Abstract. We present novel method for the organisation of events. The method is based on comparing event-by-event histograms of a chosen quantity $Q$ that is measured for each particle in every event. The events are organised in such a way that those with similar shape of the $Q$-histograms end up placed close to each other. We apply the method on histograms of azimuthal angle of the produced hadrons in ultrarelativistic nuclear collisions. By selecting events with similar azimuthal shape of their hadron distribution one chooses events which are likely that they underwent similar evolution from the initial state to the freeze-out. Such events can more easily be compared to theoretical simulations where all conditions can be controlled. We illustrate the method on data simulated by the AMPT model.

1 Introduction

In ultrarelativistic heavy-ion collisions, the distribution of the produced hadrons reflects the dynamical state of the fireball at the time of its breakup. There are anisotropies of the hadron distributions which change from one event to another. This is a clear indication of the differences in transverse expansion anisotropies which result from different initial conditions in each event. In many data analyses one takes averages over a large number of events. Naturally, questions then appear which ask about what feature of the fireball(s) can be deduced from such averaged data. Moreover, theoretical simulations must also follow the same analysis procedure and so they usually must provide a large number of events which are then averaged over.

We propose a more exclusive approach to data analysis. The method of Event Shape Sorting [1] allows to select events which are similar in all details, or at least as many of them as possible. Hence, various higher-order anisotropies remain visible in such data samples and are not washed away by averaging over different events. As a result, they can also be more directly compared to the results of simulations which can refrain from the need to average over many events.

An approach in the same spirit has been used for a while now under the name Event Shape Engineering [2]. There, the selection of events is made based on a single variable, e.g. the flow vector $q_2$, which characterises certain selected features of each event. Our method, on the other hand, looks at the whole shape of the event and takes into account as many details of it as possible.

In this short proceedings contribution we explain how the method works and provide some examples of its application.

2 The algorithm

The method that we will apply here has been proposed and used earlier for statistical analysis of a different kind of data [3, 4]. Each event will be represented by its histogram of the distribution that we focus on. Here, we shall look at distributions in the azimuthal angle, but note that an application to rapidity distributions of the produced hadrons has also been proposed [5].

In short, the method uses an iterative algorithm in order to sort events in a special way. After the sorting one arrives at an ordered sequence of events. In that sequence, events which are close to each other have histograms with similar shapes, while events which end up far away from each other look rather different from each other.

There is a slight complication when dealing with histograms of the azimuthal angle distribution of the produced hadrons. They can be arbitrarily rotated. Thus, as the first step even before the commencement of the iterative algorithm one must choose the way how each event should be rotated and then perform this rotation. This step is skipped if the algorithm is used on distributions that cannot be rotated, e.g. rapidity.

Then, the algorithm goes as follows:

1. (Rotate events appropriately, as discussed in the previous paragraph.)

2. Sort the events in a way that you consider reasonable. In fact, the final sorting does not depend on this initial sorting. Nevertheless, if the initial sorting is done wisely, it may decrease the number of iterations that the algorithm needs to perform.

3. Divide the sorted events into quantiles. Again, unless the quantiles are too large, their number should not matter much for the final results, but it does influence the performance of the algorithm. We will use deciles.

4. Determine average histogram in each quantile.

5. For each event, characterised by its histogram entries \( n_i \), calculate the conditional probability \( P(\mu | n_i) \) that it belongs to quantile \( \mu \)

\[
P(\mu | n_i) = \frac{\prod_i P(i|\mu)^{n_i} P(\mu)}{\sum_{\nu} \prod_i P(i|\nu)^{n_i} P(\nu)}.
\]

The formula has been derived in [1] and is based on Bayes’ theorem. Here, \( P(i|\mu) \) is the probability that in the quantile \( \mu \) a random hadron would be found in angular bin \( i \). It is calculated by dividing the number \( n_{i\mu,i} \) of those particles from all events in the quantile \( \mu \) that fall into angular bin \( i \) by the total number of all hadrons from all events in quantile \( \mu \), \( M_\mu \)

\[
P(i|\mu) = \frac{n_{i\mu,i}}{M_\mu}.
\]

In formula (1), \( n_i \) is the actual number of particles in the angular bin \( i \), measured in the event with the complete record \( \{n_i\} \). The priors \( P(\mu) \) and \( P(\nu) \) are 1/10 in case of using deciles.

This step is illustrated in Fig. 1. The calculated probabilities basically give answer to the question: to which quantile (blue) looks the selected event (red) similar? Among all averaged histograms in the figure, the selected event seems to be most similar to the last quantile, while it is certainly different from the fourth quantile in the upper row.
6. For each event calculate the average

$$\bar{\mu} = \sum_{\mu} \mu P(\mu|\{n_i\}) .$$

(3)

7. Sort all events according to their values of $\bar{\mu}$.

8. If the order of events has changed, return to point 3. Otherwise the algorithm converged.

### 3 Results

Let us first present the action of the sorting algorithm on a trivial example, where we can also test that it works as expected. We will analyse artificial Monte Carlo events with only the elliptic anisotropy of hadron distributions taken into account. We have generated 5000 events with only pions and their multiplicity has been varied between 300 and 3000. The distribution of azimuthal angles followed

$$P_2(\phi) = \frac{1}{2\pi} \left( 1 + 2v_2 \cos (2(\phi - \psi)) \right) .$$

(4)

(There was a tiny first-order term, which can be neglected in our discussion.) The second order term is correlated with the multiplicity. Its correlated part is determined as

$$\bar{v}_2 = aM^2 + bM + c .$$

(5)

where $a = -7.099 \times 10^{-8}$, $b = 20.06 \times 10^{-5}$, and $c = 0.07874$. The $v_2$ actually used in the event is then generated for each event as

$$v_2 = \bar{v}_2 + \tilde{v}_2 ,$$

(6)

where $\tilde{v}_2$ is a random addition determined from Gaussian distribution with the width of 0.25.

When the sorting algorithm is used with such a set of events, they come out ordered according to their value of $v_2$. This is illustrated in Fig. 2. By inspecting the average histograms in the ten deciles...
we see that the elliptic variation decreases as one moves from decile 1 towards decile 10. We have also observed that for different initial sorting, the final sorting may come out exactly reversed. This preserves the feature that similar events end up close to each other.

We now proceed to the analysis of events generated by the AMPT transport model [6]. In Fig. 3 we show the final average histograms of the deciles which result from 2000 events of Pb+Pb collisions at $\sqrt{s_{NN}} = 2.76$ TeV and 0–20% centrality class. Before the sorting iterations were started, events had been aligned according to their second-order event planes $\psi_2$.

It can be seen that the structure of the events is much more rich than in the previous toy model example. Only the deciles 7–10 show a clear dominance of the elliptic anisotropy. The rest is more complex. This is confirmed in Fig. 4, where we study the correlation between the sorting variable $\bar{\mu}$ and the elliptic flow coefficient $v_2$. The correlation is pronounced for $\bar{\mu}$ above 8. For lower $\bar{\mu}$’s the ordering is determined also by other features of the distribution. Unfortunately, we were unable to determine how exactly it is constructed.

4 Summary

Now we return to the contemplation about possible more exclusive selection of events which can then be compared to theoretical simulations. Once the sorting algorithm has converged, one just has to take a sequence of events which are placed in subsequent positions. Note that the algorithm does not decide how the events should look like. It only guarantees that the events within such a group are similar. In order to characterise them one would need to invoke other methods.

Also note that so far we have not quantified the similarity of the events. Nevertheless, it should be possible to do this with the help of some statistical method, e.g. by taking the Kolmogorov-Smirnov measure of the distance between two histograms.
Figure 3. Average histograms of ten deciles with AMPT events.

Figure 4. The correlation between average $\bar{\mu}$ and $v_2$.

With the selected group of events one could make comparisons to theoretical simulations where e.g. at the same time second and third order anisotropies would be present at fixed relative angles between $\psi_2$ and $\psi_3$. This is just one example of possible more exclusive studies.

The more exclusive selection of events might also be useful for just technical purpose. In correlation studies, one often needs reference distributions where correlation is turned off. They are usually constructed by making use of the event-mixing technique: artificial events are generated with each particle chosen from a different event. The events from which particles are selected, however, must not be too different. By choosing particles from similar events determined by our algorithm.
one would minimise any unwanted influence on the constructed correlation function due to improper
construction of the mixed-events background.

Finally, let us speculate that if this idea is pushed to the extreme, it might open the way towards
single-event femtoscopy. One of the problems in femtoscopy is the determination of the background
with the mixed-events technique. This becomes critical if studies are to be done with single events.
Nevertheless, if our method would allow to select events which are very similar or even identical,
we might proceed with the background obtained by mixing such events and the signal from a single
event. It will be interesting to work out this speculation in the future.
