu \in K.) \] (4.4)

for the Lagrangian \( L^{(0)} \) in the fixed background \( g_0 \) and with \( \epsilon^\mu \) being a Killing vector of \( g_0 \).

Comparison of (4.4) with (4.2) shows the existence of an identically conserved density current

\[ \nabla_\sigma \left( \mathcal{T}_\sigma^\mu \epsilon^\mu - \frac{\partial L^{(0)}}{\partial \nabla_\sigma \phi^A} \delta \phi^A + \epsilon^\sigma L^{(0)} \right) = 0, \quad (\epsilon^\mu \in K.), \] (4.5)

which, again, is a gift from the general covariance properties held by the theory before being truncated to a fixed background.

Some comments are in order. Equations (4.5) and (4.2) show that there are two equivalent presentations of the Noether conserved density current associated with the Killing symmetry. The ‘classical’ one would have been, by typical use of Noetherian methods, from (4.4),

\[ J^\mu_{\text{class.}} = \frac{\partial L^{(0)}}{\partial \nabla_\mu \phi^A} \delta \phi^A - \epsilon^\mu L^{(0)}, \quad (\epsilon^\mu \in K.), \]

whereas the alternative presentation is (4.3).

As far as we know, little attention is paid in the literature to the relationship existing between these two currents. Both currents differ by an identically conserved density current which must have locally the form \( J^\mu - J^\mu_{\text{class.}} = \partial_\nu N^{\mu \nu} \), with \( N^{\mu \nu} \) an antisymmetric tensor density\(^{10}\). Thus, both \( G = \int d^3x \mathcal{J}^0 \) or \( G_{\text{class.}} = \int d^3x J^0_{\text{class.}} \) generate the same transformations because they differ by a boundary term.

Just as an example, let us consider the Lagrangian

\[ L^{(0)} = \frac{1}{2} \sqrt{-g} R \phi^2 \]

which describes a non-minimal coupling of a scalar field with the metric through the curvature scalar, here for a fixed background, and suppose that \( \epsilon^\mu \) is a Killing vector for this background.

The antisymmetric tensor density mentioned above turns out to be

\[ N^{\mu \nu} = \sqrt{-g} \left( \nabla^\mu (\phi^2 \epsilon^\nu) - \nabla^\nu (\phi^2 \epsilon^\mu) - \phi^2 \nabla^\mu \epsilon^\nu \right), \quad (\epsilon^\mu \in K.), \]

so that \( \partial_\nu N^{\mu \nu} \) is the identically conserved current in (4.5) in this particular case.

### 4.1. Conformal Killing vectors

Going back to (3.6)

\[ -T^{\mu \nu} \nabla_\mu \epsilon_\nu + [L]_A \delta \phi^A + \nabla_\sigma \left( \mathcal{T}_\sigma^\mu \epsilon^\mu \right) = 0, \] (4.6)

for arbitrary \( \epsilon^\mu \), we realize that conformal Killing vectors,

\[ \nabla_\mu \epsilon_\nu + \nabla_\nu \epsilon_\mu = \lambda g_{\mu \nu}, \]

\(^{10}\) Given a totally antisymmetric tensor density \( N^{\mu_1 \mu_2 \ldots \mu_n} \), we have, with a torsionless connection,

\[ \partial_\mu N^{\mu_1 \mu_2 \ldots \mu_n} = \nabla_\mu N^{\mu_1 \mu_2 \ldots \mu_n}. \]
are Noether symmetries of the truncated Lagrangian as long as the product $T\lambda$ is a divergence, with $T$ the trace of the Hilbert tensor density. Thus the requirement is $T\lambda = \nabla_{\mu}D^\mu = \partial_{\mu}D^\mu$ for a vector density $D^\mu$. Then (4.6) will be written as

$$[\mathcal{L}]_A \delta \phi^A + \nabla_{\sigma} \left( T^\mu_{\nu} \epsilon^\mu - \frac{1}{2} D^\rho \right) = 0,$$

which identifies the new vector density current $T^\mu_{\nu} = \partial_{\rho}D^\rho$ associated with the Noether symmetry. Condition $T\lambda = \partial_{\mu}D^\mu$ amounts\(^{11}\) to require that the Euler–Lagrange derivatives of $T\lambda$ vanish,

$$\frac{\delta(T\lambda)}{\delta \phi^A} = \frac{\delta T}{\delta \phi^A} \lambda - \frac{\partial T}{\partial \nabla_{\mu} \phi^A} \partial_{\mu} \lambda = 0. \quad (4.8)$$

This is a check that must be done in a case by case basis. In the particular case of homothetic conformal Killing vectors ($\lambda = \text{constant}$), the condition to implement a Noether symmetry is that $T$ must be a divergence, that is $\frac{\delta T}{\delta \phi^A} = 0$.

Obviously $T = 0$ is a particular case of fulfillment of (4.8). In such case, all conformal Killing vectors yield Noether symmetries of the truncated theory. A well know example is Maxwell theory in a curved background—including the flat case—where the Hilbert tensor density satisfies this condition in $d = 4$ dimensions. Indeed for the Lagrangian $\mathcal{L} = -\frac{1}{4} \sqrt{-g} F^{\rho\sigma} F_{\rho\sigma}$ the Hilbert tensor density is

$$T^{\mu\nu} = -g^{\mu\nu}\mathcal{L} + \sqrt{-g} F^\rho_{\sigma} F^{\sigma\nu} \quad (4.9)$$

whose trace is $T = (4 - d)\mathcal{L}$.

5. Extended objects: the Nambu–Goto brane

Consider a Lorentzian manifold $P$—the background—and a submanifold $M$—the $p$-brane, or brane. The Levi Civita covariant derivative is defined on $P$. As notation, $x^\mu$ will be the coordinates on $P$ and $\sigma^a$ the coordinates on $M$. The embedding of the brane is locally defined by the functions $x^\mu(\sigma)$. Thus, on the tangent bundle $TM$,

$$\frac{\partial}{\partial \sigma^a} = \frac{\partial x^\mu}{\partial \sigma^a} \frac{\partial}{\partial x^\mu} = U^\mu_a \frac{\partial}{\partial x^\mu}. \quad (5.1)$$

As a matter of language, we can also say that the world volume $M$ is embedded in the target spacetime $P$.

Notice that $U^\mu_a$, defined with support on $M$, is a contravariant vector under reparametrizations of the background and a covariant vector under reparametrizations of the brane.

Let $g_{\mu\nu}$ be the background metric. The induced metric on the brane is locally given by

$$\gamma_{ab} = g_{\mu\nu} U^\mu_a U^\nu_b. \quad (5.2)$$

We consider massive branes. The $p$-brane is a $p$-dimensional spacelike object evolving along the time coordinate of the Lorentzian manifold $P$, thus the induced metric $\gamma_{ab}$ is again Lorentzian. Considering the index $a$ as a label, $U^\mu_a$ span a basis for $TM$. We can rise and lower indices with $\gamma_{ab}$, $g_{\mu\nu}$, and their inverses, so for instance $U^\mu_{\nu} := \gamma^{ab} g_{\mu\nu} U^\mu_b$. Note that

$$r^\mu_{\nu} = U^\mu_a U^\nu_b. \quad (5.1)$$

\(^{11}\) All our statements are local.
is the projector from $TP|_\mu$ to $TM$. Note also that given a vector $v^\mu$ in $TP|_\mu$, its orthogonal projection to $TM$ is $v'^\mu := \bar{U}^\mu_a v^a$ (proof: $\bar{U}^\mu_a U^a_\mu v^\mu = U^\mu_\nu v^\nu =: v'^\mu$). More geometric results are given in appendix B.

The Nambu–Goto (NG) Lagrangian of the $p$-brane is

$$L = -\kappa \sqrt{-\gamma}, \quad (5.2)$$

where $\gamma$ is the determinant of $\gamma_{ab}$ and $\kappa$ is the tension of the brane. In the following we will take $\kappa = 1$ for simplicity.

Regarding the analysis of the covariance of (5.2) with respect to spacetime diffeomorphisms, there is the crucial difference as to whether we consider a dynamical or a fixed background. Of course if the background is dynamical the variational principle with Lagrangian (5.2) is incomplete because the kinetic terms -for instance the Einstein–Hilbert Lagrangian—phisms imposes that the new spacetime metric $\bar{g}_{\mu\nu}$ is computed at the points $x'(\sigma)$ of the new embedding, Since the new embedding is $x'^\mu(\sigma) = x^\mu(\sigma) - \epsilon(\sigma)$, we obtain (to first order in the infinitesimal parameter)

$$\gamma'_{ab} = g'_{\mu\nu}(x(\sigma)) \frac{\partial x'^\mu}{\partial \sigma^a} \frac{\partial x'^\nu}{\partial \sigma^b}.$$

Notice in this expression above the subtle point that the active interpretation of diffeomorphisms imposes that the new spacetime metric $\bar{g}_{\mu\nu}$ is computed at the points $x'(\sigma)$ of the new embedding. Since the new embedding is $x'^\mu(\sigma) = x^\mu(\sigma) - \epsilon(\sigma)$, we obtain (to first order in the infinitesimal parameter)

$$\gamma'_{ab} = g'_{\mu\nu}(x(\sigma)) \frac{\partial x'^\mu - \epsilon(x(\sigma))}{\partial \sigma^a} \frac{\partial x'^\nu - \epsilon(x(\sigma))}{\partial \sigma^b}$$

and from this invariance of the induced metric we infer that $\delta L = 0$.

Note that the proof of invariance would be the same for a Lagrangian describing the minimal coupling of a $p$-brane with a $p + 1$ form, which is a generalization of the coupling of the particle to the electromagnetic gauge field: again, the change of the world volume description of the brane will be matched by the active change of the $p + 1$ form.

Thus the requisite of general covariance is satisfied. Of course under world volume diffeomorphisms the Lagrangian is not invariant but behaves as a scalar density, see details in section 6.2. Summing up,

*The Lagrangians of the NG brane and its generalizations are scalar densities under world volume diffeomorphisms and are invariant under target space diffeomorphisms.*

---

12 This result implies that for vectors already in $TM$ but expressed in the target spacetime coordinates, $U^\mu_a$ converts target spacetime indices into world volume indices.
5.2. Fixed background

In the case of a fixed background, an active diffeomorphism will move the brane and all the other existing structures and fields according to their geometric character, except for the metric, which will remain unchanged. The reason is that in the active view we do not change the coordinates and hence a fixed background remains the same.

Now the Lagrangian will have changed to \( \mathcal{L}' = -\sqrt{-\gamma'} \), where

\[
\gamma'_{ab} = g_{\mu\nu}(x'(\sigma)) \frac{\partial x'^\mu}{\partial \sigma^a} \frac{\partial x'^\nu}{\partial \sigma^b},
\]

(notice the crucial difference with the previous case: now we have written \( g \) instead of \( g' \)) and we obtain

\[
\gamma'_{ab} = (g_{\mu\nu}(x) - \mathcal{L}_\epsilon g_{\mu\nu}) U_a^\mu U_b^\nu,
\]

where \( \mathcal{L}_\epsilon \) is the Lie derivative under the vector field \( \epsilon^\mu \). As for the determinant,

\[
\gamma' = \gamma (1 - t_{\mu\nu} \mathcal{L}_\epsilon g_{\mu\nu}),
\]

with \( t_{\mu\nu} = \gamma^{ab} U_a^\mu U_b^\nu \) the projector defined above, (5.1). Finally, for the variation of the Lagrangian we obtain

\[
\delta \mathcal{L} = \mathcal{L}' - \mathcal{L} = \frac{1}{2} \sqrt{-\gamma} t_{\mu\nu} \epsilon^\mu \mathcal{L}_\epsilon g_{\mu\nu}.
\] (5.4)

Note that if \( \epsilon \) is a Killing vector of the background, then \( \mathcal{L}_\epsilon g_{\mu\nu} = 0 \), that is, the Lagrangian is invariant, but now under a rigid, not gauge, symmetry. Summing up, starting with a theory (5.2) with invariance under the target spacetime diffeomorphisms, we have ended up, after freezing the background, with a theory in which the Killing symmetries of such fixed background have morphed into rigid Noether symmetries of the new theory. This is the same phenomenon already seen in field theory, equations (4.2) and (4.3).

We can look for the conserved current under this symmetry. Since \((\mathcal{L})_{\mu} := \frac{\delta \mathcal{L}}{\delta \epsilon^\mu} \) is the Euler–Lagrange derivative

\[
\delta \mathcal{L} = |\mathcal{L}|_{\epsilon} \delta x^\mu + \partial_a (\frac{\partial \mathcal{L}}{\partial U_a^\mu} \delta x^\mu),
\] (5.5)

now for \( \delta x^\mu = -\epsilon^\mu \), with \( \epsilon^\mu \) being a Killing vector, and since \( \delta \mathcal{L} = 0 \) (from (5.4)), we infer from (5.5) that the -on shell- conserved current is the -world volume- density vector (we can always factor out the infinitesimal parameter in \( \epsilon^\mu \) so \( \epsilon^\mu \) can be taken as finite)

\[
J^\mu = \frac{\partial \mathcal{L}}{\partial U_a^\mu} \delta x^\mu = -\frac{\partial \mathcal{L}}{\partial U_a^\mu} \epsilon^\mu = \sqrt{-\gamma} U_a^\mu \epsilon^\mu = \sqrt{-\gamma} \epsilon^\mu, \quad (\epsilon^\mu \in K).
\] (5.6)

This is a nice result: according to the interpretation of \( U_a^\mu \) made after equation (5.1), we have found that

For the NG brane, the conserved density current of a Noether symmetry generated by a Killing vector of the fixed background, is the densitized projection to TM of such Killing vector.

Eventually there can be a conserved charge \( G(\tau) = \int_0^\tau d\sigma J^\sigma \), where the integration is at \( \sigma^0 \equiv \tau \) constant, but this conservation in \( \tau \) will crucially depend on the spatial boundary of the brane. In the particular case of the massive particle in a fixed background, with Lagrangian \( L = -m \sqrt{-g_{\mu\nu} x'^\mu x'^\nu} \), this conserved charge is

\[
G = \frac{1}{\sqrt{-g_{\mu\nu} x'^\mu x'^\nu}} \epsilon^\mu g_{\mu\nu} x'^\nu.
\]
But regardless of being conserved or not, $G(\tau)$ is the gauge generator in the canonical formalism. Since from (5.6) $J^\rho = \frac{\partial L}{\partial \dot{\gamma}^\rho} \dot{x}^\mu = -p_\mu \epsilon^\mu$, with $p_\mu$ the momenta canonically conjugate to the target spacetime coordinates, we obtain for the variation of the embedding the expected result,

$$\delta \dot{x}^\mu = \{x^\mu, G\}_{\text{equiv}} = \{x^\mu, -\int_\tau d\sigma \epsilon^\rho p_\rho \} = -\epsilon^\mu.$$ 

The algebra of the Noether symmetries associated with Killing symmetries of the fixed background reproduces that of the Killing symmetries. If $\epsilon$ and $\eta$ are two Killing vectors, then $G_\epsilon$ and $G_\eta$ satisfy $\{G_\epsilon, G_\eta\} = G_{[\epsilon, \eta]}$.

Again with the massive particle, consider a stationary background (with $x_0$ the background time coordinate), so that $\partial_{x_0}$ is a Killing vector ($\epsilon^\mu = \delta^\mu_0$). If $\tau$ is the world line parameter, the induced metric has a single component $\gamma_{\tau\tau} = \dot{x}^2 = \gamma$, where $\dot{x}^2 = g_{\mu\nu} \dot{x}^\mu \dot{x}^\nu$. The embedding is $U^\mu = \dot{x}^\mu$ and $U^\tau = \gamma^{-1} g_{\mu\nu} U^\nu = g_{\mu\nu} \dot{x}^\nu$ so $\sqrt{-\gamma} U^\mu = -g_{\mu\nu} \dot{x}^\nu = -p_\mu$. Applying (5.6), the conserved quantity $J^\rho \equiv G = -\delta^\mu_0 p_\mu = -p_0$, which is the expected result for a mechanical system with a cyclic coordinate $x_0$, namely that its conjugate momentum $p_0$ is a constant of motion.

6. Noether identities for the brane

It is instructive, regardless of the Killing condition, to compute directly the divergence of $\epsilon^\mu := U^\mu_0 \epsilon^\mu$ for an arbitrary, infinitesimal, $\epsilon^\mu$. We have

$$\frac{1}{\sqrt{-\gamma}} \partial_\mu (\sqrt{-\gamma} \epsilon^\mu) = \nabla_\mu \epsilon^\mu = \nabla_\mu (U^\mu_0 \epsilon^\mu) = \nabla_\mu (U^\mu_0) \epsilon^\mu + U^\mu_0 \nabla_\mu (\epsilon^\mu)$$

$$= \gamma^{ab} g_{\mu\nu} \nabla_\mu (U^\mu_b) \epsilon^a + U^\mu_0 U^\rho_a g_{\mu\nu} \nabla_\nu (\epsilon^a) = \gamma^{ab} g_{\mu\nu} K^\nu_a \epsilon^b + \frac{1}{2} \epsilon^\mu \nabla_\mu L_{g\rho\nu}, \quad (6.1)$$

(where we have used that $\nabla_\mu U^\mu_b = K^\nu_b$ is the extrinsic curvature of the brane). See the appendix B for details and also for a discussion on the covariant derivatives $\nabla_\mu, \nabla_\nu, \nabla_\rho$. Note that (6.1) can be rearranged as ($K^\nu$ is the trace of the extrinsic curvature)

$$\frac{1}{2} \sqrt{-\gamma} \epsilon^\mu \nabla_\mu L_{g\rho\nu} = -\sqrt{-\gamma} g_{\mu\nu} K^\nu \epsilon^\mu + \partial_\mu (\sqrt{-\gamma} \epsilon^\mu), \quad (6.2)$$

which is exactly (5.5) applied to our case with $\delta \dot{x}^\mu = -\epsilon^\mu$ and $\epsilon^\mu := U^\mu_0 \epsilon^\mu$. Equation (6.2) is an identity -actually, it is a Noether identity, see next subsection- with $\epsilon^\mu$ arbitrary. As a byproduct we obtain, comparing (5.5) and (6.2),

$$[L]_{\mu} := \frac{\delta L}{\delta \dot{x}^\mu} = \sqrt{-\gamma} g_{\mu\nu} K^\nu, \quad (6.3)$$

that is, we have obtained the well known result (see for instance [16]) that the EOM for the NG Lagrangian is the vanishing of the trace of the extrinsic curvature, with no need to make the explicit computation of the EOM.

6.1. Target spacetime Noether identities

As anticipated above, equation (6.2) has yet another interpretation: it is the Noether identity for the target spacetime diffeomorphism invariance of the NG Lagrangian (5.2) when the
background is dynamical. Indeed, given some fields -or field components- $\psi^A$ and expressing the active infinitesimal gauge transformation as (3.1) (with $\delta \psi^A(\sigma) = -e^\mu(\sigma)$) but now for the world volume action,

$$\delta \psi^A = R^A_{\mu} e^\mu + Q_{\rho}^A \partial_\rho e^\mu,$$

(6.4)

where $\psi^A$ is a generic field or field component and $\partial_\rho e^\mu = U_{\rho}^\mu \partial_\mu e^\nu$. The Noether identity -in the version with the arbitrary functions in it- takes the form (3.3), but with derivatives with respect to the $\sigma^a$ coordinates of the brane,

$$[L]_A \delta \psi^A = \partial_a [L]_A Q^A_{\rho} e^\rho = 0.$$

(6.5)

In our case the fields $\psi^A$ are the target coordinates $x^\mu(\sigma)$ and the metric $g_{\mu\nu}(x(\sigma))$. For the metric $\delta g_{\mu\nu} = L g_{\mu\nu}$, which implies (with $A = (\mu\nu)$), for the world volume description,

$$\delta g_{\mu\nu} = R_{(\mu
u)} e^\mu + Q_{(\mu
u)}^\rho \partial_\rho e^\nu,$$

(6.6)

then, taking this into account, together with $\delta x^\mu = -e^\mu$, we obtain the Noether identity associated with target spacetime diffeomorphism invariance of the NG brane, $(L)^{\mu\nu} = \frac{\partial L}{\partial g_{\mu\nu}}$, $[L]_\mu = \frac{\partial L}{\partial g_{\mu\nu}}$

$$[L]^{\mu\nu} \partial_\nu g_{\mu\nu} - [L]_\mu - \partial_\mu \left([L]^{\rho\nu} g_{\rho\mu} U_{\nu}^\mu + g_{\mu\nu} U_{\nu}^\mu \right) = 0,$$

(6.7)

identically. Using the fact that $\frac{\partial L}{\partial g_{\mu\nu}} = -\frac{1}{\sqrt{-g}} T^{\mu\nu}$ and equation (6.3), one can check that equation (6.7), saturated with $e^\rho$, becomes (6.2).

The advantage of the Noether identity formulation, equations (6.5)–(6.7), is that it shows how the mechanism works beyond the NG Lagrangian, that is, when we consider corrections to it. In the first term of equation (6.5) there will always be the term $\frac{\partial L}{\partial g_{\mu\nu}} \delta g_{\mu\nu}$. If the background is fixed the factor $\frac{\partial L}{\partial g_{\mu\nu}}$ will not vanish in general but $\delta g_{\mu\nu}$ will vanish -by definition- for the variations engendered by the Killing vectors of the metric, thus defining the on shell conserved current, see equations (6.5) and (6.6), $J^a = -\frac{\partial L}{\partial g_{\mu\nu}} Q_{(\mu\nu)}^a e^\rho$.

### 6.2. World volume Noether identities

Clearly, the NG Lagrangian (5.2) is generally covariant with respect to world volume diffeomorphisms, so that in the active interpretation, with $\delta \sigma^{a} = -\eta^a(\sigma)$, we will have $\delta x^\mu = \eta^a \partial_a x^\mu(\sigma)$ and, due to the variation $\delta x^\mu$, there will be a vicarious variation of $g_{\mu\nu}(x(\sigma))$, but the metric will not have any variation by its own, unlike the case of the target spacetime diffeomorphisms (both the target coordinates and the metric components are scalars under world volume diffeomorphisms). All in all we find the world volume scalar density behaviour $\delta L = \partial_a (\eta^a L)$.

The Noether identity becomes

$$[L], U_{\nu}^\mu = 0,$$

identically. Its contents for the NG case is just $K^a g_{\mu\nu} U_{\nu}^\mu = 0$, which is an identity proved directly in appendix B, see equation (B.9).

### 7. Conclusions

In this paper we have used the Noether identities for generally covariant field theories to extend the results in [1] to curved spacetime and in addition we have made a parallel analysis
for the case of extended objects embedded in the background. In the field theory case we have reobtained in particular the results of [6] concerning the relationship between the canonical tensor, Belinfante energy-momentum tensor, and Hilbert energy-momentum tensor. When these results are applied to matter Lagrangians truncated to a fixed background, we have shown that the Killing symmetries of the background become ordinary, non-gauge, Noether symmetries of the truncated theory. We stress the role of the Belinfante tensor in the construction both of the Noether conserved current and of the canonical generator of the symmetries.

We have followed similar lines to analyze the case of NG branes embedded in the background, distinguishing the two types of gauge symmetries available, namely target space diffeomorphisms and world volume diffeomorphisms. We use the Noether identities of the former type to give an alternative derivation of the EOM of the theory truncated to a fixed background. Again, the Killing symmetries of the fixed background give rise to Noether symmetries of the world volume theory, with a simple geometric interpretation of the conserved currents.

Appendix A. Poincaré symmetries as the Killing symmetries for Maxwell theory in flat spacetime

In this appendix we do not intend to give a complete analysis on how the Poincaré transformations for the Maxwell gauge field in flat spacetime can be reproduced within the canonical formalism. Our much more modest goal here is to underline the crucial relevance of the Belinfante tensor in such an endeavour.

In flat spacetime (with mostly plus metric $\eta_{\mu\nu} = (-, +, +, +)$) the Maxwell Lagrangian is $\mathcal{L} = -\frac{1}{4} F_{\mu\nu} F^{\mu\nu}$. The momentum canonically conjugate to $A_\mu$ is $\pi^\mu = \frac{\partial \mathcal{L}}{\partial \dot{A}_\mu} = -F^{0\mu}$, which identifies the primary constraint $\pi^0 \simeq 0$ (‘$\simeq$’ means equality on shell). Hilbert energy momentum tensor $T^{\mu\nu}$, (4.9), is obtained by the standard methods. Belinfante energy momentum tensor is, from (3.7),

$$T^{\mu\nu}_b = T^{\mu\nu} - \left[ \mathcal{L} \right]_A Q^{\mu}_{\sigma} \eta^{\sigma\nu} = -\eta^{\mu\nu} \mathcal{L} + F^{\mu}_{\sigma} F^{\sigma\nu} - \partial_{\rho} (F^{\rho\mu}) A_{\sigma} \eta^{\sigma\nu}.$$  

Notice that the last term, which vanishes on shell, distinguishes this tensor from Hilbert tensor $T^{\mu\nu}$.

According to (4.2), the conserved current is

$$J^\mu = T^{\mu}_{\nu} \epsilon^\nu = -\mathcal{L} \epsilon^\mu + F^{\mu}_{\sigma} F^{\sigma\nu} \epsilon^\nu - \partial_{\rho} (F^{\rho\mu}) A_{\nu} \epsilon^\nu$$

with the Killing vector $\epsilon^\nu = a^\nu + \omega^\nu_\rho x^\rho$ describing the infinitesimal Poincaré transformations.

The candidate to be the generator of these transformations is $G = \int d^3 x J^\mu$, which expressed with the canonical variables is ($\mu = 0, i$), with $B^\rho = \frac{1}{2} \epsilon^{\rho\delta} F_{\delta\lambda}$,

$$G(\epsilon^\mu) = \int d^3 x \left( \frac{1}{2} (\pi^2 + \vec{B}^2) \epsilon^0 + (\vec{\pi} \times \vec{B}) \cdot \epsilon - (\partial_\mu \pi^\mu) A_\mu \epsilon^\mu \right).$$  \hspace{1cm} (A.1)

There is an ambiguity in $G$ because a term linear in the primary constraint $\pi^0$ can be added without consequences in tangent space -the pullback of this term from phase space to tangent
space vanishes identically-. This ambiguity can be solved in the light of the analysis in [11] but we will not dwell further on this issue.

Although it is not our goal here, let us mention that, following the results in [11], one can immediately identify a problem with this expression \( \text{(A.1)} \), in what concerns its eventual role as generator of Noether symmetries. As a matter of fact,

\[
\{ G, \pi^0 \} = - (\partial_i \pi^i) e^0,
\]

where one can identify in the right hand side the secondary constraint of Maxwell theory -the Gauss law- \( \partial_i \pi^i \simeq 0 \). The presence of a -necessarily first class- secondary constraint in the rhs of the computation of the Poisson bracket of \( G \) with a -first class- primary constraint signals an obstruction for the projectability -from tangent space to phase space- of some of the transformations generated by \( G \). In our case we infer, from the results of [11] section 3.2, that this quantity \( G \) will not generate the time translation for \( A_0 \). We say that this transformation, which can be written straightforwardly in tangent space,

\[
\delta \epsilon_i = \pi^i \epsilon^0 - F_{ij} \epsilon^j + (\partial_\nu \epsilon^0) A_\nu A_i + A_\nu \partial \nu \epsilon^0 = \mathcal{L}_\epsilon A_i,
\]

(A.2)

with \( \mathcal{L}_\epsilon \) the Lie derivative under the -Poincaré- Killing vector \( \epsilon^\nu = a^\nu + \omega^\nu_\rho x^\rho \). In fact, reminiscent of the original diffeomorphism covariance -before truncation to a fixed background- of our matter Lagrangian, Equation (A.2) gives indeed the right transformation under general diffeomorphisms (arbitrary \( \epsilon^\mu \)) but only for Poincaré transformations we do have a Noether symmetry in flat spacetime.

Let us stress the crucial role played in this computation by the term \( (\partial_i \pi^i) A_\mu \epsilon^\mu \) in (A.1), which would have been missing should we had used the Hibert tensor instead of Belinfante’s. The projectability problem mentioned above is solved by adding to the generator (A.1) the generator of a particular \( U(1) \) gauge transformation. Details in the more general framework of Einstein–Yang–Mills theories are given in [14].

**Appendix B. Basic notions on the extrinsic curvature**

Consider a Riemannian or Lorentzian manifold \( P \) -the background- and a submanifold \( M \) -the brane. The Levi Civita covariant derivative is defined on \( P \). As notation, \( x^\mu \) will be the coordinates on \( P \) and \( \sigma^a \) the coordinates on \( M \). The embedding of the brane is locally defined by the functions \( x^\mu(\sigma) \). Thus, on \( TM \) (tangent space)

---

13 A parallel situation takes place in the canonical formalism of Einstein–Hilbert Lagrangian for general relativity, where some diffeomorphisms are not projectable to phase space, see [12, 13] for an analysis and a way out of that situation.
\[
\frac{\partial}{\partial x^a} = \frac{\partial x^\mu}{\partial x^a} \frac{\partial}{\partial x^\mu} =: U^\mu_a \frac{\partial}{\partial x^\mu}.
\]

Notice that \(U^\mu_a\), defined with support on \(M\), is a contravariant vector under reparametrizations of the background and a covariant vector under reparametrizations of the brane.

Let \(g_{\mu\nu}\) be the background metric. The induced metric on the brane is locally given by

\[
\gamma_{ab} = g_{\mu\nu} U^\mu_a U^\nu_b.
\]

Considering the index \(a\) as a label, \(U^\mu_a\) span a basis for \(\mathcal{T}M\). We can enlarge this basis to form a basis for \(\mathcal{T}P\big|_a (\mathcal{T}P\big|_a = TM \oplus T^*M)\) with some new vectors \(\bar{U}^\mu_a\), with labels \(a',\) which we will take orthonormal and orthogonal to \(TM\), that is, with the notation \(a = (a, a')\),

\[
g_{\mu\nu} \bar{U}^\mu_a \bar{U}^\nu_b = \eta_{ab}.
\]

We can define the matrix \(U^a_{\mu}\) as the inverse matrix to \(U^{\mu}_a\). Notice that these inverses still go through the rule of raising and lowering indices with the corresponding metric or inverse metric:

\[
U^a_{\mu} = \gamma^{ab} g_{\mu\nu} U^\nu_b, \quad U^\mu_a = \eta^{\alpha'\beta'} g_{\alpha'\beta'} U^\beta'_{\nu}.
\]

Consider vector fields \(X, Y\) in \(TM\). One can compute \(\nabla_X Y\) under the background Levi Civita covariant derivative \(\nabla\) and decompose it in its tangent part in \(TM\) and an orthogonal part in \(T^*M\). In fact we have

\[
\delta^\mu_{\nu} = U^\mu_a U^\nu_b + U^\nu_a U^\mu_b =: t^\mu_{\nu} + h^\mu_{\nu},
\]

where \(t^\mu_{\nu}\) projects onto \(TM\) and \(h^\mu_{\nu}\) onto \(T^*M\). The projection to \(TM\) will define the induced covariant derivative on \(TM\) and the projection to \(T^*M\) will define the extrinsic curvature.

### B.1. Induced covariant derivative

With \(X = X^a \partial_a = X^\mu \partial_\mu\) (that is, \(X^\mu = X^a U^\mu_a\)) and same for \(Y\), we obtain, for the tangent part,

\[
(X^\mu \nabla_\mu Y^\nu) t^\nu_{\rho} \partial_\rho = X^\mu \left( \partial_\mu Y^\nu + (\partial_\mu U^\rho_b + U^\rho_a U^\nu_b \Gamma^\nu_{\rho\mu}) U^\nu_b Y^\rho \right) \partial_\rho,
\]

which defines the induced covariant derivative \((X^\mu \nabla_\mu Y^\nu) \partial_\rho\) with connection

\[
\Gamma^\nu_{\rho\mu} := (\partial_\mu X^\rho + U^\rho_a U^\nu_b \Gamma^\nu_{\rho\mu}) U^\nu_b.
\]

This induced connection is obviously torsionless. One can easily check that it is metric compatible by taking for instance adapted coordinates. Thus we infer that \(\Gamma^\nu_{\rho\mu}\) is the Levi Civita connection for \(M\).

### B.2. Extrinsic curvature

The \(T^*M\) component of \(\nabla_X Y\) will define the second fundamental form or extrinsic curvature, \(K^a(X, Y) = (\nabla_X Y^\nu) h^\nu_{\nu}\). Its components in the basis \(U^\nu_b\) of \(T^*M\) turn out to be

\[
K^a_{\nu\mu} = (\partial_\nu X^\rho + U^\rho_a U^\nu_b \Gamma^\nu_{\rho\mu}) U^\nu_b,
\]

which is obviously symmetric. Note that from (B.4) and (B.5) we can write

\[
\partial_\nu X^\rho + U^\rho_a U^\nu_b \Gamma^\nu_{\rho\mu} = \Gamma^\nu_{\mu\nu} U^\nu_c + K^c_{\nu\mu} U^\rho_b.
\]
Now let us remember what we said on the double vector character of $U^\mu_b$ under background and brane reparametrizations. To take into account both behaviours, the complete covariant derivative $\nabla_a$ is defined so that

$$\tilde{\nabla}_a U^\mu_b = \partial_a U^\mu_b + U^\mu_{a\nu} \Gamma^\nu_{\mu\rho} U^\rho_b - \Gamma^\nu_{ab} U^\rho_c.$$  \hspace{1cm} (B.7)

which, in view of (B.6), can be written as

$$\tilde{\nabla}_a U^\mu_b = K^\mu_{ab} U^\nu_c.$$  \hspace{1cm} (B.8)

Now we can directly prove that $K^\mu_{ab}$ is orthogonal to $TM$. Let us compute, using (B.8),

$$A_{abc} = K^\mu_{ab} g_{\mu\nu} U^\nu_c = (\tilde{\nabla}_a U^\mu_b) g_{\mu\nu} U^\nu_c = \tilde{\nabla}_a (U^\mu_b g_{\mu\nu} U^\nu_c) - U^\mu_b g_{\mu\nu} (\tilde{\nabla}_a U^\nu_c) = \nabla_a (\gamma_{bc}) - (\tilde{\nabla}_a U^\nu_c) g_{\mu\nu} U^\rho_b = -A_{abc},$$  \hspace{1cm} (B.9)

but it is well known that a three index quantity $A_{abc}$ symmetric in two indices $(a, b)$ and antisymmetric in two indices $[b, c]$ must vanish.

### B.3. Expressions for the extrinsic curvature

Since $U^\mu_{a\nu}$ are taken orthonormal, we have

$$K^\nu_{ab} = \eta^{cd} K^\nu_{ab} g_{\mu\nu} U^\mu_{cd} = \eta^{cd} (\tilde{\nabla}_a U^\mu_b) g_{\mu\nu} U^\nu_{cd} = -\eta^{cd} U^\mu_b g_{\mu\nu} \nabla_a U^\nu_{cd} = -\eta^{cd} U^\mu_b g_{\mu\nu} U^\rho_a \nabla_\nu U^\rho_{cd}$$  \hspace{1cm} (B.10)

or

$$\nabla_a U^{\nu\nu} = K^\nu_{ab} g^{bc} U^\rho_c.$$  \hspace{1cm} (B.11)

In the particular case of a spacelike codimension one brane on a Lorentzian background, then $c' = 0$, $\eta^{00} = -1$ (mostly plus), $U^\mu_{cd} = n^\mu$ (notice from (B.2) that $n_\mu n^\mu = -1$), $K^\nu_{ab} = : K_{ab}$, which is of interest for the ADM formalism of general relativity [15], we will have, from (B.11) and using $n_\mu \nabla_\mu n^\mu = 0$, $\nabla_\mu n^\mu = K_{ab} n^b$.

If we take an adapted coordinatization, so that $\sigma^\alpha = x^\alpha$ (a subset of the background coordinates) and $M$ is locally defined by the remaining background coordinates $x^\alpha$ as functions of $x^\alpha$, we will have $U^\mu_{a\nu} = \delta^\mu_{a\nu}$ etc, so, from (B.10),

$$K^\nu_{ij} = -\eta^{cd} g_{\mu\nu} \nabla_\nu U^\mu_{ij} = -\eta^{cd} \nabla_\nu U^\mu_{ij} = -\eta^{cd} \Gamma^\nu_{ij} U^\mu_{cd} = -\eta^{cd} \Gamma^\nu_{ij} U^\mu_{j'd},$$

where $U_{j'd} = 0$ has been used in the last two equalities. In the ADM case $M$ will be an equal time surface and we will have $K^\nu_{ij} = \nabla_\nu n_i = \Gamma^\nu_{ij} n_0$.

Continuing with adapted coordinates, the $i,j$ components of the Lie derivative of the background metric read

$$L_{\nu\mu} g_{ij} = U^\mu_{a\nu} \nabla_\mu g_{ij} = g_{ij} \nabla_\nu U^\mu_{a\nu} - g_{ij} \nabla_\nu U^\rho_{a\nu} = -2 \nabla_\nu U^\rho_{ij} = 2 \eta_{ij} \eta^{cd} K^\nu_{ij},$$

so

$$K^\nu_{ij} = \frac{1}{2} \eta^{cd} L_{\nu\mu} g_{ij},$$

which in the ADM case yields $K^\nu_{ij} = -\frac{1}{2} L_n g_{ij}$. 

```
B.4. Dynamical interpretation of the extrinsic curvature

Here we show that the vanishing of the trace of the extrinsic curvature is just the contents of the EOM of the NG brane.

First let us write the trace of the extrinsic curvature, from (B.8)

\[ K^\rho = \gamma^{ab} \tilde{\nabla}_a U_b^\rho = \Box t^\rho + \Gamma^\rho_{\mu\nu}, \]

where \( \Box \) is the Dalembertian of the world volume (the brane) with \( x^\mu \) taken, as it is, as a scalar under world volume diffeomorphisms, and \( \mu^\nu = \gamma^{ab} U^\mu_b U^\nu_a \) is the projector onto \( TM \) defined in (B.3).

Now consider the NG dynamics, defined by the Lagrangian \( L = -\kappa \sqrt{-\gamma} \), with \( \gamma \) the determinant of \( \gamma^{ab} \). The E-L functional derivatives turn out to be

\[ \delta L \delta x^\mu = \kappa g_{\mu\nu} \sqrt{-\gamma} K^\nu. \]

Thus the contents of the EOM is the vanishing of the trace of the extrinsic curvature - the curvature vector [16]. For the 0-brane (particle), \( K^\mu = 0 \) is the geodesic equation with arbitrary time parameter. In fact

\[ K^\mu_{\text{particle}} = \frac{1}{\gamma} P^\mu_\sigma (\dot{x}^\sigma + \dot{x}^\mu \dot{x}^\nu \Gamma^\sigma_{\mu\nu}), \text{ with } P^\mu_\sigma = (\delta^\mu_\sigma - g_{\sigma\lambda} \gamma^{-1}), \]

where \( \gamma = g_{\mu\nu} \dot{x}^\mu \dot{x}^\nu \) and \( P^\mu_\sigma \) is the projector orthogonal to the velocity \( i^\mu \). So \( K^\mu = 0 \) means that \( \dot{x}^\mu + \dot{x}^\mu \dot{x}^\nu \Gamma^\sigma_{\mu\nu} = \alpha x^\sigma \) for some function \( \alpha \). This function \( \alpha \) vanishes when \( \tau \) is taken to be the proper time, or a parameter proportional to it.
