Section 2: Experimental details

General methods
All manipulations were performed using standard air-free techniques on a Schlenk line under an argon atmosphere or in a nitrogen-filled glovebox, unless otherwise indicated.

Chemicals
Toluene (99.5%), phenyl isothiocyanate (98%), 4-(trifluoromethyl)phenyl isothiocyanate (97%), and dodecylamine (98%) were obtained from Aldrich and used without further purification. 3,5-bis(trifluoromethyl)phenyl isothiocyanate (97+%) was obtained from Maybridge and used without further purification. Tetrachloroethylene (anhydrous, ≥99%) and diglyme (anhydrous, 99.5%) were obtained from Aldrich, transferred to a nitrogen-filled glovebox, shaken with activated alumina, filtered, and stored over activated 3 Å molecular sieves for 24 hours prior to use. Hexadecane (99%) and diphenyl ether (≥99%) were obtained from Aldrich, stirred with calcium hydride overnight, distilled under vacuum (30 mtorr), transferred to a nitrogen-filled glovebox, and stored over activated 3 Å molecular sieves for 24 hours prior to use. o-toluidine (≥99%) and 2-isopropylaniline (97%) were obtained from Aldrich, distilled under vacuum (30 mtorr), and stored in a nitrogen-filled glovebox prior to use.

New thioureas
Lead oleate and thiourea syntheses were carried out according to Hendricks et. al. Selenourea syntheses were carried out according to Campos et. al.\textsuperscript{1-2}

Fitting of in situ PDF data to candidate PbS solute structures.

Discrete Debye Scattering Equation based calculations were performed using the DiffpyCMI complex modeling framework using DebyePDFGenerator. The structures are refined using least squares analysis with isotropic ADPs on Pb, S, O, a scale factor, a quadratic correlated motion correction for relative low-\(r\) peak intensities, and an isotropic stretching factor of the XYZ coordinate matrix as variables in the fit. Structural optimizations were carried out using DFT implemented in the Jaguar 9.1 suite of \textit{ab initio} quantum chemistry programs. Geometry optimizations were performed with the MO6-2X functional using the LACVP** basis set. The absence of imaginary frequencies in the calculated harmonic vibrational frequencies were used to confirm that the calculated geometries represent minima on the potential energy surface. Initial guesses for the geometry were generated by molecular mechanics as implemented in Avogadro version 1.2.0 using the UFF force field.

Estimation of error in [NC].

The [NC] was determined using a previously determined size-dependent extinction coefficient, as described in the Experimental section of this manuscript. Therefore, the almost all of the uncertainty in [NC] will derive from error in the extinction coefficient we used. As with most extinction coefficient measurements, the largest source of error arises from the nanocrystal size
measurement. To account for this, we estimated an error of two monolayers (~0.6 nm) in the nanocrystal diameter. Propagating this to an uncertainty in the nanocrystal volume we arrive at an error between 20-40%, with the percent error decreasing with nanocrystal size. Using this error in the nanocrystal volume we estimated the [NC] as shown in Figure 6B.
Section 3: Comment on $k_r$ fit quality

The single exponential fit is an approximation since the exact rate law is not known. However, the single exponential describes the data quite well. As mentioned previously, the overall fit provides a good description of most of the data and provides a reliable estimate of the reaction rate constant. However, $t_{ind}$ is very sensitive to small changes in the fit and often the residuals are highest at the early time points (Figure S6A and S6C).

Figure S6. Difference between overall fit and early time points fit.

In extreme cases, for short induction times, $t_{ind}$ can be smaller than $t_{inj}$, leading to negative induction times. Therefore, to correctly identify $t_{ind}$, the algorithm applies another fit over the early time points (Figure S6B and S6D). Of course, this leads to a slightly different rate constant. However, the average variability is about 10% and for most data sets, the variability is under 20% (see Figure S7 for a histogram of the variability).
Figure S7. Histogram of the variability on the rate constant between the overall and early time point fit.
Section 4: Setup and collection of in situ X-ray total scattering measurements

Experimental Set Up

The peristaltic pump which flows the reaction solution in front of the beathpath is controlled externally outside the hutch with custom written code. Briefly, the injection of the S/Se precursor is remotely triggered and then the persitaltic pump is run on max setting for ten seconds to ensure the solution has flowed through the entire flow cell prior to acquisition. Then the pump is set to a slower speed and the acquisition of X-ray diffraction patterns is initiated. The total solution volume of the viton tubing between the flask and the X-ray beam is approximately 2 mL. This leads to a dead time of 30 seconds for the PbS and PbSe reaction conditions respectively. During the period following the beginning of acquisitions the acquired 30 second diffraction pattern(s) are of the reaction solution which was pumped out while the pump was operating in fast mode. Therefore, we have corrected the timing to reflect the fact that the acquisition during this dead time reflects the reaction solution which was pumped out between 10-15 seconds following initiation of the reaction in the flask. Given the likelihood that the reaction still proceeds to some extent in the Viton tubing, and these scans represent averaged diffraction intensities over the whole 30 second acquisition period these “in flask” reaction times are an approximation. This approximation is necessitated by the finite time needed to acquire sufficient S/N to produce diffuse scattering data which can be meaningfully used to generate a PDF as well as the need for a relatively slow pump rate to allow for data collection over an extended period of time without recirculating the solution.

Figure S8. Custom designed X-ray Flow Cell benchmarked at NSLS-II 28-ID-2 beamline. A remotely triggered injector initiates the nanoparticle reaction by injecting a syringe of the
chalcogenourea precursor into a hot lead oleate solution. Then, a peristaltic pump flows the nanocrystal solution in front of the X-Ray beam path allowing for time resolved diffraction measurements of the evolving nanocrystal reaction solution.

**Figure S9.** Custom designed X-ray flow cell, the solution is flowed through kapton tubing which is aligned with the X-ray beam.

### Total Scattering Structure Function, $S(Q)$, Raw Data

The nominal composition for normalization of the total scattering structure function

$$
\mathbb{S}(Q) = \frac{I(Q)_{coh} + \langle f(Q) \rangle^2 - \langle f^2(Q) \rangle}{\langle f(Q) \rangle^2}
$$

was chosen to be “PbS” or “PbSe” for *in-situ* nanocrystal reactions which form PbS or PbSe respectively. $f(Q)$ is the Q dependent X-Ray form factor.\(^7\) In the case of lead oleate this was chosen to be the molecular formula of lead oleate.
Figure S10. *In-situ* total scattering structure function, $S(Q)$, of a PbS nanoparticle reaction with 30 second scans intervals.

Figure S11. *In-situ* total scattering structure function, $S(Q)$, of a PbSe nanoparticle reaction with 30 second scans intervals.

Figure S12. PbS nanoparticle reaction timepoints at late times process with varying ranges of $F(Q)$ (left) used in the Fourier transform to generate $G(r)$ (right). A $Q_{\text{max}}$ of 10 Å$^{-1}$ is accessible throughout the reaction.
Section 5: Virtual crystal modeling of PbS and PbSe nanocrystal formation

To model the time dependent evolution of the PDF $G(r,t)$ we have applied an established treatment of the finite size effects of nanocrystals on the pair distribution function.$^{8-9}$ The PDF is modeled as the PDF of the bulk lattice multiplied by a spherical envelope function $f(r,d)$ dependent on nanocrystal diameter $d$ as $G(r,d) = G(r)_{\text{bulk}} \ast f(r,d)$. Specifically,

$$f(r,d) = \left[ 1 - \frac{3r^2}{2d} + \frac{1}{2} \left( \frac{r}{d} \right)^3 \right] \ast h(d - r)$$  \hspace{1cm} (S2)

where $h(d - r)$ is the heaviside step function which is zero for $r$ greater than $d$, and 1 for $r \leq d$.\(^{10}\) In this case, $G(r)_{\text{bulk}}$ is the rock salt PbS or PbSe lattice. Fitting parameters related to experimental resolution – the finite $Q$ space resolution gaussian dampening factor $Q_{\text{damp}}$ as well as the empirical broadening factor $Q_{\text{broad}}$ – were acquired by fitting the PDF of a Ni standard taken in the same size Kapton tubing as that used in the flow cell in the same sample orientation. Correlated atomic motion was treated by optimizing an empirical quadratic correlated atomic motion correction factor, $\delta^2$, which was fit using the PDF of the final nanocrystal product. The atomic displacement parameters of Pb and S/Se atoms in the nanocrystalline product were refined for the final nanocrystal only to prevent overparameterization of the model during fitting of the full time series. The resulting real space gaussian peak width correction factor to a correlation at separation $r_{ij}$ is

$$\sigma_{ij} = \sigma'_{ij} \sqrt{1 - \frac{\delta^2}{r_{ij}^2} + \frac{Q_{\text{broad}}^2}{r_{ij}^2}}$$  \hspace{1cm} (S3)

where $\sigma'_{ij}$ is the uncorrelated peak width calculated from the atomic displacement parameters of the atoms at positions $i$ and $j$.\(^{11-12}\)

In order to fit each timepoint to best match the experimental data in the reaction, three parameters are refined using least-squares refinement implemented in PDFgui – a scale factor, a nanocrystal diameter $d$, and the cubic lattice constant of the rock salt lattice.\(^{12}\) The goodness of fit is quantified by the residual fit function.
\[
R_w = \sqrt{\frac{\sum_{i=1}^{n} [G_{obs}(r_i) - G_{calc}(r_i)]^2}{\sum_{i=1}^{n} G_{obs}(r_i)^2}}
\]  
(S4)

It is seen that the \( R_w \) as a function of time, \( R_w(t) \), quickly approaches low values indicative of a good fit to a nanocrystal proxy model several minutes following nucleation in each case and asymptotically approaches the final value (Figure S13A). The time evolution of \( R_w(t) \) which shows poor agreement at early times to the nanocrystal proxy model (Figure S13B) and excellent agreement at latter times is indicative of the progression from a \((\text{PbS})_x(\text{Pb(oleate)}_2)_y\) solute to final rock salt PbS nanocrystal products.

**Figure S13.** Refined parameters from virtual crystal modeling fitting of 110 °C *in-situ* PbS reaction. (A) Temporal evolution of the spherical envelope function diameter (*i.e.*, size of rock salt crystalline domains) and (B) \( R_w(t) \).
**Figure S14.** Observed and best fit (nanoparticle model) calculated reduced PDF pattern for the final product of an *in-situ* PbS reaction run at 110 °C.

**Figure S15.** Observed and best fit (nanoparticle model) calculated reduced PDF pattern for the final product of an *in-situ* PbSe reaction run at 110 °C.
Figure S16. Early time PbS (top) and PbSe (bottom) PDF patterns as shown in Figure 4 (black) and fits using virtual crystal models of the respective materials (pink). We note the poor fit of both virtual crystal models to the collected PDF patterns at early times. Low-\(r\) data for each material is also shown, highlighting the differences in both relative peak intensities and peak positions of the experimental local structure (first nearest neighbor and second nearest correlations) to the virtual crystal model at early times.

Figure S22. Fit of two candidate DFT PbS solute structures (insets) to an early-time PDF pattern collected in situ at 110 °C of a PbS reaction. The patterns were fit across the $r = 0.2$–0.5 nm (left) and $r = 0.2$–1.0 nm range (right).
Figure S23. Candidate DFT PbS solute structures used to fit early-time PDF patterns collected in situ at 110 °C of a PbS reaction (atom labels: dark grey = Pb; yellow = S; red = O; light grey = C; white = hydrogen).
Section 6: Calculation of $t_{1/2,\text{[NC]}}$ / $t_{1/2,\text{rxn}}$ and its associated error

The relative duration of PbS nucleation was estimated across a range of PbS forming conditions by fitting plots of [NC] versus time to

$$[\text{NC}] = [\text{NC}]_{\text{final}}\left(1 - e^{-k_{\text{[NC]}}(t-t_{\text{ind}})}\right)$$  \hspace{1cm} (7)

where [NC] is the concentration of nanocrystals, $[\text{NC}]_{\text{max}}$ is the maximum concentration of PbS nanocrystals, and $k_{\text{[NC]}}$ is a rate constant (Figure S24). $k_{\text{[NC]}}$ is used as a proxy for the speed in which the [NC] increases over the course of a reaction. While not grounded in a particular rate law, we believe the closeness of fit for equation 7 justifies its usage. We converted values of $k_{\text{[NC]}}$ to $t_{1/2,\text{[NC]}}$ to approximate the absolute duration of nucleation in each PbS reaction. $t_{1/2,\text{[NC]}}$ could be determined by the half life equation for a first order reaction

$$t_{1/2,\text{[NC]}} = \frac{\ln 2}{k_{\text{[NC]}}}$$  \hspace{1cm} (S5)

Since the absolute duration of nucleation is dependent upon the overall length of the PbS reaction, we normalize each $t_{1/2,\text{[NC]}}$ value by $t_{1/2,\text{rxn}}$, which represents the overall PbS forming reaction. Here, $t_{1/2,\text{rxn}}$ was calculated in the same manner as $t_{1/2,\text{[NC]}}$ but using the $k_r$ value for the reaction. We approximate $t_{1/2,\text{[NC]}} / t_{1/2,\text{rxn}}$ to be the fraction of total reaction time in which nuclei are added to formed in a given PbS reaction.

![Figure S24. Fitting the temporal evolution of [NC] using equation 7 for the reaction of Pb(oleate)$_2$ and N,N’-4-methoxy-phenyl-dodecylthiourea at 80 °C.](image)

Figure S24. Fitting the temporal evolution of [NC] using equation 7 for the reaction of Pb(oleate)$_2$ and N,N’-4-methoxy-phenyl-dodecylthiourea at 80 °C.
Since the absolute duration of nucleation is dependent upon the overall length of the PbS reaction, we normalize each $t_{1/2,[NC]}$ value by $t_{1/2,rxn}$ which represents the overall PbS forming reaction. Here, $t_{1/2,rxn}$ was calculated in the same manner as $t_{1/2,[NC]}$ but using the $k_r$ value for the reaction. We approximate $t_{1/2,[NC]} / t_{1/2,rxn}$ to be the fraction of total reaction time in which nuclei are added to formed in a given PbS reaction. Several example fittings for the [NC] and PbS yield temporal evolution is displayed above (Figure S25). The thiourea and reaction temperature for each set of plots is shown.

Figure S25. Fittings (solid lines) of the temporal evolution of [NC] (pink points) and PbS yield (black points) for several PbS conditions.

To estimate the uncertainty of $t_{1/2,[NC]} / t_{1/2,rxn}$ we measured the relative uncertainty of both $t_{1/2,[NC]}$ and $t_{1/2,rxn}$ based on the goodness of fit to a single exponential growth function. We find that uncertainty in $t_{1/2,rxn}$ is minimal compared to $t_{1/2,[NC]}$. In general error in $t_{1/2,rxn}$ was
found to be < 5% while error in \( t_{1/2,[NC]} \) ranged from < 5% to > 100% (Figure S24). The cases in which the error in \( t_{1/2,[NC]} \) were largest for PbS reactions run at higher temperatures (≥ 120 °C) and with the larger final nanocrystal sizes.

For reactions > 120 °C, we do not have a quantitative estimate for \( t_{1/2,[NC]} \) because equation 7 does not captures the overall shape of the [NC] versus time plots. However, we note that qualitatively the duration in which [NC] is increasing is shorter than the time resolution on our measurements, implying \( t_{1/2,[NC]} << 5 \) s. Interestingly, for the data at 110 °C and 120 °C in Figure S25, the [NC] appears to peak and then slightly decrease. We attribute the rise, then decrease in [NC] to the size-dependent extinction we used to calculate these values. Because those constants are empirically determined, variations in the peak width (i.e., size distribution) may lead to variation in the determined [NC]. This will naturally be more apparent at smaller sizes where the small variations in total nanocrystal volumes can cause larger differences in nanocrystal size. That is, at smaller sizes, changes in nanocrystal volume lead to larger differences in nanocrystal diameter. Independent measurements of the [NC] using small angle X-ray scattering techniques for analogous PbS forming conditions have confirmed the monotonic increase in [NC].
Section 7: Estimation of single-particle linewidths

To estimate the linewidths of the nanocrystal electronic transitions, we use a modified version of the transient spectral hole burning experiments described in Norris et al.\textsuperscript{14} Similar to what we have previously reported, dynamics were checked to ensure spectral are evaluated at times much longer than carrier cooling. Briefly, features in the $t = 2$ ns transient absorption spectra are fit using a set of negative amplitude Gaussian function ($\lambda = 902$ and 984 nm). For larger particle sizes ($\lambda = 1152$ and 1230 nm), and additional set of a bordering positive amplitude Gaussian functions were required as well. The positive function accounts for spectral shifts associated with the excited state of the quantum dot (also known as the biexciton effect) and additional weakly allowed excited state transitions.\textsuperscript{14-16} Representative fits for high energy excitation are shown in Figure S26. A linear baseline was used to account for the background photoinduced absorption signals. In all cases, the linewidth of the transition is taken to be the width of the negative Gaussian signal component (with variance $\sigma^2_{measured}$).

We account for the finite width of the laser pulse spectrum using by fitting it to a Gaussian lineshape (whose variance is $\sigma^2_{laser}$). Deconvolution is used to obtain the corrected linewidths (with variance of $\sigma^2_{particle}$) as a function of excitation energy:

$$\sigma^2_{measured} = \sigma^2_{laser} + \sigma^2_{particle}$$

The finite bandwidth of the laser pulse minimally affects the measured linewidth. For the sample with $\lambda = 984$ nm shown in Figure S27, the measured and deconvoluted linewidths differ by only 5%. This is a typical value for the range of samples reported here (2–7% difference). The high excitation energy ensemble linewidth is independent of the laser pulse spectrum since the spectrum is featureless and absorbs roughly equally over the excitation pulse width in that spectral region. As such, no deconvolution of the laser lineshape is used to determine the ensemble widths (extracted using the Gaussian fitting procedure described above).

The $1S_e - 1S_h$ transition is fit to a Gaussian function on an eV scale. The resulting $c$ (width) parameter is multiplied by the percent narrowing obtained from spectral hole burning measurements, giving the homogeneous linewidth $c_0$. 

23
Figure S26. Example of the fit procedure used to extract linewidths for several PbS samples described herein. The top panel (grey line) is the residual of the fit shown in the middle panel. The middle panel displays the collected data (black) and fit (red). The bottom panel shows the individual Gaussian components of the fit. A linear baseline (red dashed line) is used to account for the broad photoinduced background signal.

Figure S27. PbS nanocrystal extinction spectrum for a sample with $\lambda = 984$ nm along with the spectra of the laser pulses used to excitation (top). Transient spectra recorded at $t = 2$ ns as a function of wavelength (middle). Transient spectra as a function of photon wavelength that are offset to account for differences in the ground state bleach minima (bottom).
Figure S28. Final FWHM and exciton position plotted for a series of PbSe reactions run between 60–140 °C. The homogeneous linewidth for several PbSe sizes (white dots) is shown. A polynomial fit ($\text{FWHM} = A'e^{B'\lambda}$) to the homogeneous linewidth points (black line) is shown to compare with smaller final PbSe sizes.

Figure S29. Final FWHM and exciton position plotted for a series of PbS reactions run between 80–140 °C. The homogeneous linewidth for several PbS sizes (white dots) is shown. A polynomial fit ($\text{FWHM} = Ae^{Bx}$, $A = 73.8$, $B = 2.33$, $x =$ first excitonic transition energy) to the homogeneous linewidth points (black line) is shown to compare with smaller final PbS sizes. Data points showing the homogeneous linewidth for PbS from another method are also displayed for reference (grey dots).\textsuperscript{17}
Figure S30. Plot of percent narrowing versus the position of the lowest energy excitonic transition for PbS (left) and PbSe (right). Percent narrowing describes how much narrower the intrinsic linewidth is from the observed absorbance linewidth. Percent narrowing is calculated using the same method as described previously for PbSe using the data in Figures 7B and S28–S29.¹

Figure S31. Final FWHM and exciton position for the PbS forming conditions shown in Figure 7B color coated based on thiourea used.

Section 9: *In situ* absorption data and fittings

As described in the experimental section the data were fit in two ways. Here we present the raw data from the dip probe experiments ($\lambda = 400$ nm) and (i) the overall fit to a single exponential and (ii) the second fit, designed to carefully capture the induction delay and the critical monomer concentration.
