(Received 29 March 2010; revised manuscript received 30 June 2010; published 8 September 2010)

Two members of the isostructural $\text{R}_2\text{CoGa}_8$ intermetallic series, $\text{Er}_2\text{CoGa}_8$ and $\text{Tm}_2\text{CoGa}_8$, have been studied by powder neutron diffraction. Antiferromagnetic ordering of the rare-earth sublattices was confirmed to occur at 3.0 K and 2.0 K, respectively. Furthermore, determination of the critical exponent showed $\text{Er}_2\text{CoGa}_8$ to adopt a three-dimensional universality class. In spite of a common magnetic easy axis and similar structural characteristics, the antiferromagnetic structures were found to be different for the erbium- and thulium-based compounds. The corresponding magnetic space groups were determined to be $P_{2_1}mmm'$ and $P_{n}mmm$. The difference in magnetic structures is discussed based on crystal electric field effects that are known to be prevalent in such materials.

I. INTRODUCTION

Rare-earth intermetallic compounds are a class of material that exhibit a diverse range of fascinating physical properties. For example heavy-fermion behavior, Kondo ground states, quantum criticality, and pressure-induced superconductivity have all been found. These phenomena are likely to be due to the competition of microscopic electronic interactions such as the magnetism and crystal electric field (CEF). A common theme in many intermettalic is the dependence of the electronic properties on the rare-earth ion. For example, $\text{CeCu}_2\text{Si}_2$ was found to undergo a transition into a superconducting state below $\sim 1$ K that did not comply with the conventional Bardeen-Cooper-Schrieffer theory of superconductivity. However, $\text{LaCu}_2\text{Si}_2$ remains in a normal state down to 50 mK. Further, a number of different magnetic structures have been measured across the series, solely dependent upon the choice of rare-earth ion. The role of the rare-earth ion in the microscopic behavior of these systems remains an important question, specifically the interaction of the 4f magnetism with the CEF. In this paper we concentrate on the newly synthesized $\text{R}_2\text{CoGa}_8$ series, which has been shown to exhibit a strong coupling between the 4f magnetism and the CEF. Consequently, a variety of electronic properties have been shown to be dependent upon the rare-earth ion.

The $\text{R}_2\text{CoGa}_8$ series is limited to $\text{R}=\text{Gd-Lu}$ and $\text{Y}$ due to an instability in the crystallization of the lighter rare-earth compounds. The series is isostructural, adopting at room temperature the tetragonal space group $P4/mmm$. This type of structure hosts a number of recently discovered heavy-fermion superconductors such as $\text{Ce}_2\text{CoIn}_8$, $\text{Ce}_2\text{RhIn}_8$, and $\text{Ce}_2\text{PdIn}_8$. The crystal structure can be thought of as a stacking of $\text{RGa}_3$ units between CoGa$_3$ layers in the direction of the fourfold tetragonal axis. A thorough survey of magnetization and transport properties was published by Joshi et al., in which an in-depth comparison between the $\text{R}_2\text{CoGa}_8$ series and other rare-earth intermetallic compounds was presented. Of particular interest is the dependence of the magnetic anisotropy upon the rare-earth ion radii. This splits the series into four groups. These are the diamagnetic compounds with $\text{R}=\text{Y}$ and Lu, isotropic Gd$_2\text{CoGa}_8$ (as for Gd$^{3+}$ $L=0$), $\text{R}=\text{Tb, Dy, and Ho}$ compounds with a magnetization easy axis parallel to the c axis and finally $\text{R}=\text{Er}$ and Tm compounds, which have a magnetization easy axis perpendicular to the c axis. In this study we focus on the latter erbium and thulium based members. The two compounds antiferromagnetically order at $T_N=3.0$ K and 2.0 K, respectively, and $\text{Er}_2\text{CoGa}_8$ is on the border between having a magnetization easy axis parallel or perpendicular to the c axis.

In order to properly explain the bulk magnetic properties one must account for CEF effects. This is particularly apparent through CEF calculations that can explain the rare-earth-dependent anisotropy of magnetization, correctly predicting the direction of the magnetic easy axis and its dependence on rare-earth substitution. Furthermore, across the series, the antiferromagnetic transition temperatures are found to be higher than those predicted by de Gennes scaling. This can also be explained through CEF calculations.

To better understand the varied macroscopic properties of intermetallic materials we require a probe of the microscopic electronic ordering phenomena. The only previously published magnetic structure of any member of the $\text{R}_2\text{CoGa}_8$ series was that of $\text{Ho}_2\text{CoGa}_8$, determined by resonant magnetic x-ray scattering. We have performed the first neutron diffraction study of this intermetallic series. We show that $\text{Er}_2\text{CoGa}_8$ and $\text{Tm}_2\text{CoGa}_8$ develop collinear antiferromagnetic structures below their respective Néel temperatures. In both materials, magnetic moments align parallel to the b axis, however they differ in propagation vector, $\mathbf{k}=(0,1/2,0)$ for $\text{Er}_2\text{CoGa}_8$ and $\mathbf{k}=(1/2,0,1/2)$ for $\text{Tm}_2\text{CoGa}_8$, due to CEF effects.

II. EXPERIMENT

Single-crystal samples of $\text{Er}_2\text{CoGa}_8$ and $\text{Tm}_2\text{CoGa}_8$ were grown by the gallium flux technique. Laboratory-based x-ray powder diffraction confirmed the $\text{Er}_2\text{CoGa}_8$ and $\text{Tm}_2\text{CoGa}_8$ room-temperature crystal structures to be tetrag-
A copper wire with a thick copper head, covered with a Cd mask, placed in a cryostat to achieve sample temperatures of less than 300 mK.

A He insert was employed within a standard Oxford Instruments cryostat to achieve sample temperatures of less than 300 mK. Shorter data collections were performed using the FULLPROF suite of programs. Neutron powder diffraction data were collected on both samples using the WISH time of flight instrument on the second target station at the ISIS facility. A 3He sorption insert was employed within a standard Oxford Instruments cryostat to achieve sample temperatures of less than 300 mK. Each sample was loaded into a 6 mm diameter vanadium can with a thick copper head, covered with a Cd mask, placed in contact with the 3He pot. A copper wire (cold finger) was run through the length of the can to ensure better thermal conductivity through the sample. Data were collected with high counting statistics above $T_N$ and at 300 mK, the base temperature of the 3He insert. Shorter data collections were performed upon warming through the transition to determine the temperature dependence of the magnetic scattered intensity. Determinations of the nuclear and magnetic structures were performed using the FULLPROF suite of programs.

### III. RESULTS AND DISCUSSION

The crystal structures of both compounds were refined above, and below, the respective magnetic transitions in the tetragonal $P4/mmm$ space group, as has been reported for Ho$_2$CoGa$_8$. In order to properly reproduce the experimental data, it was necessary to account for additional reflections due to extraneous scatter from the sample can. We therefore included in the refinements a copper nuclear phase (Cu cold finger). This phase was fitted by Le Bail intensity fitting as opposed to the 3He insert. The copper wire was found to be extremely textured. In both samples we found no detectable changes of structural parameters above and below the magnetic transition, indicating that magnetoelastic coupling was negligibly small. We therefore only present the refinements of data measured below $T_N$ at 300 mK. The lattice parameters and fractional coordinates of the inequivalent atom sites are presented in Tables I and II.

![Fig. 1](image.png) FIG. 1. (Color online) Rietveld refinement pattern for Er$_2$CoGa$_8$ at 300 mK. Only data from bank 3 (average $2\theta=90^\circ$) of the WISH instrument was required to achieve high resolution over a sufficiently large time of flight interval to capture all the magnetic reflections. The top, middle, and bottom tick marks refer to Er$_2$CoGa$_8$-nuclear, Cu-nuclear (cold finger), and Er$_2$CoGa$_8$-magnetic phases, respectively. The difference pattern is shown at the bottom of the figure. A number of prominent magnetic reflections are indexed.

for Er$_2$CoGa$_8$ and Tm$_2$CoGa$_8$, respectively. This is in agreement with bulk magnetometry results. Further, by fitting a power law to the Er$_2$CoGa$_8$ data we find a critical exponent of $\beta = 0.33 \pm 0.02$, suggesting that these compounds adopt either the 3D-Ising or 3D-XY universality class. In either case we predict a three-dimensional magnetic system with one-dimensional or two-dimensional order parameters, respectively.

### FIG. 1. (Color online) Rietveld refinement pattern for Er$_2$CoGa$_8$ at 300 mK. Only data from bank 3 (average $2\theta=90^\circ$) of the WISH instrument was required to achieve high resolution over a sufficiently large time of flight interval to capture all the magnetic reflections. The top, middle, and bottom tick marks refer to Er$_2$CoGa$_8$-nuclear, Cu-nuclear (cold finger), and Er$_2$CoGa$_8$-magnetic phases, respectively. The difference pattern is shown at the bottom of the figure. A number of prominent magnetic reflections are indexed.
In the refinement of the magnetic structures, it was assumed that only the rare-earth ions are magnetic. The cobalt ions are expected to be nonmagnetic due to an effective filling of the transition metal 3d states by an excess of gallium 4p electrons in the conduction band. This is confirmed by the fact that $Y_2CoGa_8$ and $Lu_2CoGa_8$ are diamagnetic metals. Furthermore, the low transition temperatures are a signature of probable rare-earth ordering.

Despite having very similar crystal structures and common magnetic easy axes, the 300 mK diffraction patterns (Fig. 1 and 2) clearly show that the two samples have different magnetic propagation vectors. These were determined to be associated with the $X[k=(0,1/2,0)]$ and $R[k=(1/2,0,1/2)]$ points of symmetry (Miller and Love notations) for the erbium and thulium compositions, respectively. In tetragonal symmetry, the choice of the $a$ and $b$ axes is arbitrary when defining the propagation vectors. Here, the $a$ and $b$ axes have been defined such that the magnetic moments lie parallel to the $b$ axis, as will become apparent later. In both cases there are eight one-dimensional irreducible representations (irreps) associated with the corresponding wave vector groups. Six of them enter into the global reducible magnetic representation on the 2g Wyckoff positions of the $P4/mmm$ space group occupied by Er or Tm. The symmetrized combinations of the axial vectors transforming as basis functions of these irreps correspond to the moment directions along the $a$, $b$, and $c$ axes with parallel and antiparallel alignment on the Er/Tm(1) and Er/Tm(2) sites.

Magnetic structure refinements corresponding to the six possible single-irrep models were performed for each sample. The magnetic and structural reliability factors ($R_{Mag}$ and $R_{Bragg}$) and $\chi^2$ for the refinements are given in Table III. It is clear that for each sample only a single model successfully fits the data, as highlighted in bold in Table III and shown in Figs. 1 and 2. We note that for all $Tm_2CoGa_8$ models, the $\chi^2$ values are similar. This is due to the magnetic reflections being weak compared to both the structural reflections and the background. However the $R_{Mag}$ values, which are also large due to the weak magnetic reflections, clearly show the correct model. For both $Er_2CoGa_8$ and $Tm_2CoGa_8$, the fitted magnetic structures correspond to moment directions aligned parallel to the $b$ axis (with respect to our defined propagation vectors) and an AFM stacking along the $c$ axis of $(+-+)$ and $(++-)$, respectively. In a magnetic reso-
nant x-ray diffraction study on Ho2CoGa8 (Ref. 15) it was not possible to determine whether the holmium moments stacked (++−−) or (+−−−) along the c axis. Tm2CoGa8 also adopts a similar c axis stacking, however our results are not ambiguous, and clearly show a single magnetic structure solution.

It should be pointed out that the wave vector stars related to the X and R reciprocal points both consists of two arms. The corresponding noncollinear two-k magnetic structures are undistinguishable from the discussed above collinear single-k models in the powder diffraction experiments. The discrimination can be done only based on monodomain single-crystal measurements or based on observation of nuclear satellite reflections associated with the \[M[k=(1/2, 1/2, 0)]\] reciprocal point and having a specific critical behavior. These reflections are expected in the case of the two-k structures due to the presence of appropriate coupling invariants in a polynomial decomposition of the Landau free energy. The observation of these extremely weak reflections is a difficult experimental task and is possible only in single crystal measurements. However, taking into account the simple exchange topology of the rare-earth sublattice in \([R]_{2}CoGa_{8}\), without geometrical frustration, the noncollinear two-k structures are considered here to be unlikely.

The magnitudes of the magnetic moments at 300 mK were refined to be 4.71(3)\(\mu_B/Er\) and 2.35(4)\(\mu_B/Tm\), as given in Table II. These values are in good agreement with those obtained from bulk magnetization measurements; extrapolating the isothermal magnetization data measured by Joshi et al.11 gives zero field magnetic moments of 4.6 \(\pm 0.1\mu_B/Er\) and 2.90 \(\pm 0.03\mu_B/Tm\). The rare-earth ion moments are found to be much smaller than their theoretical free-ion values of 9\(\mu_B/Er\) and 7\(\mu_B/Tm\). This is expected in such systems where the magnetic behavior is dominated by CEF effects.10

The ground state multiplet degeneracy of the \(R^{3+}\) ions is lifted by the CEF. The wave functions of the split energy invariants in a polynomial decomposition of the Landau free energy. The observation of these extremely weak reflections is a difficult experimental task and is possible only in single crystal measurements. However, taking into account the simple exchange topology of the rare-earth sublattice in \([R]_{2}CoGa_{8}\), without geometrical frustration, the noncollinear two-k structures are considered here to be unlikely.

The ground state multiplet degeneracy of the \(R^{3+}\) ions is lifted by the CEF. The wave functions of the split energy levels were calculated from the CEF parameters found by Joshi et al.,11 in terms of the basis states \([J_z, J]\), using the MCPHASE software package.22 The zero-field ground states of both Er\(^3+\) (doublet) and Tm\(^3+\) (singlet) are nonmagnetic. The state energies and associated \(\langle J_z \rangle\) were calculated as a function of internal magnetic field. For Er\(^3+\), \(\langle J_z \rangle=4.0\mu_B\) in the field range 18–47 T, and for Tm\(^3+\), \(\langle J_z \rangle=2.7\mu_B\) in the field range 1.5–76 T. These values, clearly illustrating the reduction in moment due to the CEF, are close to those determined from neutron powder diffraction. The deviation from the empirically determined values is likely to be due to uncertainties in the CEF parameters, upon which the calculation is based.

In Er\(_2\)CoGa\(_8\) magnetism propagates antiferromagnetically (AFM) along the b axis in the direction of the moments, which ferromagnetically (FM) couple along the a axis (Fig. 4 top). The ab planes of rare-earth ions, containing the easy axis of magnetization, are stacked AFM (++−−) along the c axis. The magnetic space group is \(P_{21}mmm\) (No. 355) (Ref. 23) with lattice vectors being (0,2,0), (0,0,1), and (1,0,0) with respect to the basis of the parent \(P4/mmm\)11 grey group. By contrast, in Tm\(_2\)CoGa\(_8\), the moments in the ab plane align in an opposite fashion to Er\(_2\)CoGa\(_8\), i.e., FM along the b axis and AFM along the a axis (Fig. 4 bottom). Furthermore, the planes are stacked alternately FM/AFM along the c axis (++−−). This magnetic structure can be described by the \(P_{21}mmm\) (No. 353) (Ref. 23) space group with (2,0,0), (0,0,−2), and (0,1,0) basis vectors with respect to \(P4/mmm\)11.

The above magnetic space groups are orthorhombic and as such the tetragonal symmetry of the crystal structure in the paramagnetic phase must be broken below \(T_N\). There was no evidence in our powder-diffraction data of a lowering of crystal symmetry, however the crystallographic distortions due to the magnetostriiction are expected to be extremely small (of the order 10\(^{-4}–10^{-6}\)); beyond the instrument resolution. The crystal structure was therefore refined in tetragonal symmetry below \(T_N\), as given above, despite the symmetry lowering. In this scenario the magnetic structure with \(k=(0,1/2,0)\) and moments parallel to the b axis (in the case...
of Er$_2$CoGa$_8$) is exactly equivalent to a structure with $k = (1/2, 0, 0)$ and moments parallel to the $a$ axis. In fact, these cases correspond to two different domains associated with the different arms of the same wave vector star. Indeed, refinements of both magnetic structures gave equivalent $R_{Bragg}$ and $\chi^2$.

The spacing of the rare-earth ions is approximately ten times greater than the typical radius of the localized, magnetically ordered rare-earth 4$f$ states (~0.5 Å). There is insufficient overlap of wave functions for direct exchange to occur. The dominant exchange interaction in these compounds is therefore the Ruderman-Kittel-Kasuya-Yosida (RKKY) interaction that supports both FM and AFM exchange, dependent upon the interatomic distances. In competition with the RKKY exchange integral are the CEF terms of the Hamiltonian. As a consequence, rare-earth intermetallic systems may exhibit a wide variety of magnetic structures ranging from collinear FM (Ref. 24) to spin glasses. As both Er$_2$CoGa$_8$ and Tm$_2$CoGa$_8$ have similar interatomic distances between the rare-earth ions, we suggest that the difference in magnetic structures is due primarily to the CEF terms. Joshi et al. showed that the extreme magnetic anisotropy exhibited by this intermetallic series can be accounted for by CEF effects. The magnetic structures refined for Er$_2$CoGa$_8$ and Tm$_2$CoGa$_8$ clearly give easy axes lying in the $ab$ plane. The CEF results in a higher susceptibility in the $ab$ plane and the magnetic structure allows for a canted moment in the same direction. Furthermore, in their calculations of the CEF, they find the in-plane and c-axis nearest-neighbor exchange constants to be $J_{ab}/k_B = -0.35$ K and $J_c/k_B = -0.32$ K for Er$_2$CoGa$_8$, and $J_{ab}/k_B = -0.53$ K and $J_c/k_B = -0.075$ K for Tm$_2$CoGa$_8$.

In Er$_2$CoGa$_8$, $J_c$ is approximately equal to $J_{ab}$. Our results show that this scenario favors a $(+ - -)$ AFM stacking of planes, with an equivalent, anisotropic AFM coupling in the $ab$ plane, along the $b$ axis. By comparison, in Tm$_2$CoGa$_8$, $J_c$ is small compared to the large $J_{ab}$ value. The magnetic structure is therefore dominated by a strong, in-plane AFM coupling with a favored $(++-)$ $c$-axis stacking. Our refined magnetic structures are consistent with, and reinforce, the calculated CEF-dependent exchange constants. Importantly, this shows that by choice of the rare-earth ion one can modify the CEF within the R$_2$CoGa$_8$ series in order to predetermine the magnetic structure.

The R$_2$CoGa$_8$ crystal structure can be thought of as a stacking of RGa$_3$ units, separated by CoGa$_2$ layers. By comparing RGa$_3$ to R$_2$CoGa$_8$, the similar $a$ lattice parameter and the requirement of heavier rare-earth mass for stable crystallization suggests that the RGa$_3$ units are key building blocks in the formation of the ternary compound. An analogous argument is also made for R$_2$CoIn$_8$ (Refs. 8 and 11) and Ce$_2$RhIn$_8$ (Ref. 26) compounds. Indeed, in Ce$_2$RhIn$_8$ this is supported by the common rare-earth magnetic structures of Ce$_2$RhIn$_8$ and CeIn$_3$. It suggests that the RhIn$_2$ layers have little influence on the magnetic structure, giving 2D characteristics. We note that this is not the case in the R$_2$CoGa$_8$ series. The simple collinear magnetic structures refined in this paper do not reflect the more complicated magnetic structures of the RGa$_3$ ($R =$ Er and Tm) compounds. For example, the TmGa$_3$ magnetic structure is multiaxial, involving two or three propagation vectors. Indeed, the evaluation of the critical exponent predicts a magnetic structure that is three-dimensional. Further work is required to understand the role of the CoGa$_2$ layers and their counterparts in the other intermetallics, particularly when considering the dimensionality of the magnetic structure.

IV. CONCLUSIONS

We have solved the magnetic structure of two, newly synthesized intermetallic compounds, Er$_2$CoGa$_8$ and Tm$_2$CoGa$_8$. In both materials, magnetic moments were refined and found to lie parallel to the $b$ axis, with magnitudes 4.71(3)$\mu_B$/Er and 2.35(4)$\mu_B$/Tm. Despite having common easy axes of magnetization (in the $ab$ plane) the magnetic propagation vectors were found to be different; in Er$_2$CoGa$_8$ $k = (1/2, 0, 0)$ and in Tm$_2$CoGa$_8$, $k = (1/2, 0, 1/2)$. The different magnetic structures are due to a competition between crystal electric field effects and the RKKY exchange interaction. We show that the magnetic order parameter adopts either the 3D-Ising or 3D-XY universality class, with transition temperatures of 3.0 K and 2.0 K, for the erbium and thulium compounds, respectively. Further, by comparison of the R$_2$CoGa$_8$ and RGa$_3$ magnetic structures, we suggest that the CoGa$_2$ layers play an important role in the 3D magnetism in this series, as opposed to inducing a quasi-2D magnetic structure as in Ce$_2$RhIn$_8$.
