ABSTRACT
Since its characterization two decades ago, the phosphatase PHOSPHO1 has been the subject of an increasing focus of research. This work has elucidated PHOSPHO1’s central role in the biomineralization of bone and other hard tissues, but has also implicated the enzyme in other biological processes in health and disease. During mineralization PHOSPHO1 liberates inorganic phosphate (P) to be incorporated into the mineral phase through hydrolysis of its substrates phosphocholine (PCho) and phosphoethanolamine (PEA). Localization of PHOSPHO1 within matrix vesicles allows accumulation of P, within a protected environment where mineral crystals may nucleate and subsequently invade the organic collagenous scaffold. Here, we examine the evidence for this process, first discussing the discovery and characterization of PHOSPHO1, before considering experimental evidence for its canonical role in matrix vesicle-mediated biomineralization. We also contemplate roles for PHOSPHO1 in disorders of dysregulated mineralization such as vascular calcification, along with emerging evidence of its activity in other systems including choline synthesis and homeostasis, and energy metabolism.

KEY WORDS: PHOSPHO1; PHOSPHOCHOLINE; INORGANIC PHOSPHATE; BIOMINERALIZATION; MATRIX VESICLE

Introduction
Biomineralization of the skeleton is a fundamental process indispensable for health and wellbeing throughout life. The vertebrate skeleton is a complex organ that performs varied and diverse functions encompassing its action as a biomechanical and protective scaffold in conjunction with the musculature, its role in calcium and phosphate ion homeostasis, and recent evidence demonstrating its capacity as an endocrine organ involved with energy homeostasis.(1) At the level of molecular constituents bone is composed of a combination of inorganic mineral, type I collagen, noncollagenous proteins (NCPs), and water, arranged into an extremely ordered hierarchical structure.(2) The fine details of this architecture remain controversial at the nanostructural level,(3) particularly with respect to differences between embryonic and mature tissue; however, the mineral phase has come to be regarded as a poorly-crystalline substituted hydroxyapatite phase, mainly composed of calcium phosphate.

Biominalization of the skeleton therefore requires generation and manipulation of calcium and phosphate ions on a massive scale. The biological mechanisms through which ions are liberated, contained, and targeted to the developing collagenous framework, and ultimately nucleate mineral in a controlled manner, remain the subject of intense research. Phosphatase enzymes are essential in promoting biomineralization as one pathway through which inorganic phosphate (P) may be liberated from biological molecules. These include enzymes with a canonical role in bone development such as tissue nonspecific alkaline phosphatase (TNAP). Although TNAP activity has long been implicated in the mineralization process, it is now recognized that TNAP is only one component and the full story requires a more complex biochemical system.

Orphan phosphatase 1 (PHOSPHO1; EC 3.1.3.75; encoded by the Phospho1 gene in the mouse and the PHOSPHO1 gene in humans) has been an increasing focus of research in this field over the last 20 years and now holds an established function in biomineralization. Here we review the scientific literature on the characterization, localization, regulation, and activity of PHOSPHO1 with respect to its role in physiological and pathological biomineralization, along with potential contributions to other biological processes.

Characterization, Protein Structure, and Substrate Specificity
PHOSPHO1 (originally known as 3X11A) was initially cloned from chick hypertrophic growth plate chondrocytes, in which a
Bone Biology and Mineralization

The ubiquitous phosphatase TNAP has a long-established role during skeletal biomineralization. Mutations in the ALPL gene are associated with several skeletal disorders in humans including various forms of hypophosphatasia. Genetic ablation of TNAP in a mouse model induced a phenotype mimicking infantile hypophosphatasia with severe skeletal abnormalities, including those in dental and craniofacial mineralization and morphology. Detailed ultrastructural examination of these mice revealed that although hypomineralization of the skeleton was evident, hydroxyapatite mineral crystals were generated as normal. The hypomineralized phenotype was therefore attributed to the inability of the mineral phase to propagate in the absence of TNAP’s hydrolysis of the potent mineralization inhibitor pyrophosphate (PPi).

These observations led to the hypothesis that another phosphatase was active during skeletal biomineralization with PHOSPHO1 a strong candidate to fulfill this role. Following the observation of PHOSPHO1 upregulation in mineralizing hypertrophic chondrocytes, immunohistochemistry revealed localization of the protein to these cells in the chick growth plate, along with active bone surfaces at the ossification front and in the trabecular compartment. Whole-mount in situ hybridization in the embryonic chick lower limb furthermore demonstrated expression of PHOSPHO1 restricted to the developing bones during ossification. In vivo suppression of PHOSPHO1 activity using the noncompetitive inhibitor lansoprazole (identified specifically as an inhibitor of PHOSPHO1 during chick development induced ablation of mineralization in the lower limb bones). Together these data provided strong evidence that this novel phosphatase plays a critical role in the very first steps of skeletal biomineralization.

The generation of the PHOSPHO1 knockout mouse (Phospho1−/−) enabled the detailed investigation of its phenotype and thereby allowed interrogation of the enzyme’s specific function in the skeleton. Huesa and colleagues used a variety of compositional and biomechanical analyses to show that the mineral:matrix ratio of femora of juvenile Phospho1−/− mice was significantly lower than wild-type controls, accompanied by plastic deformation upon three-point bending and a reduced hardness and elastic modulus. A further investigation of the mechanical properties of these bones corroborated this high fracture toughness and also showed significantly higher indentation distance increases under reference point indentation compared to wild-type controls. Histological examination of Phospho1−/− long bones revealed reduced mineralization in the trabecular compartment, whereas 10% to 15% of 10-day-old mice exhibited a complete lack of secondary ossification center development. These bones also demonstrated osteoid accumulation, a hallmark of hypophosphatasia. Interestingly, micro-computed tomography (μCT) revealed no differences between 4-week-old Phospho1−/− and wild-type mice in bone volume relative to tissue volume (BV/TV), but rather a significantly reduced bone mineral density (BMD) that was accompanied by diverse spontaneous greenstick fractures and marked thoracic scoliosis. Similarly, PHOSPHO1 plays a critical role in fracture healing, with induced tibial fractures in Phospho1−/− mice demonstrating osteoid accumulation and elastic deformation upon loading at 4 weeks postsurgery.

These findings have been extended to investigate the function of PHOSPHO1 in the development of bone’s hydroxyapatite mineral phase at the smallest length scales. X-ray diffraction (XRD) along with thermogravimetric analysis (TGA) revealed a lower bulk mineral content with significantly lower mineral:matrix ratio in Phospho1−/− femurs, also accompanied by a smaller apatite crystal size. Backscattered scanning electron microscopy (BSE-SEM) furthermore revealed generalized hypomineralization relative to wild-type mice in transverse tibial cross-sections of the same animals. Further analysis of the Phospho1−/− microstructure exposed diffuse regions of hypomineralization in diaphyseal cortical and trabecular bone with large areas of osteoid accumulation. Interestingly, there

...
was no discernible anatomical pattern between individual Phospho1−/− animals, but regions lacking mineral exhibited small focal areas of mineral nucleation at their borders, which failed to propagate more widely.

In the very early studies of its function, characterization of the Phospho1−/− bone phenotype was performed in young juvenile mice, and therefore to examine the bone phenotype more fully Javaheri and colleagues (31) investigated whether PHOSPHO1 plays a persistent long-term role in the adult bone’s biology where skeletal turnover is relatively slow. Using digital image correlation (DIC) the expected lower stiffness of Phospho1−/− was found, which was corrected with age. µCT analysis demonstrated several differences in tibial trabecular microarchitecture, including trabecular number and connectivity, between Phospho1−/− and wild-type mice, which changed transiently across four age groups, with significant differences detected in the 5-week and 34-week age groups, but not in the 7-week or 16-week groups. Upon examination of the cortical bone, however, the authors noted a significant reduction in BV/TV in animals from 7 weeks of age that was not corrected over time. NanoCT scanning (0.6-µm resolution) furthermore revealed a greater number of larger osteocyte lacunae, along with higher vascular porosity in Phospho1−/− tibias, a surprising finding which was compounded by an early increase in both Pdpn (embryonic day 11 [E11]) mRNA expression in primary osteoblast cell cultures, potentially indicating accelerated terminal osteocyte differentiation in these cells. (31) PHOSPHO1 may therefore play a role in regulation of osteocytogenesis, which in turn may regulate bone microarchitecture in skeletally mature animals. Further research is required, however, to assess whether this relationship is mediated through reduced mineralization, or whether PHOSPHO1 may act within a distinct mechanism altogether. Our data also shows that the Phospho1−/− phenotype is present during skeletal development, with murine embryos exhibiting a reduced extent of mineralization across all bones during embryogenesis (unpublished data; Fig. 2).

One-year-old Phospho1+/− mice showed reduced plasma concentrations of TNAP with a concomitant increase in ectonucleotide pyrophosphatase/phosphodiesterase1 (NPP1), thereby resulting in significantly higher PPi concentrations compared with wild-type controls. (25) Intriguingly, high serum PPi is a key characteristic of infantile hypophosphatasia in humans, with the resulting inhibition of mineralization attributed to the ensuing rickets/osteomalacia. (17,32) Yadav and colleagues (25) attempted to rescue the Phospho1−/− phenotype by cross-breeding with mice overexpressing TNAP (ApoE-Tnap) and thereby reduce PPi concentration. Although the authors did indeed observe an approximately fourfold increase in TNAP in plasma and a significant reduction in PPi, the hypomineralized Phospho1−/− phenotype was not present.
corrected, with animals exhibiting persistent skeletal defects at 7 months. Furthermore PHOSHO1; TNAP double knockout (Phospho1−/−; Alpl−/−) mice exhibited complete ablation of skeletal mineralization and perinatal lethality. These data were augmented and confirmed in vitro with osteoblast-like MC3T3-E1 cell lines (clones 14 and 24) along with ex vivo metatarsal cultures using specific PHOSPHO1 and TNAP inhibitors in culture.

PPi is known to regulate the expression of other mineralization-associated proteins, particularly osteopontin (OPN; Spp1). Along with PPi, OPN is another potent mineralization inhibitor. The protein’s inhibitory effects are mediated through its phosphorylation status, and this has been shown to be regulated by TNAP. Significantly elevated OPN, which also exhibited a greater degree of phosphorylation compared to controls, was found at the protein and gene levels in serum and spinal lysates of Phospho1−/− mice at 1 month and 3 months postnatally. Interestingly, no differences were observed in femoral lysates. Yadav and colleagues investigated the interplay between PHOSPHO1 and OPN through the generation of Phospho1−/−; Spp1−/− mice and found a partial rescue of the Phospho1−/− phenotype, with animals at 1 month and 3 months of age exhibiting a reduction in the typical hyperosteoidosis and thoracic scoliosis that characterizes the single knockout animal. The Phospho1−/− hypomineralized mouse phenotype is therefore partially attributable to an increased expression of OPN, which may obstruct mineralization during bone formation. This is likely exacerbated by a relative hyperphosphorylation of OPN, mediated by the established reduced expression of Alpl in Phospho1−/− mice.

Collectively these findings establish a nonredundant role of PHOSPHO1 in mediating biomineralization of the skeleton, as well as its regulated synergy with TNAP, along with other mineralization-associated factors including PPi and OPN, as part of this process.

Dental Mineralization

Along with its established role in bone biomineralization, PHOSPHO1 has also been implicated in the mineralization process of the dentition. McKee and colleagues studied dentin formation in perinatal mice and found localization of PHOSPHO1 to odontoblasts during the very first steps of dentin formation. Phospho1−/− mice exhibited reduced mineralization in the dentin by histology, µCT, and radiography, a phenotype that was aggravated by the additional deletion of one Alpl allele (Phospho1−/−; Alpl−/−). Others have examined PHOSPHO1 function in the other dental hard tissues, namely cementum and enamel. PHOSPHO1 was found to show expression in osteoblasts and cementoblasts of alveolar bone and cementum, respectively, during their mineralization phases where osteoid accumulation...
was evident in the bone and was accompanied by delayed mineralization of the cellular cementum in Phospho1−/− animals. Intriguingly, acellular cementum formation was normal, despite downregulation of Phospho1−/− in a bone sialoprotein knockout model in this region. PHOSPHO1 is therefore an enzyme critical for the integrity of the periodontal tissue interface, along with normal development of these hard tissues. In enamel, Phospho1−/− mice exhibited a 25% increase in tissue volume, with a significantly reduced level of mineralization. The authors furthermore reported that ablation of PHOSPHO1 caused loss of enamel prism morphology and an impaired crystal organization compared to wild-type mice.

At the level of local cellular regulation, control of mineralization through the PHOSPHO1 pathway has been shown to be influenced by the TRPS1 transcription factor in an odontoblast-like cell line. Mutations in the Trps1 gene are associated with trichorhinophalangeal syndrome in humans and manifest craniofacial and skeletal dysplasias associated with defective endochondral mineralization. Loss of TRPS1 has also been implicated in abnormal tooth development and mineralization. Kuzynski and colleagues over-expressed Trps1 in preodontoblastic 17IIA11 cells and found reduced mineralization compared with controls. Interestingly, reduction of Trps1 expression also ablated mineralization and was associated with downregulation of Phospho1 and Alpl expression. The authors proposed that TRPS1 acts to repress mineralization associated genes in dentin in a biphasic manner to first inhibit ectopic mineralization, and further to prevent hypermineralization by modulation of osteogenic gene expression, including Phospho1.

**The PHOSPHO1 Mineralization Mechanism: Matrix Vesicle–Mediated Biominalization**

Matrix vesicles (MVs) are membrane-bound nanospherical bodies of approximately 100 to 300 nm in diameter that are typically rich in lipids and proteins known to chelate Ca2+ and P, and which are associated with both physiological and pathological biominalization. Their function continues to be remain controversial since their discovery in 1967 in growth plate cartilage, with some authors attributing these as specimen-preparation artifacts. Nevertheless, many in vitro and in vivo studies have shown the first mineral crystals in diverse mineralized tissues such as bone, dentin, cartilage, and mineralized vasculature are associated with these structures in the extracellular matrix (ECM).

The structure and function of MVs in skeletal and vascular mineralization has recently been reviewed by several authors. The biogenesis of these vesicles may occur through multiple proposed mechanisms; however, the most prevalent theories include polarized budding from the parental cell membrane, or from microvilli on the cell surface, as demonstrated in hypertrophic chondrocytes and SaOS-2 osteoblast-like cells. The theorized function of MVs in biominalization is to facilitate a localized concentration of Ca2+ and P, protected from the ECM, from which hydroxyapatite or its precursors may form. Vesicles may also assist in concentrating P to engender a P/PP ratio that is permissible for mineralization. MVs are known to be enriched in Ca2+ by way of their intracellular biogenesis from mitochondria under oxidative stress, at least in growth-plate chondrocytes. Recently published research by Chaudhary and colleagues may correlate well with these findings, showing that P stimulates release of MVs from osteogenic cells, although the authors did not comment on their mitochondrial origin.

P accumulation within MVs is thought to be mediated by extravascular and intravascular phosphatases, of which PHOSPHO1 plays a critical role. Stewart and colleagues were the first to suggest PHOSPHO1 as a major intravascular phosphatase, showing its presence in MVs isolated from embryonic chick growth plates. This was more recently confirmed in MVs isolated from the ECM of both cultured MC3T3 and SaOS-2 osteoblast-like cells using Western blotting and quantitative proteomics. Further work using both growth plate–derived and primary osteoblast–derived vesicles established that although TNAP does indeed liberate P extravascularly, PHOSPHO1 is biochemically active intravascularly. Therefore, it is hypothesized that accumulation of P inside MVs occurs via a combination of the intravascular action of PHOSPHO1 and intravascular trafficking of TNAP-generated P, via a Type III Na-P, co-transporter, P:T1 (encoded by the Slc20a1 gene in mice) (Fig. 3A). Experimental evidence for this hypothesis comes from the work of Yadav and colleagues, who generated a cartilage specific P:T1 knockout mouse driven by a col2a1-Cre on a Phospho1-null background (Phospho1−/−; P:T1Col2a1/Col2a1). The authors report an exacerbation of the Phospho1−/− phenotype, including growth plate defects, extensive hyperosteoideosis, decreased BMD, and impaired mechanical properties. MVs isolated from differentiating chondrocytes in these animals furthermore demonstrated a loss of their capacity to nucleate hydroxyapatite crystals compared to both Phospho1−/− and wild-type controls. Interestingly, both Phospho1−/− and P:T1Phospho1−/−; P:T1Col2a1/Col2a2 MVs were reduced in numbers compared to wild-types, potentially indicating a role for PHOSPHO1 in MV biogenesis. Together, these studies, along with those characterizing the Alpl−/− and Phospho1−/−; Alpl−/− mice, afford good evidence for this mechanism integrating the PHOSPHO1 and TNAP P generation pathways.

Although this work provides a strong evidence base for the pivotal role of PHOSPHO1 in vesicle-mediated biominalization, the specific biochemical pathway within it by which it achieves intravascular P liberation remains unclear. Stewart and colleagues proposed a mechanism through which PHOSPHO1’s substrates PEA and PCHO may be generated intravascularly by enzymatic action upon the vesicle’s phospholipid membrane, as mediated by a phospholipase A2 (PLA2) and ectonucleotide pyrophosphatase/phosphodiesterase 6 (NPP6) (Fig. 3B). The PL2 family of enzymes catalyze cleavage of the acyl group at the sn-2 acyl position of glycerophospholipids resulting in a free fatty acid and lysophospholipid (LPL). These enzymes may therefore act to breakdown phosphatidylcholine (PC) and phosphatidylethanolamine (PE) in the MV membrane, forming lysophosphatidylethanolamine and lysophosphocholine LPLs, respectively, along with arachidonic acid. Indeed, the MV membrane has been shown to be enriched in phospholipids containing PCho and PEA, which progressively decline during mineralization, whereas PCho was also identified as an abundant metabolite in developing mouse long bones by matrix-assisted laser desorption/ionization-imaging mass spectrometry. There are upward of 30 identified mammalian PL2 enzymes that exhibit a huge range of localizations (including secreted, cytosolic, and lysosomal groups) and have been shown to be involved with many physiological and pathological processes.
reviewed the evidence for the role of phospholipases in mineralization, noting several experimental studies confirming expression of both secreted and cytosolic PLA2s in chondrocytes and osteoblasts where they play several roles. Although some specific PLA2s have been shown to have an effect on bone formation,(90) it is currently unclear whether these act directly within the mineralization process. Therefore, further research is required to identify specific candidate proteins that fulfill this niche.

A second enzymatic processing phase is hypothesized to convert generated LPL to PCho for direct hydrolysis by PHOSPHO1, mediated by NPP6.(82) NPP6 is a member of the nucleotide pyrophosphatase/phosphodiesterase family and has been shown to possess lysophospholipase C activity, catalyzing the conversion of lysophosphocholine with a monoacylglycerol by-product.(91–93) Expression of NPP6 has been demonstrated in bone tissue lysate and was immunolocalized to hypertrophic chondrocytes and forming bone surfaces.(82) Specific localization of NPP6 to MVs has yet to be established, however.

Alternative biochemical pathways through which PHOSPHO1 substrates may be generated have also been proposed (Fig. 3C). Neutral sphingomyelinase 2 (nSmase2) is encoded by the Smpd3 gene in mice and is capable of catalyzing the hydrolysis of another MV membrane phospholipid, sphingomyelin, to produce PCho with a ceramide by-product.(94) The fro mutation in the Smpd3 gene generates a distinctive phenotype with extensive musculoskeletal defects resulting in dwarfism.(95,96) Khavandgar and colleagues(97) demonstrated that the fro/fro mouse exhibits delayed mineralization of the long bones and calvaria, along with impaired hypertrophy in growth plate chondrocytes during embryonic development. Using tissue-specific mouse knockout models it was also established that Smpd3 expression is required in both osteoblasts and chondrocytes in a cell-autonomous manner for normal bone development.(97,98) These effects were moreover shown to influence mineralization during tooth development and fracture healing.(99,100) Like PC and PE, sphingomyelin is enriched in MV preparations and declines during mineralization,(74,86,87) whereas the nSmase2 enzyme has been localized to MV isolates in conjunction with PHOSPHO1.(79) nSmase2-mediated production of PCho may therefore provide another pathway for the intravesicular generation of PHOSPHO1 substrates. Another potential alternative pathway includes generation of PCho by phosphorylation of choline through the action of the α and β choline kinases (encoded by the Chkα and Chkβ genes, respectively). Although mice lacking Chka display lethality during embryonic development,(101) the Chkβ−/− mouse exhibits forelimb deformities and delayed mineralization, accompanied by an extended and disorganized hypertrophic zone within the growth plates at the distal radius and ulna.(102) PCho was also shown to be reduced by ~75% in primary chondrocytes isolated from these animals.(102) Intriguingly, PHOSPHO1 was upregulated in Chkβ−/− primary chondrocytes, potentially indicating compensation for a restricted substrate availability.(102) Both

Fig. 3. Schematic diagram illustrating the hypothesized mechanism of PHOSPHO1 function within MVs. (A) PHOSPHO1 functions synergistically with TNAP: (1) TNAP hydrolyses its substrates to produce P, extravesicularly; (2) extravesicular P is transported into the MV via PT1; (3) PHOSPHO1 hydrolyses Pcho intravesicularly to further accumulate P_. (B) Generation of PHOSPHO1 substrates within MVs: (1) an unidentified PLA2 converts PC from the vesicle membrane to lysoPC; (2) NPP6 subsequently catalyses the hydrolysis of lysoPC to generate Pcho; (3) PHOSPHO1 liberates P_ from Pcho. (C) Alternative pathways of PCho generation: (1) nSmase2 breaks down SM from the MV membrane to form Pcho; (2) the α/β choline kinases phosphorylate choline to form Pcho; (3) PHOSPHO1 generates P_ from Pcho.
Chka and Chkb were found to be expressed in human osteoblast-like MG-63 cells, and gene silencing of Chka resulted in a reduction of ~70% in cellular PCho with an accompanied inhibition of TNAP activity and mineralization in culture.\(^{103}\)

**Endocrinology and Regulation**

As a critical effector of biomineralization it is likely that PHOSPHO1 expression and function will be stringently controlled at both the local and systemic level. As a major organ, and one which is metabolically expensive to produce and maintain, it is well established that bone formation and resorption are tightly controlled by many factors during development and in adulthood, some of the most significant of which include the sex steroids,\(^{104\text{-}106}\) vitamin D,\(^{107\text{-}109}\) and parathyroid hormone (PTH).\(^{110\text{-}112}\) Whether the observed differences in mineralization caused by regulatory influences are caused wholly or partly by control of PHOSPHO1 or other associated proteins is as yet unknown.

Some evidence for the systemic regulation of PHOSPHO1 comes from work surrounding the effect of PTH on osteoblasts, with RNA-seq in an osteocyte-like cell line (IDG-SW3 cells) stimulated with PTH in culture demonstrated an effect on both Phosha1 and Smpd3 expression.\(^{113}\) Houston and colleagues\(^{114}\) extended these analyses, examining the expression of Phosha1, Smpd3, and Alpl specifically in MC3T3 osteoblast-like cells and ex vivo calvaria culture models with continuous PTH exposure. The authors report rapid and coordinate downregulation of Phosha1 and Smpd3 expression after the addition of PTH to culture media, which was likely regulated through the cAMP/PKA signaling pathway. This downregulation of both Phosha1 and Smpd3 was independently found in Kusa 4b10 cells and in young rats exposed to PTH and PTH-related protein 1 (PTHrP).\(^{115\text{-}116}\) The catalytic effects of continuous PTH on the skeleton are well demonstrated in human conditions such as hyperparathyroidism; however, much research has associated this with the upregulation of osteoclastogenesis through the RANKL/OPG axis.\(^{117\text{-}119}\) These data may indicate, however, a simultaneous mechanism effecting inhibition of bone formation as mediated by PHOSPHO1. The transcription and posttranslational modification (phosphorylation) of Runx2, the transcription factor and master regulator of osteoblast differentiation, is also strongly enhanced by PTH.\(^{120}\) Interestingly, the overexpression of Runx2 in mouse limb bud cultures simultaneously enhances the expression of both Phosha1 and Smpd3.\(^{121}\)

Collectively, these data surrounding PTH tentatively suggest that control of bone biomineralization may occur by modulating PHOSPHO1 expression, and thereby the MV-mediated biomineralization mechanism. This relationship is, however, currently far from explicit and much further research is required to establish the regulatory mechanisms behind PHOSPHO1 expression and function within the context of the MV.

**PHOSPHO1 in Pathologies of Mineralization**

Aside from its central function in mediating physiological biomineralization, PHOSPHO1 may also have a role to play in the onset of pathological mineral formation; for example in vascular calcification. Phosha1 is upregulated during mineralization of vascular smooth muscle cells (VSMCs) in culture, whereas Phosha1\(^{-/-}\) VSMCs exhibited a significant reduction in mineral generation.\(^{122}\) Also, the PHOSPHO1 inhibitor, MLS-0263839 reduced calcification of cultured VSMCs by ~60% and when combined with the TNAP inhibitor MLS-0038949, calcification of VSMCs was reduced by ~80%.\(^{122}\) Phosha1 is also upregulated during atherosclerotic vascular calcification in a rabbit model.\(^{123}\) Furthermore, Hortells and colleagues\(^{124}\) induced aortic calcification in a rat nephrectomy model with a 1.2% phosphorus diet for 12 weeks postsurgery and observed significant upregulation of Phosha1 expression in animals exhibiting calcification, along with several other mineralization-associated genes. These studies suggest that PHOSPHO1 has a critical role in VSM mineralization and that “phosphatase inhibition” may offer therapeutic strategies to mitigate vascular calcification.

Several authors have investigated the process responsible for vascular calcification, with some implicating PHOSPHO1 and TNAP as part of the MV mechanism.\(^{125\text{-}126}\) Scanning electron microscopy (SEM) and focused ion beam scanning electron microscopy (FIB-SEM) of human calcified valves and vascular tissue revealed spherical particles composed of crystalline calcium phosphate.\(^{127}\) Using in vitro models together with calcified human tissue, these particles were later implicated in the formation of mineralized atherosclerotic plaques through their initial aggregation and nucleation of the mineral phase.\(^{128}\) Furthermore, particles isolated from mineralized aortas were subsequently shown to induce pathological changes in valvular endothelial cells (VECs) and valvular interstitial cells (VICS) in culture.\(^{129}\) These studies demonstrate compelling similarities between calcified particles found in the vasculature and MVs. The localization of PHOSPHO1 or other MV-associated enzymes with these structures has not as yet, however been confirmed and so the mechanism behind their generation remains elusive.

There is now substantial evidence that the mineralization status of the subchondral bone is altered in osteoarthritis, and that this may lead to modified mechanical integrity, engendering greater articular cartilage degeneration.\(^{130}\) Phosha1 is upregulated during chondrocyte differentiation,\(^{131}\) and aged hypomineraled Phosha1\(^{-/-}\) mice exhibit increased articular cartilage degradation and osteophyte formation, when compared to the age-matched wild-type mice.\(^{132}\) Further, non-invasive loading of Phosha1\(^{-/-}\) mouse knee joints revealed diminished loading-induced changes in the subchondral bone plate thickness and epiphyseal trabecular bone microarchitecture.\(^{132}\) Together, these data suggest that the hypomineraled bone phenotype in Phosha1\(^{-/-}\) mice provokes osteoarthritis pathology. This therefore implies that local modifications in the bone matrix mineralization may underpin subchondral bone sclerosis in osteoarthritis; however, further analyses are required to fully define this relationship.

There are also more speculative roles for PHOSPHO1 in osteoarthritis because of its role as a phosphatase capable of hydrolyzing PCho and PEA. Lipidomic analysis of the synovial fluid from patients with osteoarthritis suggests that alterations in the phospholipid composition and concentrations are associated with disease development, due to the lubricating function of the synovial fluid in the joints.\(^{133}\) Specifically, PC concentrations are increased in the synovial fluid of both early (2.7-fold) and late (5.4-fold) osteoarthritis patients in comparison to controls.\(^{133}\) Similarly, there has been reported high activity of PLA2, thought to break down PC, in the synovial fluid of osteoarthritis patients\(^{134}\) and a role for PLA2 in articular cartilage chondrocyte function.\(^{135}\) It has been suggested that...
the ratio of PC to lysophosphatidylcholine is a good diagnostic marker for rheumatoid arthritis. However, whether this is the case for osteoarthritis and the potential involvement of PHOSPHO1 in this is yet to be established.

**Other Physiological Roles**

In the 20 years since its characterization, the vast majority of research focusing on PHOSPHO1 has concentrated on biomineralization. However, as a phosphatase capable of hydrolyzing PCho and PEA with the generation of metabolites such as choline, PHOSPHO1 has the potential for activity in many other body systems. PC and PE are two of the most abundant lipids in the body, comprising 40% to 50% and 15% to 20%, respectively, of total cellular phospholipids of any given tissue in mammals. These molecules are therefore of critical importance in a huge variety of biological systems, from the integrity of plasma membranes, and other structures such as vesicles, lipoproteins and chylomicrons, to regulating the activity of proteins at the cell membrane. Interestingly, the breakdown products from PC in particular have also been implicated as signaling molecules. Although speculative, it is therefore an intriguing possibility that PHOSPHO1 may have a role to play in the biosynthesis and catalysis pathways of these phospholipids, regulating substrate availability. Choline is the breakdown product from PHOSPHO1 activity on the LPL lysophosphatidylcholine derived from PC, and is an essential dietary nutrient in mammals. Although choline is primarily used in PC biosynthesis, it may also be used to generate betaine in the liver and kidney, or acetylated to form the neurotransmitter acetylcholine in the brain.

PHOSPHO1 may therefore be an appealing candidate to act within a secondary mechanism of choline homeostasis in these and other tissues. Indeed, gut enteroids maintained in choline-deficient media exhibited hypomethylation at 3’ CpG islands within the Phospho1 gene, potentially regulating gene expression.

One system within which PHOSPHO1 plays a significant role in this regard is erythropoiesis. An expression quantitative trait locus (eQTL) analysis initially found that single-nucleotide polymorphisms (SNPs) associated with β-thalassemia in human peripheral blood samples were also associated with changes in PHOSPHO1 expression. PHOSPHO1 was also found to be substantially enriched in erythroblasts undergoing differentiation. Subsequently Huang and colleagues investigated PHOSPHO1 in terminal erythropoiesis; a process during which the phospholipid composition of red cells is substantially altered. PHOSPHO1 expression was significantly upregulated during erythroblast differentiation, and moreover loss of PHOSPHO1 induced defective erythropoiesis accompanied by a lack of choline generation and an increased phosphocholine:choline ratio.

Several other studies have found intriguing associations between PHOSPHO1 expression and disorders of altered energy metabolism such as diabetes and obesity. Epigenome-wide association studies (EWAS) have found significant associations between methylation at loci within the PHOSPHO1 and the future risk of type-2 diabetes in human cohorts. Indeed, Willmer and colleagues highlighted differential methylation at sites within the PHOSPHO1 gene as a potentially useful biomarker for clinical application in the early detection of type-2 diabetes. Moreover, increased methylation was positively correlated with high density lipoprotein (HDL) concentration in blood and was decreased in muscle tissue from diabetic patients. This relationship with HDL concentration was also reproduced independently in an EWAS focused on serum lipid profiles conducted in a separate cohort. Relatedly, Wu and colleagues further found an association between PHOSPHO1 and SNPs relating to clinical measures of obesity in a Chinese population. These studies provide a promising avenue of investigation for future research to consider the mechanisms through which PHOSPHO1 may act to influence lipid metabolism and disorders of its dysregulation such as diabetes and obesity. Supporting this idea, changes in Phospho1 expression have been found in several studies examining the thermogenic brown adipose tissue (BAT) and the browning of white adipose tissue (WAT), of great relevance to obesity. Phospho1 is expressed at a higher level in BAT than WAT, and suppression of fatty acid oxidation in adipose tissues causes a downregulation in expression during cold challenge. Furthermore, studies that have investigated creatine metabolism as an alternative pathway for thermogenesis in beige fat have implicated PHOSPHO1 in this process, although the specific mechanism remains elusive.

**Inhibition of PHOSPHO1—a Therapeutic Target?**

The LOPAC and Spectrum chemical reference libraries were used to identify potential chemical inhibitors of PHOSPHO1 and semiautomated high-throughput chemical screening used to test inhibition of PEA hydrolysis. Of those identified, three molecules, Lansoprazole, Ebselein, and SCH202676, exhibited noncompetitive inhibition of recombinant PHOSPHO1 activity by 80% or more. This study showed that neither Lansoprazole nor SCH202676 inhibited TNAP activity, but Lansoprazole has recently been shown to act as a noncompetitive inhibitor of TNAP. Following this, Bravo and colleagues synthesized a series of benzoisothiazolone inhibitors of PHOSPHO1; the final selection from these inhibitors was tested and passed medicinal chemistry criteria in deliverability, metabolic stability, solubility, and permeability, while also demonstrating no cellular toxicity.

The development of these compounds opens the potential for inhibition of PHOSPHO1 activity as a therapeutic intervention. Although there has been no experimental research exploring this possibility to date, the imputation of PHOSPHO1’s association with pathologies in both biomineralization and lipid metabolism may make it an attractive drug target in the future. In terms of disorders of pathological mineralization, although the PHOSPHO1-mediated mineralization mechanism is critical for the proper development of the skeleton in immature organisms, as has been discussed here, there is currently no evidence to suggest that it plays an active role in maintenance of the skeleton in adulthood. Ablation of mineralization in the adult may be desirable when attempting to control soft tissue mineralization, eg, vascular calcification and also ectopic bone formation, as is the case in several musculoskeletal disorders including osteoarthritis. In these instances pharmacological inhibition of PHOSPHO1 may prove to represent an effective intervention that also entails limited adverse off-target effects.

**Outlook**

Over the past 20 years PHOSPHO1 has been an increasing focus of research in the bone biology and biomineralization communities. Work performed in our and in other groups has succeeded in establishing its canonical role in MV-mediated biomineralization of the skeleton and dentition, while opening
new fields of investigation into its function in other body systems. Many questions remain to be answered surrounding aspects of PHOSPHO1’s biology, including detailed elucidation of its upstream biochemical mechanism, targeting of the enzyme to MVs, how local and systemic regulation is integrated with other aspects of bone biology during the bone formation process, and the precise role of PHOSPHO1 in musculoskeletal disease. Future studies integrating aspects of structural biology and biomineralization with cellular and molecular biology and endocrinology will give us a holistic appreciation of these processes and contribute to our understanding in this fundamental aspect of bone biology.

Disclosures

All authors state that they have no conflicts of interest.

Acknowledgments

This work was supported by the Biotechnology and Biological Sciences Research Council (BBSRC) through an EASTBIO Doctoral Training Partnership studentship award (1803936) and Institute Strategic Programme Grant Funding (BB/J004316/1); and the National Institutes of Health (NIH) under award number (ARS3102).

Authors’ roles: SD, KAS, JLM, and CF contributed to writing and reviewing the manuscript, and approved the final version.
