In the first part of this letter we discuss electrodynamics of an excitonic condensate in a bilayer. We show that under certain conditions the system has a dominant energy scale and is described by the effective electrodynamics with “planar magnetic charges”. In the second part of the paper we point out that a vortex liquid state in bilayer superconductors also possesses dipolar superfluid modes and establish equivalence mapping between this state and a dipolar excitonic condensate. We point out that a vortex liquid state in an N-layer superconductor possesses multiple topologically coupled dipolar superfluid modes and therefore represents a generalization of the dipolar superfluidity concept.

The progress in semiconductor technology has made it feasible to produce bilayers where the interparticle distance is larger than the separation of the layers and which are expected to have interlayer excitonic states \[1, 2, 3, 4\] (as shown in Fig. 1) with a significant lifetime. Some signatures of Bose-Einstein condensate (as shown in Fig. 1) with a significant life time. Some signatures of Bose-Einstein condensate (as shown in Fig. 1) with a significant lifetime. Some signatures of Bose-Einstein condensate (as shown in Fig. 1) with a significant life time. Some signatures of Bose-Einstein condensate (as shown in Fig. 1) with a significant

To describe topological defects we should include dynamics of the gauge field in the model \[3\]. Consider a system of two thin parallel layers with positive and negative charges bound in pairs (as shown in Fig. 1). Here,

\[
\nabla \times \mathbf{B} = \mathbf{J} = e[\delta(z_--) - \delta(z_+)] \times \left\{ \frac{i}{2} (\psi \nabla \psi^* - \psi^* \nabla \psi) - e|\psi|^2 [\mathbf{A}(r_+) - \mathbf{A}(r_-)] \right\} \tag{2}
\]

where \(\mathbf{J}\) is the electric current, \(\psi\) is the DEC order parameter, \(z_{(+,-)}\) are the \(z\)-axis positions of the upper and lower planes and \(r_{(+,-)} = (x, y, z_{(+,-)})\). Topological defects in this system correspond to the situation where the phase, \(\theta\), of the order parameter, \(\psi\), changes by \(2\pi n\). A configuration of accompanying magnetic field should be determined by minimization of the energy taking into account (i) the kinetic energy of currents in two planes, (ii) the potential energy of the corresponding Ginzburg-Landau functional, (iii) the energy of the three dimensional magnetic field configuration. This problem is non-local and the field-inducing current itself depends on the gauge field, i.e., should be determined in a self-consistent way. However we show here that there is a regime when the system is accurately described by an unusual, on the other hand tractable effective model. That is, let us consider the situation where the separation of the layers \(d\) is small compared to the system size and \(\mathbf{A}(r_+) - \mathbf{A}(r_-) \approx d \partial_z \mathbf{A}(r)\). Then in the hydrodynamic limit the effective model is

\[
\mathcal{F}_{eff} = \frac{1}{2} \delta(z) \rho \left( \nabla \theta + e d [\hat{\mathbf{R}} \mathbf{B}_m(r)] \right)^2 + \frac{1}{2} \mathbf{B}_m^2(r) \tag{3}
\]

Where \(\mathbf{B}_m\) is the field in the dipolar layer. Consider a vortex with \(\Delta \theta = 2\pi\). Then \(\nabla \theta = \frac{1}{\rho} \mathbf{e}_\theta\), which produces a logarithmic divergence of the energy in a neutral system. However eq. 43 suggests that for a given phase winding, the system can minimize its energy by generating a certain configuration of \(\mathbf{B}_m\). Note that the second term in

\[
\mathcal{F} = \frac{\rho}{2} \left( \nabla \theta + e d [\hat{\mathbf{R}} \mathbf{H}^{ext}] \right)^2 \tag{1}
\]
depends quadratically on $B$ and does not allow a configuration of $B_{in}$ which would completely compensate the phase gradient in the first term. A configuration of the interplane field, which would partially compensate the divergence caused by $\nabla \theta$, should satisfy the condition: $ed(\hat{R}B_{in}) \propto \epsilon_{d} e_{\theta}$ ($r \gg r_{core}$). This implies the following self-induced interplane field:

$$B_{in} = \frac{1}{ed \ r^2} \begin{cases} a \ < \ 0, & r = (x, y, 0) \end{cases}$$

At a first glance, eq. (4) appears to violate the condition that the magnetic field should be divergenceless. This problem is resolved by including in the picture the “out-of-plane” magnetic fields. These, as schematically shown in Fig. 2, can restore the $\nabla \cdot B = 0$ constraint in three dimensional physical space while permitting the in-plane field to have the form required by (4) with a natural cutoff close to the vortex core. From the $\nabla \cdot B = 0$ condition it follows that both the interlayer $B_{in}$ field and the out-of-plane field carry the same flux. However for a given magnetic flux, the out-of-plane field has the freedom to spread in the positive and negative $z$-axis directions. Since the magnetic flux is $\int B \cdot dS$, while the magnetic field energy is $(1/2) \int B^2$, the out-of-plane field will have a finite value of the integral $(1/2) \int_{r \in [z] \ 2} B^2$ over entire three dimensional space excluding the bilayer space. On the other hand the magnetic field inside the bilayer behaves as $|B_{in}| \propto 1/r$ and thus has logarithmically divergent energy $(1/2) \int_{r \in [z] \ 2} B^2$. Therefore from the condition $\nabla \cdot B = 0$ and geometry of the problem it follows that the energy of out-of-plane magnetic fields is negligible compared to the energy of magnetic field in the dipolar bilayer for a sample with $d$ small compared to the system size.

Thus we have identified the regime where the dynamics of the magnetic field is dominated by its most energetically costly (weakly divergent) interlayer part, $B_{in}$, which leads to an interesting two-dimensional effective model where the magnetic field $B_{in}$ is not subject to the constraint that $\nabla \cdot B_{in} = 0$.

**FIG. 2: (color online) A schematic picture of a magnetic field configuration in DEC with vortices. Side view: the out-of-plane magnetic field $B$ carries the same flux as the interplane field $B_{in}$, however it has the freedom to minimize energy by spreading above and below the top and bottom layers. Top view: the in-plane magnetic field $B_{in}$ configuration for vortices with phase windings $\Delta \theta = \pm 2\pi$.**

The energy of such a vortex placed in the center of a circle-shaped system of a radius $R$ is:

$$E \approx \frac{\pi \mu m^2}{1 + \rho c^2 d} \ln \frac{R}{r_{core}}$$

where $r_{core}$ is the vortex core size. Even though this energy is logarithmically divergent, these vortices can in principle be induced in a DEC by an external in-plane magnetic field because their magnetic field also has divergent energy. This provides a possibility to obtain a negative contribution to the Gibbs energy from $\int_{v} \mathcal{E} \cdot B$. For example, in principle, an experimentally realizable configuration of induction elements can produce the following external in-plane field $H \approx \gamma \frac{\mu}{r} \mathcal{E}$; $|r| = (x, y, 0)$; $r > r_{0}$ where $r_{0}$ is some cutoff length. Then, for a vortex with $\Delta \theta = 2\pi$, the integral $\int_{v} \mathcal{E} \cdot B$ provides a negative logarithmically divergent contribution to the Gibbs energy $G = \int_{v} \mathcal{E} \cdot \mathcal{E}$. There is a critical value of the coefficient, $\gamma$ at which the creation of a vortex becomes energetically favorable (below we set $r_{0} \approx r_{core}$ without loss of generality). In the regime $\rho c^{-2} d \ll 1$ we obtain $\gamma_{c} \approx \frac{1}{2 c^2 d}$. In general case the energetic favorability of a vortex state depends on the integral $\int_{v} \mathcal{E} \cdot B$. An external field which is significantly stronger than that corresponding to $\gamma_{c}$ favors a higher phase winding number of the induced vortex structure, however on the other hand, the vortex energy depends quadratically on $n$ [see eq. (5)]. Therefore, a stronger field should normally produce a state with multiple one-dipolar-quantum vortices.
In a planar $U(1)$-symmetric system, thermal fluctuations can excite finite-energy pairs of vortices with opposite windings. In the model [5] the interaction between a vortex with $\Delta \theta = 2\pi$ located at $\mathbf{r}_1$ and an antivortex with $\Delta \theta = -2\pi$ located at $\mathbf{r}_2$ originates from two sources. The usual current-current interaction produces the attractive force

$$ F_J = -2\pi \rho \left( 1 - \frac{\rho e^2 d}{\rho e^2 d + 1} \right)^2 \left( \frac{\mathbf{r}_2 - \mathbf{r}_1}{|\mathbf{r}_2 - \mathbf{r}_1|^2} \right). \tag{9} $$

the other contribution comes from the $B_{in}^2$ term:

$$ F_B = -2\pi \rho \frac{\rho e^2 d}{|\mathbf{r}_2 - \mathbf{r}_1|^2} \left( \frac{\mathbf{r}_2 - \mathbf{r}_1}{|\mathbf{r}_2 - \mathbf{r}_1|^2} \right). \tag{10} $$

A system of these vortices and antivortices can be mapped onto a Coulomb gas which at a temperature $T_{KT}$ undergoes a KT transition:

$$ T_{KT} = \frac{\pi}{2} \rho(T_{KT}) \frac{1}{1 + \rho(T_{KT}) e^2 d}. \tag{11} $$

Therefore, the temperature of the condensation transition in DEC will be suppressed compared to the value of the condensation temperature in a neutral system with similar density. While the suppression for realistic DECs is tiny, there is an interesting aspect in it because in contrast to the superfluid density jump $\rho(T_{KT}) = 2/\pi$ in regular superfluids here one should define a “generalized superfluid density jump” which depends on the electric charge and on a nonuniversal parameter: the layer separation.

As is well known, one of the ways to detect a KT transition/crossover in superconducting films is associated with a peculiar reaction to an applied current [7]. In a superconducting film an external current results in Lorentz forces acting on a vortex and antivortex in opposite ways, causing a pairbreaking effect. Free vortices create dissipation which is manifested in IV characteristics [7]. In DEC, vortices have magnetic field which can be viewed as that of “magnetic charges” and, correspondingly, they are sensitive to an applied external uniform in-plane magnetic field. Such a field, at finite temperature, should create a KT-specific modification of the zero-temperature response discussed in [4].

We note that because of small carrier density and layer separation in the presently available semiconductor bilayers [6] a dipolar vortex would carry only about $10^{-7}$ flux quanta, which, though may be resolved with a modern SQUID, makes observation of these effects difficult. This raises the question if there could be strong-coupling dipolar superfluids in principle. Below we show that the concept to dipolar superfluidity arises in a system principally different from DEC, without interlayer pairing problem (which limits dipolar coupling strength in DEC). This provides a possibility to have larger flux of a dipolar vortex and more pronounced phenomena associated with it.

Moreover there the concept of dipolar superfluidity allows generalization.

Consider a layered superconductor (LSC), i.e. a multiple superconducting layers separated by insulating layers (to effectively eliminate interlayer Josephson coupling) so that the layers are only coupled by the gauge field. This system has been extensively studied in the past [8]. In the hydrodynamic limit its free energy density is

$$ F = \sum_{i=1}^{N} \frac{1}{2} \delta(z_i) \left| \left( \nabla - ie \mathbf{A}(x,y,z_i) \right) \psi_i(x,y,z_i) \right|^2 + \frac{\left( \nabla \times \mathbf{A}(x,y,z) \right)^2}{2} \tag{12} $$

where $\psi_i(x,y,z_i) = |\psi_i(x,y,z_i)| e^{i \theta_i(x,y,z_i)}$, $z_i + d_i = z_{i+1}$. This model indeed does not feature dipolar superfluidity of the DEC type. Here, the main distinction is the reaction to the external field which is screened because of the Meissner effect (the effective screening length in a planar superconductor is $\lambda^2$/[layer thickness]). However there are situations where the superconductivity can be eliminated in this system by topological defects. That is, if to apply an external field along $z$-direction one can produce a lattice of vortex lines with phase winding in each layer ($\Delta \theta_l(z_i) = 2\pi$, ...,$\Delta \theta_N(z_N) = 2\pi$) [8]. Enclosed magnetic flux gives such a vortex line a finite tension. At elevated temperatures the lattice of these vortices melts but importantly normally there is a range of parameters (which depends on the strength of the applied field and temperature) where the vortex lines forming a liquid retain tension [8, 9]. If the vortex lattice is not pinned or if one has a tensionfull vortex liquid the charge transfer in superconducting layers is dissipative. However in such situations a system nonetheless retains broken symmetries associated with the phase differences between the order parameters, and correspondingly dissipationless countercurrents [10], in this particular case a broken symmetry is retained in the phase difference between the layers. Physically the situation which occurs is the following: consider the $N = 2$, $|\psi_1| = |\psi_2| = |\psi|$ case. Currents in individual layers move unpinned vortices which produce dissipation. However as long as a vortex line threading the system has a finite tension, equal countercurrents in different layers deform but not move a vortex line and therefore do not create dissipation. For small layer separation $d$, the dissipationless countercurrents can approximately be described by extracting phase difference terms [10]. Then the part of the model (12) which retains a broken symmetry is:

$$ F_d \approx \frac{1}{4} |\psi|^2 \left( \nabla (\theta_1(x,y,z_1) - \theta_2(x,y,z_2)) \right) $$

$$ -e(\mathbf{A}(x,y,z_1) - \mathbf{A}(x,y,z_2)) \right|^2 + \frac{d}{2} B_{in}^2. \tag{13} $$

The vortices in this system are related to dipolar vortices in DEC. The simplest vortices with a topological charge
in the phase difference are \((\Delta \theta_1 = \pm 2\pi, \Delta \theta_2 = 0)\) and \((\Delta \theta_1 = 0, \Delta \theta_2 = \pm 2\pi)\). We denote them by a pair of integers \((\pm 1,0)\) and \((0, \pm 1)\). For a vortex \((\pm 1,0)\) the currents in two layers are: \(j_1 = e|\psi|^2 \nabla \theta_1 - e^2|\psi|^2 A(x, y, z_1)\); \(j_2 = -e^2|\psi|^2 A(x, y, z_2)\). Like in a DEC, in the case of a finite \(d\), the vortex features in-plane radial magnetic field \([\hat{r} \hat{B}_m] \approx \partial_r \mathbf{A}(r)\). These vortices can be induced by an external in-plane magnetic field, like in a DEC. However there are indeed also principal differences. LSC is a system with more degrees of freedom and the above considerations apply only to the state when superconductivity in individual layers is removed e.g. by a molten lattice of \((1,1)\) vortices, or thermally excited \((\pm 1, \pm 1)\) vortices. Note also that the molten lattice of \((1,1)\) vortices does not automatically preclude a formation of an ordered state of \((\pm 1,0)\) and \((0, \pm 1)\) vortices because a vortex \((1,1)\) does not have a topological charge in the phase difference sector \(\nabla (\theta_1 - \theta_2)\), and their disordered states can not eliminate corresponding phase stiffness. The density of \((1,1)\) vortices and correspondingly the temperature of their lattice melting is controlled by the strength of the magnetic field in \(z\)-direction while the density of \((\pm 1,0)\) and \((0, \pm 1)\) vortices is controlled by the in-plane magnetic field. The system therefore possesses a control parameter which allows for the ordered structures of \((\pm 1,0)\) and \((0, \pm 1)\) vortices to coexist with a liquid of \((1,1)\) vortices.

The dipolar superfluidity in LSC has a number of detectable physical consequences. Namely the LSC in the vortex liquid state should have a dipolar superfluid response, analogous to that discussed in great detail in [4]. Also the system in the vortex liquid state should possess aspects of planar electrodynamics with effective magnetic charges discussed above in connection with DEC which may be observable in the temperature dependency of the dipolar response. The general case of \(N\) layers, especially with the variable interlayer distances and the condensate densities, has much richer structure than DEC because the dipolar superfluid modes are multiple and coupled. That is, for \(N\) layers one can have multiple combinations of counterflows in different layers which will not move a tensionfull vortex line, therefore one has to consider all possible combinations of phase differences to describe dipolar modes. In the limit of very small \(d\) the kinetic terms for countercurrents approximately can be expressed as:

\[
\begin{align*}
P^{SF}_d & \approx \sum_{i,j=1}^N \frac{|\psi|^2}{4N} \left[ \nabla (\theta_i(x, y, z_i) - \theta_j(x, y, z_j) - e(A(x, y, z_i) - A(x, y, z_j)) \right]^2. \\
& \approx \sum_{i,j=1}^N \frac{|\psi|^2}{4N} \left[ \nabla (\theta_i(x, y, z_i) - \theta_j(x, y, z_j)) \right]^2. \\
\end{align*}
\]

This generalization of DEC may be called “multiflavor dipolar condensate”.

In both cases of DEC and LSC the dipolar superfluidity will be destroyed by interlayer tunneling, but for small interlayer tunneling some of its physical manifestations will in some cases remain [3].

In conclusion we have considered the possible physical effects dictated by the symmetry and dynamics of a gauge field in dipolar condensates. For DEC, we started by constructing an effective model, based on symmetry and energy scales of the problem. In this framework we described topological defects which emit a nonuniversally quantized radial magnetic flux. We pointed out that because of the existence of well separated energy scales in the regime, when interlayer distance is smaller than other length scales in the problem, the system possesses effective planar electrodynamics with “magnetic charges” (planar analogue of magnetic monopoles) arising from topological excitations. Therefore at finite temperature an applied inplane magnetic field should have a vortex-antivortex pairbreaking effect. Experimentally it may manifest itself through a counterpart of Halperin-Nelson response which may be observable in systems with sufficiently strong dipolar coupling. In the second part of the paper we map DEC onto the tensionfull vortex liquid state in layered superconductors. In that system we point out the emergence of a dipolar superfluidity which has a different origin because there is no interlayer pairing and carriers in layers have the same sign of electric charge. There the analogue of the dipolar superfluidity arises as a consequence of the fact that a molten lattice of composite vortices makes currents in individual layers dissipative while the counter-currents in different layers remain dissipationless. In these systems there is no need for interlayer pairing and carrier density is higher so the effective dipolar coupling may be relatively large. Besides that, the dipolar response can be used as an experimental tool to study vortex liquids in LSC, e.g. to unequivocally distinguish a tensionfull vortex liquid state.

We thank J.M. Speight for discussions and S. Shevchenko for communications and for informing us about a perturbative study of the weak dipolar coupling regime [2] and a study of Josephson coupling in DEC [3].
