ABSTRACT

All famous machine learning algorithms that correspond to both supervised and semi-supervised learning work well only under a common assumption: training and test data follow the same distribution. When the distribution changes, most statistical models must be reconstructed from new collected data that, for some applications, may be costly or impossible to get. Therefore, it became necessary to develop approaches that reduce the need and the effort of obtaining new labeled samples by exploiting data available in related areas and using it further in similar fields. This has given rise to a new machine learning framework called transfer learning: a learning setting inspired by the capability of a human being to extrapolate knowledge across tasks to learn more efficiently. Despite a large amount of different transfer learning scenarios, the main objective of this survey is to provide an overview of the state-of-the-art theoretical results in a specific and arguably the most popular sub-field of transfer learning called domain adaptation. In this sub-field, the data distribution is assumed to change across the training and the test data while the learning task remains the same. We provide a first up-to-date description of existing results related to domain adaptation problem that cover learning bounds based on different statistical learning frameworks.

Keywords Transfer learning · Domain adaptation · Learning theory

This survey is a shortened version of the recently published book “Advances in Domain Adaptation Theory” [Redko et al., 2019c] written by the authors of this survey. Its purpose is to provide a high-level overview of the latter work and update it with some recent references. All proofs and most of mathematical developments are omitted in this version to keep the document at a reasonable length. For more details, we refer the interested reader to the original papers or the full version of the book available at http://tiny.cc/mj2dnz.

1 Introduction

The idea behind transfer learning is inspired by the human being’s ability to learn with minimal or no supervision based on previously acquired knowledge. It is not surprising that this concept was not invented in the machine learning community in the proper sense of the term, since the notion “transfer of learning” had been used long before the construction of the first computer and is found in the psychology field papers from early 20th century. From the statistical point of view, this learning scenario is different from supervised learning as the former does not assume that the training and test data have to be drawn from the same probability distribution. It was argued that this assumption is often too restrictive to hold in practice as in many real-world applications a hypothesis is learned and deployed in environments that differ and exhibit an important shift. A typical example often used in transfer learning is to consider
a spam filtering task where the spam filter is learned using an arbitrary classification algorithm for a corporate mailbox of a given user. In this case, the vast majority of e-mails analyzed by the algorithm are likely to be of a professional character with very few of them being related to the private life of the considered person. Imagine further a situation where this same user installs a mailbox software on the personal computer and imports the settings of its corporate mailbox hoping that it will work equally well on it too. This, however, is not likely to be the case as many personal e-mails may seem like spam to an algorithm learned purely on professional communications due to the differences in their content and attached files as well as the non-uniformity of email addresses. Another illustrative example is that of species classification in oceanographic studies where one relies on a video coverage of a certain sea area in order to recognize species of the marine habitat. For instance, in the Mediterranean sea and in the Indian ocean, the species of fish that can be found on the recorded videos are likely to belong to the same family, even though their actual appearance may be quite dissimilar due to different climate and evolutionary background. In this case, the learning algorithm trained on the video coverage of the Mediterranean sea will most likely fail to provide a correct classification of species in the Indian ocean without being specifically adapted by an expert.

For this kind of applications, it may be desirable to find a learning paradigm that can remain robust to a changing environment and adapt to a new problem at hand by drawing parallels and exploiting the knowledge from the domain where it was learned in the first place. In response to this problem, the quest for new algorithms able to learn on a training sample and then have a good performance on a test sample coming from a different but related probability distribution gave rise to a new learning paradigm called transfer learning. Its definition is given as follows.

**Definition 1.** (Transfer learning) We consider a source data distribution \( S \) called the source domain, and a target data distribution \( T \) called the target domain. Let \( X_S \times Y_S \) be the source input and output spaces associated to \( S \), and \( X_T \times Y_T \) be the target input and output spaces associated to \( T \). We denote by \( S_X \) and \( T_X \) the marginal distributions of \( X_S \) and \( X_T \), by \( t_S \) and \( t_T \) the source and target learning tasks depending on \( Y_S \) and \( Y_T \), respectively. Then, transfer learning aims to help to improve the learning of the target predictive function \( f_T : X_T \to Y_T \) for \( t_T \) using knowledge gained from \( S \) and \( t_S \) where \( S \neq T \).

Note that the condition \( S \neq T \) implies either \( S_X \neq T_X \) (i.e., \( X_S \neq X_T \) or \( S_X(X) \neq T_X(X) \)) or \( t_S \neq t_T \) (i.e., \( Y_S \neq Y_T \) or \( S(Y|X) \neq T(Y|X) \)). In transfer learning, one often distinguishes three possible learning settings based on these different relations (illustrated in Figure 1):

1. **Inductive transfer learning** where \( S_X = T_X \) and \( t_S \neq t_T \);
   For example, \( S_X \) and \( T_X \) are the distributions of the data collected from the mailbox of one particular user, with \( t_S \) being the task of detecting a spam, while \( t_T \) being the task of detecting a hoax;

2. **Transductive transfer learning** where \( S_X \neq T_X \) but \( t_S = t_T \);
   For example, in the spam filtering problem, \( S_X \) is the distribution of the data collected for one user, \( T_X \) is the distribution of data of another user and \( t_S \) and \( t_T \) are both the task of detecting a spam;
3. **Unsupervised transfer learning** where $t_S \neq t_T$ and $S_X \neq T_X$:

For example, $S_X$ generates the data collected from one user and $T_X$ generates the content of web-pages collected on the web with $t_S$ consisting in filtering out spams, while $t_T$ is to detect hoax.

Arguably, the vast majority of situations where transfer learning proves to be the most needed falls into the second category. This latter has the name of *domain adaptation*, where we suppose that the source and the target tasks are the same, but where we have a source data set with an abundant amount of labeled observations and a target one with no (or little) labeled instances. In this survey, we concentrate on theoretical advances related to the latter case and highlight their differences with respect to the traditional supervised learning paradigm. A brief overview of the considered works is given in Table 1 and 2 for for learning bounds and hardness results, respectively.

**Table 1:** A summary of contributions presented in this survey for learning bounds in domain adaptation. (Task) refers to the considered learning problem; (Framework) specifies the statistical learning framework used in the analysis; (Divergence) is the metric used to compare the source and target distributions; (Link) stands for the dependence between the source error and the divergence term; (Non-estim.) indicates the presence of a non-estimable term in the bounds.

The rest of this survey is organized as follows. In Section 2, we briefly present the traditional statistical learning frameworks that are referred to throughout the survey. In Section 3, we present the first theoretical results of the domain adaptation theory from the seminal works of [Ben-David et al., 2007, Mansour et al., 2009a, Cortes and Mohri, 2011] that rely on the famous \(\mathcal{H}\Delta \mathcal{H}\) and discrepancy distances. We further turn our attention to hardness results for domain adaptation problem in Section 4. Section 5 presents several works establishing the generalization bounds for domain adaptation based on the popular integral probability metrics (IPMs). In Section 6, we highlight several learning bounds proved using the PAC-Bayesian framework. Finally, in Section 7 we give an overview of the contributions that take the actual learning algorithm into account when deriving the learning bounds and conclude the survey in Section 8.

2 Preliminary knowledge

Below we recall the usual supervised learning setup and different quantities used to derive generalization bounds in this context. This includes the notions of Vapnik-Chervonenkis (VC) [Vapnik, 2006, Vapnik and Chervonenkis, 1971] and Rademacher complexities [Koltchinskii and Panchenko, 1999], the definitions related to the PAC-Bayesian theory [McAllester, 1999] and those from the more recent algorithmic stability [Bousquet and Elisseeff, 2002] and algorithmic robustness [Xu and Mannor, 2010] frameworks.

2.1 Definitions

Let a pair \((X, Y)\) define the input and the output spaces where \(X\) is described by real-valued vectors of finite dimension \(d\), i.e., \(X \subseteq \mathbb{R}^d\) and for \(Y\) we distinguish between two possible scenarios: 1) when \(Y\) is continuous, e.g., \(Y = [-1, 1]\) or \(Y = \mathbb{R}\), we talk about regression; 2) when \(Y\) is discrete and takes values from a finite set, we talk about classification. Two important cases of classification are binary classification and multi-class classification where \(Y = \{-1, 1\}\) (or \(Y = \{0, 1\}\)) and \(Y = \{1, 2, \ldots, C\}\) with \(C > 2\), respectively.
We assume that $X \times Y$ is drawn from an unknown joint probability distribution $\mathcal{D}$ and that we observe them through a finite training sample (also called learning sample) $S = \{ (x_i, y_i) \}_{i=1}^m \sim (\mathcal{D})^m$ of $m$ independent and identically distributed (i.i.d.) pairs (also called examples or data instances). We further denote by $\mathcal{H} = \{ h : X \rightarrow Y \}$ a hypothesis space (also called hypothesis class) consisting of functions that map each element of $X$ to $Y$. These functions $h$ are usually called hypotheses, or more specifically classifiers or regressors depending on the nature of $Y$.

Let us now consider a loss function $\ell : Y \times Y \rightarrow [0, 1]$ that gives a cost of $h(x)$ deviating from the true output $y \in Y$. We can define the true risk and the empirical risk with respect to $\mathcal{D}$ and $S$ respectively, as follows.

**Definition 2. (True risk) Given a loss function $\ell : Y \times Y \rightarrow [0, 1]$, the true risk (also called generalization error) $R_\mathcal{D}^\ell(h)$ for a given hypothesis $h \in \mathcal{H}$ on a distribution $\mathcal{D}$ over $X \times Y$ is defined as

$$R_\mathcal{D}^\ell(h) = \mathbb{E}_{(x, y) \sim \mathcal{D}} \ell(h(x), y).$$

By abuse of notations, for a given pair of hypotheses $(h, h') \in \mathcal{H}^2$, we write

$$R_\mathcal{D}^\ell(h, h') = \mathbb{E}_{(x, y) \sim \mathcal{D}} \ell(h(x), h'(x)).$$

**Definition 3. (Empirical risk) Given a loss function $\ell : Y \times Y \rightarrow [0, 1]$ and a training sample $S = \{ (x_i, y_i) \}_{i=1}^m$ where each example is drawn i.i.d. from $\mathcal{D}$, the empirical risk $R_S^\ell(h)$ for a given hypothesis $h \in \mathcal{H}$ is defined as

$$R_S^\ell(h) = \frac{1}{m} \sum_{i=1}^m \ell(h(x_i), y_i),$$

where $\mathcal{D}$ is the empirical distribution associated to the sample $S$.

The most natural loss function that can be used to count the number of errors committed by a hypothesis $h \in \mathcal{H}$ on the distribution $\mathcal{D}$ is the $0 - 1$ loss function $\ell_{0-1} : Y \times Y \rightarrow \{0, 1\}$ which is defined for a training example $(x, y)$ as

$$\ell_{0-1}(h(x), y) = \mathbb{I} [h(x) \neq y] = \begin{cases} 1, & \text{if } h(x) \neq y, \\ 0, & \text{otherwise}. \end{cases}$$

A popular proxy to this non-convex function is the hinge loss defined for a given pair $(x, y)$ by

$$\ell_{\text{hinge}}(h(x), y) = [1 - y h(x)]_+ = \max(0, 1 - y h(x)).$$

Another loss function often used in practice that extends the $0 - 1$ loss to the case of real values is the linear loss $\ell_{\text{lin}} : \mathbb{R} \times \mathbb{R} \rightarrow [0, 1]$, defined by:

$$\ell_{\text{lin}}(h(x), y) = \frac{1}{2} (1 - y h(x)).$$

The three above-mentioned loss functions are illustrated in Figure 2. Note that in this figure, the X-axis are $y h(x)$ values as $h(x) = y$ is equivalent to $y h(x) \geq 0$ when $Y = \{-1, 1\}$.

**Notations** Below, we present the notations that are used throughout the survey.

| Symbol       | Description                           |
|--------------|---------------------------------------|
| $X$          | Input space                           |
| $Y$          | Output space                          |
| $\mathcal{D}$ | A domain: a yet unknown distribution over $X \times Y$ |
| $\mathcal{D}_X$ | Marginal distribution of $\mathcal{D}$ on $X$ |
| $\mathcal{D}_X$ | Empirical distribution associated with a sample drawn from $\mathcal{D}_X$ |
| $\text{supp}(\mathcal{D})$ | Support of distribution $\mathcal{D}$ |
| $\Pr(\cdot)$ | Probability of an event               |
| $\mathbb{E}(\cdot)$ | Expectation of a random variable      |
| $x = (x_1, \ldots, x_d)^\top \in \mathbb{R}^d$ | A $d$-dimensional real-valued vector |
| $(x, y) \sim \mathcal{D}$ | $(x, y)$ is drawn i.i.d. from $\mathcal{D}$ |
| $S = \{ (x_i, y_i) \}_{i=1}^m \sim (\mathcal{D})^m$ | Labeled learning sample constituted of $m$ examples drawn i.i.d. from $\mathcal{D}$ |
| $S_u = \{ (x_i) \}_{i=1}^m \sim (\mathcal{D}_X)^m$ | Unlabeled learning sample constituted of $m$ examples drawn i.i.d. from $\mathcal{D}_X$ |
VC (Vapnik-Chervonenkis) dimension defined as follows.

Vapnik-Chervonenkis (VC) bounds [Vapnik and Chervonenkis, 1971, Vapnik, 2006] are based on the original definition where

\( \varepsilon > 0 \), \( \delta \in (0, 1] \). This expression essentially tells us that we want to upper-bound the gap between the true risk and its estimated value by the smallest possible value of \( \varepsilon \) and with a high probability over the random choice of the training sample \( S \). The major question now is to understand whether \( R_S^\ell(h) \) converges to \( R_D^\ell(h) \) with an increasing number of samples and what is the speed of this convergence. We now proceed to a presentation of several theoretical paradigms that were proposed in the literature in order to show different characteristics of a learning model or a data sample that this speed can depend on.

### 2.2 Probably approximately correct (PAC) setting

Statistical learning theory [Vapnik, 1995] provides us with the results regarding the conditions that ensure the convergence of the empirical risk to the true risk for a given hypothesis class. These results, known as generalization bounds, are usually expressed in the form of Probably Approximately Correct (PAC) inequalities [Valiant, 1984] that have the following form:

\[
\Pr_{S \sim (D)^m} \{|R_S^\ell(h) - R_D^\ell(h)| \leq \varepsilon\} \geq 1 - \delta,
\]

where \( \varepsilon > 0 \) and \( \delta \in (0, 1] \). This expression essentially tells us that we want to upper-bound the gap between the true risk and its estimated value by the smallest possible value of \( \varepsilon \) and with a high probability over the random choice of the training sample \( S \). The major question now is to understand whether \( R_S^\ell(h) \) converges to \( R_D^\ell(h) \) with an increasing number of samples and what is the speed of this convergence. We now proceed to a presentation of several theoretical paradigms that were proposed in the literature in order to show different characteristics of a learning model or a data sample that this speed can depend on.

### 2.3 Vapnik-Chervonenkis complexity

Vapnik-Chervonenkis (VC) bounds [Vapnik and Chervonenkis, 1971, Vapnik, 2006] are based on the original definition that allows to quantify the complexity of a given hypothesis class. This notion of complexity is captured by the famous VC (Vapnik-Chervonenkis) dimension defined as follows.

**Definition 4.** (VC dimension) The VC dimension \( VC(\mathcal{H}) \) of a given hypothesis class \( \mathcal{H} \) for the problem of binary classification is defined as the largest possible cardinality of some subset \( X' \subset X \) for which there exists a hypothesis \( h \in \mathcal{H} \) that perfectly classifies elements from \( X' \) whatever their labels are. More formally, we have

\[
VC(\mathcal{H}) = \max\{|X'| : \forall y_i \in \{-1, +1\}^{\|X'\|}, \exists h \in \mathcal{H} \text{ so that } \forall x_i \in X', h(x_i) = y_i\}.
\]

As it follows from the definition, the VC dimension is the cardinality of the biggest subset of a given sample that can be subject to perfect classification provided by a hypothesis from \( \mathcal{H} \) for all possible labellings of its observations. To illustrate it, we can consider a classical example given in Figure 3, where the hypothesis class \( \mathcal{H} \) consists of half-planes in \( \mathbb{R}^d \). In this particular case with \( d = 2 \), we can perfectly classify only \( d + 1 \) elements regardless their labeling as for the case with \( d + 2 \) points it will no longer be possible. It means that the VC dimension of the class of half-planes in \( \mathbb{R}^d \) is equal to \( d + 1 \). Note that the obtained result reveals that in this particular scenario the VC dimension is equal to the number of parameters needed to define the function of the hypothesis plane. This, however, is not true in general as some classes may have an infinite VC dimension despite a finite number of parameters needed to define the hypothesis class. A common example used in the literature to show this is given by

\[
\mathcal{H} = \{h_\theta(x) : X \rightarrow \{0, 1\} : h_\theta(x) = \frac{1}{2} \sin(\theta x), \theta \in \mathbb{R}\}.
\]

It can be proven that the VC dimension of this class is infinite.

The following theorem uses the VC dimension of a hypothesis class to upper-bound the gap between the true and the empirical error for a given loss function and a finite sample of size \( m \).
Theorem 1. Let \( X \) be an input space, \( Y = \{-1, +1\} \) the output space, and \( D \) their joint distribution. Let \( S \) be a finite sample of size \( m \) drawn i.i.d. from \( D \) and \( H = \{ h : X \to Y \} \) be a hypothesis class of VC dimension \( VC(H) \). Then for any \( \delta \in (0, 1) \) with probability at least \( 1 - \delta \) over the random choice of the training sample \( S \sim (D)^m \) the following holds

\[
\forall h \in H, \quad R_D^S(h) \leq R_S^S(h) + \sqrt{\frac{4}{m} \left( VC(H) \ln \frac{2em}{VC(H)} + \ln \frac{4}{\delta} \right)}.
\]

2.4 Rademacher complexity

Intuitively, the Rademacher complexity measures the capacity of a given hypothesis class to resist against noise that may be present in the data. This, in its turn, was shown to lead to more accurate bounds than those based on the VC dimension [Koltchinskii and Panchenko, 1999]. In order to present Rademacher bounds, we first give a definition of a Rademacher variable.

Definition 5. (Rademacher variable) A random variable \( \kappa \) defined as

\[
\kappa = \begin{cases} 
1, & \text{with probability } \frac{1}{2} \\
-1, & \text{otherwise}
\end{cases}
\]

is called Rademacher variable.

From this definition, a Rademacher variable defines a random binary labeling as it takes values \(-1\) and \(1\) with equal probability and allows to introduce the Rademacher complexity for an unlabeled sample of size \( m \) as follows.

Definition 6. (Rademacher complexity) For a given unlabeled sample \( S = \{(x_i)\}_{i=1}^m \) and a given hypothesis class \( H \), the Rademacher complexity is defined as follows:

\[
\mathcal{R}_S(H) = \mathbb{E}_\kappa \left[ \sup_{h \in H} \frac{2}{m} \sum_{i=1}^m \kappa_i h(x_i) \right],
\]

where \( \kappa \) is a vector of \( m \) independent Rademacher variables. The Rademacher complexity for the whole hypothesis class is thus defined as the expected value of \( \mathcal{R}_S(H) \) by

\[
\mathcal{R}_m(H) = \mathbb{E}_{S \sim (D)^m} \mathcal{R}_S(H).
\]

In this definition, \( \mathcal{R}_S(H) \) encodes the complexity of a given hypothesis class \( H \) based on the observed sample \( S \) while \( \mathcal{R}_m(H) \) stands for the expected value of this complexity over all possible samples that were drawn from some joint probability distribution. Contrary to the VC dimension, this complexity measure is defined in terms of the expected value over all labelings and not only the worst one. The following theorem presents the Rademacher-based generalization bound [Koltchinskii and Panchenko, 1999, Bartlett and Mendelson, 2002].

Theorem 2. Let \( S = \{(x_i, y_i)\}_{i=1}^m \) be a finite sample of \( m \) examples drawn i.i.d. from \( D \) and \( H = \{ h : X \to Y \} \) be a hypothesis class. Then, for any \( \delta \in (0, 1] \) with probability at least \( 1 - \delta \) over the choice of the sample \( S \sim (D)^m \) the following holds

\[
\forall h \in H, \quad R_D^S(h) \leq R_S^S(h) + \mathcal{R}_m(H) + \sqrt{\frac{\ln \frac{1}{\delta}}{2m}}.
\]

2.5 PAC-Bayesian bounds

The PAC-Bayesian approach [Shawe-Taylor and Williamson, 1997, McAllester, 1999] provides generalization bounds for hypothesis expressed as a weighted majority vote over the hypothesis space \( H \) as, for instance, in ensemble methods [Dietterich, 2000, Re and Valentini, 2012]. In this section, we recall the general PAC-Bayesian generalization bound as presented in [Germain et al., 2015] in the setting of binary classification where \( Y = \{-1, 1\} \) with the 0–1 loss or the linear loss. To derive such a generalization bound, one assumes a prior distribution \( \pi \) over \( H \) which models an \( a \) priori belief on the hypotheses from \( H \) before the observation of the training sample \( S \sim (D)^m \). Given \( S \), the learner aims at finding a posterior distribution \( \rho \) over \( H \) that leads to a well-performing \( \rho \)-weighted majority vote \( B_\rho(x) \) (also called the Bayes classifier) defined as

\[
B_\rho(x) = \text{sign} \left[ \mathbb{E}_{h \sim \rho} h(x) \right].
\]
In other words, rather than finding the best hypothesis from $\mathcal{H}$, we want to learn $\rho$ over $\mathcal{H}$ such that it minimizes the true risk $R_D(B_\rho)$ of the $\rho$-weighted majority vote. However, PAC-Bayesian generalization bounds do not directly focus on the risk of the deterministic $\rho$-weighted majority vote $B_\rho$ but on giving an upper bound over the expectation over $\rho$ of all the individual hypothesis’ true risks called the *Gibbs risk*: $E_{h \sim \rho} R_D^\ell(h)$. The Gibbs risk is associated to a stochastic classifier called the Gibbs classifier which draws a hypothesis $h$ from $\mathcal{H}$ according to the posterior distribution $\rho$ and predicts the label of $x$ given by $h(x)$. An important behavior of the Gibbs risk is that it is closely related to the deterministic $\rho$-weighted majority vote. Indeed, if $B_\rho$ misclassifies $x \in X$, then at least half of the classifiers (under measure $\rho$) make a prediction error on $x$. Therefore, we have

$$R_D^\ell(B_\rho) \leq 2 E_{h \sim \rho} R_D^\ell(h).$$

(2)

Thus, an upper bound on $E_{h \sim \rho} R_D^\ell(h)$ provides an upper bound on $R_D^\ell(B_\rho)$ as well.

Note that, PAC-Bayesian generalization bounds do not directly take into account the complexity of the hypothesis class $\mathcal{H}$ contrary to the Rademacher complexity or the VC dimension, but measure the deviation between the prior distribution $\pi$ and the posterior distribution $\rho$ on $\mathcal{H}$ through the Kullback-Leibler divergence:

$$KL(\rho|\pi) = E_{h \sim \rho} \ln \frac{\rho(h)}{\pi(h)}.$$

The following result is a general PAC-Bayesian theorem which takes the form of an upper bound on the deviation between the true and empirical Gibbs risks when measured by a convex function $D : [0, 1] \times [0, 1] \rightarrow \mathbb{R}$.

**Theorem 3** (Germain et al., 2009, Germain et al., 2015). For any distribution $D$ on $X \times Y$, for any hypothesis class $\mathcal{H}$, for any prior distribution $\pi$ on $\mathcal{H}$, for any $\delta \in (0, 1]$, for any convex function $D : [0, 1] \times [0, 1] \rightarrow \mathbb{R}$, with a probability at least $1 - \delta$ over the random choice of $S \sim (\mathcal{D})^m$, we have, for all posterior distribution $\rho$ on $\mathcal{H}$,

$$D \left( E_{h \sim \rho} R_D^\ell(h), E_{h \sim \rho} R_D^\ell(h) \right) \leq \frac{1}{m} KL(\rho|\pi) + \ln \left( \frac{1}{\delta} \mathbb{E}_{S \sim (\mathcal{D})^m} E_{h \sim \pi} e^m D(R_S^\ell(h), R_D^\ell(h)) \right).$$

By upper-bounding $E_{S \sim (\mathcal{D})^m} E_{h \sim \pi} e^m D(R_S^\ell(h))$ and by selecting a well-suited deviation function $D$, we can retrieve the classical versions of the PAC-Bayesian theorem (i.e., [McAllester, 1999, Seeger, 2002, Catoni, 2007]).

### 2.6 Uniform stability

As the complexity of the hypothesis class intuitively depends directly on the properties of a learning algorithm, it may be desirable to have the generalization bounds that manifest this relationship explicitly. Bousquet and Elisseeff [Bousquet and Elisseeff, 2002] introduced generalization bounds that provide a solution to this problem based on the notion of uniform stability of a learning algorithm. We now give its definition.

**Definition 7.** (Uniform stability) An algorithm $A$ has uniform stability $\beta$ with respect to the loss function $\ell$ if the following holds

$$\forall S \in \{X \times Y\}^m, \forall i \in \{1, \ldots, m\}, \sup_{(x, y) \in S} |\ell(h_S(x), y) - \ell(h_{S \setminus i}(x), y)| \leq \beta,$$

where the hypothesis $h_S$ is learned on the sample $S$ while $h_{S \setminus i}$ is obtained on $S$ with its $i$th observation being deleted.

The intuition behind this definition is to say that an algorithm that is expected to generalize well should be robust to small perturbations in the training sample. Consequently, stable algorithms should have their empirical error remaining close to their generalization error. This idea is confirmed by the following theorem.

**Theorem 4.** Let $A$ be an algorithm with uniform stability $\beta$ with respect to a loss function $\ell$ such that $0 \leq \ell(h_S(x), y) \leq M$, for all $(x, y) \in (X \times Y)$ and all sets $S$. Then, for any $m \geq 1$, and any $\delta \in (0, 1]$, the following bound holds with probability at least $1 - \delta$ over the random choice of the sample $S$,

$$R_D^\ell(h) \leq R_S^\ell(h) + 2\beta + (4m\beta + M) \sqrt{\frac{\ln \frac{1}{\delta}}{2m}}.$$
2.7 Algorithmic robustness

The main underlying idea of algorithmic robustness [Xu and Mannor, 2010] is to say that a robust algorithm should have similar performance in terms of the classification error on testing and training samples that are close. The measure of similarity used to define if two samples are close or not relies on partitioning the joint space $X \times Y$ in a way that puts two similar points of the same class to the same partition. This partition is further defined using the notion of covering numbers [Kolmogorov and Tikhomirov, 1959] introduced below.

**Definition 8.** (Covering number) Let $(Z, \varrho)$ denote a metric space with metric $\varrho(\cdot)$ defined on $Z$. For $Z' \subset Z$, we say that $Z'$ is a $\gamma$-covering of $Z'$ if for any element $t \in Z'$ there is an element $\hat{t} \in Z'$ such that $\varrho(t, \hat{t}) \leq \gamma$. Then the number of $\gamma$-covering of $Z'$ is expressed as

$$N(\gamma, Z', \varrho) = \min \left\{ |\hat{Z}'| : \hat{Z}' \text{ a } \gamma\text{-covering of } Z' \right\}.$$

In the case where $X$ is a compact space, its covering number $N(\gamma, X, \varrho)$ is finite. Furthermore, for the product space $X \times Y$, the number of $\gamma$-covering is also finite and equals $|Y| N(\gamma, X, \varrho)$. As previously explained, the above partitioning ensures that two points from the same subset are from the same class and close to each other with respect to metric $\varrho$. Bearing this in mind, the algorithmic robustness is defined as follows.

**Definition 9.** (Algorithmic robustness) Let $S$ be a training sample of size $m$ where each example is drawn from the joint distribution $D$ on $X \times Y$. An algorithm $A$ is $(M, \epsilon(S))$-robust on $D$ with respect to a loss function $\ell$ for $M \in \mathbb{N}$ and $\epsilon : (X \times Y)^m \rightarrow \mathbb{R}$ if $X \times Y$ can be partitioned into $M$ disjoint subsets denoted by $\{Z_j\}_{j=1}^M$ so that for all $(x, y) \in S$ and $(x', y')$ drawn from $D$ and $j \in \{1, \ldots, M\}$ we have

$$((x, y), (x', y')) \in Z_j^2 \quad \rightarrow \quad |\ell(h_S(x), y) - \ell(h_S(x'), y')| \leq \epsilon(S),$$

where $h_S$ is a hypothesis learned by $A$ on $S$.

We are now ready to present the generalization guarantees that characterize robust algorithms verifying the definition presented above.

**Theorem 5.** Let $S$ be a finite sample of size $m$ drawn i.i.d. from $D$, $A$ be $(M, \epsilon(S))$-robust on $D$ with respect to a loss function $\ell(\cdot, \cdot)$ such that $0 \leq \ell(h_S(x), y) \leq M\epsilon$, for all $(x, y) \in (X \times Y)$. Then, for any $\delta \in (0, 1]$, the following bound holds with probability at least $1 - \delta$ over the random draw of the sample $S \sim (D)^m$,

$$R_D^\ell(h) \leq R_S^\ell(h) + \epsilon(S) + M\epsilon \sqrt{\frac{2M \ln 2 + 2 \ln \frac{1}{\delta}}{m}},$$

where $h_S$ is a hypothesis learned by $A$ on $S$.

Note that the algorithmic robustness focuses on measuring the divergence between the costs associated to two similar points assuming that the learned hypothesis function should be locally consistent. Uniform stability, in its turn, explores the variation in the cost due to by perturbations of the training sample and thus assumes that the learned hypothesis does not change much.

3 Seminal divergence-based learning bounds

In this section, we give a description of domain adaptation generalization bounds for domain adaptation that laid the foundation of their field. These seminal bounds mainly relied on traditional divergence measures between the probability distributions in order to relate the source and the target domains.

3.1 Learning bound based on the $L^1$-distance

From a theoretical point of view, the domain adaptation problem was rigorously investigated for the first time in [Ben-David et al., 2007] and [Ben-David et al., 2010a]1. The authors of these papers focused on the domain adaptation problem following the VC theory (recalled in Section 2.3) and considered the $0 - 1$ loss (Equation 1) function in the setting of binary classification with $Y = \{-1, +1\}$. They further proposed to make use of the $L^1$-distance whose definition is given below.

---

1Note that in [Ben-David et al., 2010a], the authors presented an extended version of the results previously published in [Ben-David et al., 2007] and [Blitzer et al., 2008].
Definition 10. \((L^1\text{-distance})\) Denote by \(B\) the set of measurable subsets under two probability distributions \(D_1\) and \(D_2\). The \(L^1\)-distance or the total variation distance between \(D_1\) and \(D_2\) is defined as

\[
d_1(D_1, D_2) = 2 \sup_{B \in B} \left| \Pr_{D_1}(B) - \Pr_{D_2}(B) \right|.
\]

The \(L^1\)-distance is a proper metric on the space of probability distributions that informally quantifies the largest possible difference between the probabilities that the two probability distributions \(D_1\) and \(D_2\) can assign to the same event \(B\). This distance is quite popular in many real-world applications such as image denoising or numerical approximations of partial derivative equations.

Starting from Definition 10, the first important result proved in their work was formulated as follows.

Theorem 6 (\cite{Ben-David et al., 2007}). Given two domains \(S\) and \(T\) over \(X \times Y\) and a hypothesis class \(\mathcal{H}\), the following holds

\[
\forall h \in \mathcal{H}, \quad R_{\mathcal{T}}^{\delta_{01}}(h) \leq R_{\mathcal{S}}^{\delta_{01}}(h) + 2 \mathbb{E}_{x \sim \mathcal{S}_X} \| f_S(x) - f_T(x) \| + 2 \mathbb{E}_{x \sim \mathcal{T}_X} \| f_T(x) - f_S(x) \|,
\]

where \(f_S(x)\) and \(f_T(x)\) are the source and target true labeling functions associated to \(S\) and \(T\), respectively.

This theorem presents a first result that relates the performance of a given hypothesis function with respect to two different domains. It implies that the error achieved by a hypothesis in the source domain upper-bounds the true error on the target domain where the tightness of the bound depends on the distance between their distributions and that of the labeling functions.

3.2 Learning bound based on \(\mathcal{H}\mathcal{\Delta}\mathcal{H}\)-divergence

Despite being the first result of this kind proposed in the literature, the idea of bounding the error in terms of the \(L^1\)-distance between the marginal distributions of the two domains presents two important restrictions: 1) the \(L^1\)-distance cannot be estimated from finite samples for arbitrary probability distributions; 2) it does not allow to link the divergence measure to the considered hypothesis class and thus leads to very loose inequality.

In order to address these issues, the authors further defined the \(\mathcal{H}\mathcal{\Delta}\mathcal{H}\)-divergence based on the \(A\)-divergence introduced in \cite{Kifer et al., 2004} for data stream change detection. We give its definition below.

Definition 11 (Based on \cite{Kifer et al., 2004}). Given two domains’ marginal distributions \(\mathcal{S}_X\) and \(\mathcal{T}_X\) over the input space \(X\), let \(\mathcal{H}\) be a hypothesis class, and denote \(\mathcal{H}\mathcal{\Delta}\mathcal{H}\) the symmetric difference hypothesis space defined as

\[
h \in \mathcal{H}\mathcal{\Delta}\mathcal{H} \iff h(x) = g(x) \oplus g'(x),
\]

for some \((g, g')^2 \in \mathcal{H}^2\), where \(\oplus\) stands for the XOR operation. Let \(I(h)\) denote the set for which \(h \in \mathcal{H}\mathcal{\Delta}\mathcal{H}\) is the characteristic function, i.e., \(x \in I(h) \iff g(x) = 1\). The \(\mathcal{H}\mathcal{\Delta}\mathcal{H}\)-divergence between \(\mathcal{S}_X\) and \(\mathcal{T}_X\) is defined as:

\[
d_{\mathcal{H}\mathcal{\Delta}\mathcal{H}}(\mathcal{S}_X, \mathcal{T}_X) = 2 \sup_{h \in \mathcal{H}\mathcal{\Delta}\mathcal{H}} \left| \Pr_{\mathcal{S}_X}(I(h)) - \Pr_{\mathcal{T}_X}(I(h)) \right|.
\]

The \(\mathcal{H}\mathcal{\Delta}\mathcal{H}\)-divergence solves both problems associated with the \(L^1\)-distance. First, from its definition we can see that \(\mathcal{H}\mathcal{\Delta}\mathcal{H}\)-divergence explicitly takes into account the considered hypothesis class. This fact ensures that the bound remains meaningful and directly related to the learning problem at hand. On the other hand, the \(\mathcal{H}\mathcal{\Delta}\mathcal{H}\)-divergence for any class \(\mathcal{H}\) is never larger than the \(L^1\)-distance and thus can lead to a tighter bound. Finally, for a given hypothesis class \(\mathcal{H}\) of finite VC dimension, the \(\mathcal{H}\mathcal{\Delta}\mathcal{H}\)-divergence can be estimated from finite samples using the following lemma.

Lemma 7. Let \(\mathcal{H}\) be a hypothesis space of VC dimension \(VC(\mathcal{H})\). If \(S_u, T_u\) are unlabeled samples of size \(m\) each, drawn independently from \(\mathcal{S}_X\) and \(\mathcal{T}_X\) respectively, then for any \(\delta \in (0, 1)\) with probability at least \(1 - \delta\) over the random choice of the samples we have

\[
d_{\mathcal{H}\mathcal{\Delta}\mathcal{H}}(\mathcal{S}_X, \mathcal{T}_X) \leq \hat{d}_{\mathcal{H}\mathcal{\Delta}\mathcal{H}}(S_u, T_u) + 4\sqrt{\frac{2 VC(\mathcal{H}) \log(2m) + \log(\frac{2}{\delta})}{m}},
\]

where \(\hat{d}_{\mathcal{H}\mathcal{\Delta}\mathcal{H}}(S_u, T_u)\) is the empirical \(\mathcal{H}\mathcal{\Delta}\mathcal{H}\)-divergence estimated on \(S_u\) and \(T_u\).

Inequality (3) shows that with an increasing number of instances and for a hypothesis class of finite VC dimension, the empirical \(\mathcal{H}\mathcal{\Delta}\mathcal{H}\)-divergence can be a good proxy for its true counterpart. The former can be further calculated thanks to the following result.
Figure 4: Illustration of the $\Delta H$-divergence when the hypothesis class consists of linear (top row) and non-linear (bottom row) classifiers. Note that the indicated value of $\Delta H$ is the error of the obtained classifier without subtracting 1 and multiplying the result by two as in Lemma 8.

**Lemma 8** ([Ben-David et al., 2010a]). Let $\mathcal{H}$ be a hypothesis space. Then, for two unlabeled samples $S_u$, $T_u$ of size $m$ we have

$$
\hat{d}_{\Delta H}(S_u, T_u) = 2 \left(1 - \min_{h \in \mathcal{H}\Delta H} \left[ \frac{1}{m} \sum_{x: h(x) = 0} I[x \in S_u] + \frac{1}{m} \sum_{x: h(x) = 1} I[x \in T_u] \right] \right).
$$

One may note that the expression of the empirical $\Delta H$-divergence given above is essentially the error of the best classifier for the binary classification problem of distinguishing between the source and target instances pseudo-labeled with 0’s and 1’s. In practice, it means that the value of the $\Delta H$-divergence depends explicitly on the hypothesis class used to produce such a classifier. This dependence, as well as the intuition behind the $\Delta H$-divergence, are illustrated in Figure 4. In this figure, we consider two different domain adaptation problems where for one of them the source and target samples are well separated, while for the other, source and target data is mixed together. In order to calculate the value of the $\Delta H$-divergence, we need to choose a hypothesis class used to produce a classifier distinguishing between them. Here, we consider two different families of classifiers: a linear SVM classifier and its non-linear version with RBF kernels. For each solution, we also plot the decision boundaries in order to see how the source and target instances are classified in both cases. From the visualization of the decision boundaries, we note that the linear classifier fails to distinguish between the mixed source and target instances while the non-linear classifier manages to do it quite well. This is reflected by the value of the $\Delta H$-divergence that is equal to zero in the first case for both classifiers and is drastically different for the second adaptation problem. Having two different divergence values for the same adaptation problem may seem surprising at the first sight but it has a simple explanation. By choosing a richer hypothesis class composed of non-linear functions, we increased the VC dimension of the considered hypothesis.
space and thus increased the complexity term in Lemma 7. This shows the trade-off that one has to bear in mind when calculating the $\mathcal{H}\mathcal{H}$-divergence in the same way as it is suggested by the general VC theory.

At this point, we already have a “reasonable” version of the $L^1$-distance used to derive the first seminal result. We have also presented its finite sample approximation but we have not applied it to relate the source and target error functions yet. The next lemma gives the final key needed to obtain a learning bound for domain adaptation that is linked to a specific hypothesis class and is derived for available source and target finite size samples. It reads as follows.

**Lemma 9** ([Ben-David et al., 2010a]). Let $S$ and $T$ be two domains on $X \times Y$. For any pair of hypotheses $(h, h') \in \mathcal{H}\mathcal{H}^2$, we have

$$\left| R_T^{f_S}(h, h') - R_S^{f_T}(h, h') \right| \leq \frac{1}{2} d_{\mathcal{H}\mathcal{H}}(S_X, T_X).$$

Note that in this lemma, the source and target risk functions are defined for the same pairs of hypotheses while the true risk should be calculated based on a given hypothesis and the corresponding labeling function. This result, presenting the complete learning bound for domain adaptation with $\mathcal{H}\mathcal{H}$-divergence, is established by the means of the following theorem.

**Theorem 10** ([Ben-David et al., 2010a]). Let $\mathcal{H}$ be a hypothesis space of VC dimension $\text{VC}(\mathcal{H})$. If $S_u, T_u$ are unlabeled samples of size $n'\ell^2$ each, drawn independently from $S_X$ and $T_X$ respectively, then for any $\delta \in (0, 1)$ with probability at least $1 - \delta$ over the random choice of the samples, we have that for all $h \in \mathcal{H}$

$$R_T^{f_S}(h) \leq R_S^{f_T}(h) + \frac{1}{2} d_{\mathcal{H}\mathcal{H}}(S_u, T_u) + 4 \sqrt{\frac{2 \text{VC}(\mathcal{H}) \log(2m') + \log(\frac{2}{\delta})}{m'}} + \lambda,$$

where $\lambda$ is the combined error of the ideal hypothesis $h^*$ that minimizes $R_S(h) + R_T(h)$.

As pointed out in the beginning of this section, a meaningful domain adaptation generalization bound should include two terms that reflect both the divergence between the marginal distribution of the source and target domains and the divergence between their labeling functions. The first term here is obviously reflected by the $\mathcal{H}\mathcal{H}$-divergence between the observable samples while the second one is given by the $\lambda$ term since it depends on the true labels (and can be seen as a measure of capacity to adapt). It is important to notice that without information on the target labels it is impossible to estimate $\lambda$, implying that the bound can be very loose.

The presence of the trade-off between source risk, divergence and capability to adapt, is a very important phenomenon in domain adaptation. Indeed, it shows that reducing the divergence between the samples can be insufficient when there is no hypothesis that can achieve a low-error on both source and target samples.

**Semi-supervised case** In the unsupervised case that we have considered previously, it is assumed that one has no access to labeled instances in the target domain that can help to guide adaptation. For this case, the main strategy leading to an efficient adaptation is to learn a classifier on a target-aligned labeled sample from the source domain and to apply it directly in the target domain afterwards. While this situation occurs quite often in practice, many applications can be found where several labeled target instances are available during the learning stage. In what follows, we consider this situation and give a generalization bound for it showing that the error obtained by a classifier learned on a mixture of source and target labeled data can be upper-bounded by the error of the best classifier learned using the target domain data only.

To proceed, let us now assume that we possess $\beta m$ instances drawn independently from $T$ and $(1 - \beta)m$ instances drawn independently from $S$ and labeled by $f_S$ and $f_T$, respectively. A natural goal for this setting is to use the available labeled instances from the target domain to find a trade-off between minimizing the source and the target errors depending on the number of instances available in each domain and the distance between them. In this case, we can consider the empirical combined error [Blitzer et al., 2008] defined as a convex combination of errors on the source and target training data for $\alpha \in [0, 1]$:

$$\hat{R}^\alpha(h) = \alpha R_T^{f_S}(h) + (1 - \alpha)R_S^{f_T}(h).$$

The use of the combined error is motivated by the fact that if the number of instances in the target sample is small compared to the number of instances in the source domain (which is usually the case in domain adaptation), minimizing only the target error may not be appropriate. Instead, one may want to find a suitable value of $\alpha$ that ensures the minimum of $R^\alpha(h)$ with respect to a given hypothesis $h$. Note that in this case the shape of the generalization bound that we are interested in becomes different. Indeed, in all previous theorems the goal is to upper-bound the target error
by the source error, while in this case one would like to know if learning a classifier minimizing the combined error is better than minimizing the target error using the available labeled instances alone. The answer to this question is given by the following theorem.

**Theorem 11** ([Blitzer et al., 2008, Ben-David et al., 2010a]). Let $\mathcal{H}$ be a hypothesis space of VC dimension $\text{VC}(\mathcal{H})$. Let $S$ and $T$ be the source and target domain, respectively, defined on $X \times Y$. Let $S_u$, $T_u$ be unlabeled samples of size $m'$ each, drawn independently from $S_X$ and $T_X$ respectively. Let $S$ be a labeled sample of size $m$ generated by drawing $\beta m$ points from $T$ ($\beta \in [0, 1]$) and $(1 - \beta)$ $m$ points from $S$ and labeling them according to $f_S$ and $f_T$, respectively. If $\hat{h} \in \mathcal{H}$ is the empirical minimizer of $R^\star(h)$ on $S$ and $h_T^\star = \arg\min_{h \in \mathcal{H}} R_T^\star(h)$ then for any $\delta \in (0, 1)$, with probability at least $1 - \delta$ over the random choice of the samples, we have

$$R_T^\star(\hat{h}) \leq R_T^\star(h_T^\star) + c_1 + c_2,$$

where

$$c_1 = 4 \sqrt{\frac{\alpha^2}{\beta} + \frac{(1 - \alpha)^2}{1 - \beta}} \sqrt{\frac{2 \text{VC}(\mathcal{H}) \log(2(m + 1)) + 2 \log(\frac{8}{\delta})}{m}},$$

and

$$c_2 = 2(1 - \alpha) \left( \frac{1}{2} d_{\mathcal{H}\mathcal{H}}(S_u, T_u) + 4 \sqrt{\frac{2 \text{VC}(\mathcal{H}) \log(2m') + \log(\frac{8}{\delta})}{m'}} + \lambda \right),$$

where

$$B = \sqrt{\frac{2 \text{VC}(\mathcal{H}) \log(2(m + 1)) + 2 \log(\frac{8}{\delta})}{m}},$$

is a complexity term that approximately equals $\sqrt{\text{VC}(\mathcal{H})/m}$ and

$$A = \frac{1}{2} d_{\mathcal{H}\mathcal{H}}(S_u, T_u) + 4 \sqrt{\frac{2 \text{VC}(\mathcal{H}) \log(2m') + \log(\frac{8}{\delta})}{m'}} + \lambda$$

is the total divergence between the two domains.

This theorem presents an important result that reflects the usefulness of the combined minimization of the source and target errors based on the available labeled samples in both domains compared to the minimization of the target error only. It essentially shows that the error achieved by the best hypothesis of the combined error in the target domain is always upper-bounded by the error achieved by the best target domain’s hypothesis. Furthermore, it implies two important consequences:

1. if $\alpha = 1$, the term related to the $\mathcal{H}\mathcal{H}$-divergence between the domains disappears as in this case we possess enough labeled data in target domain and a low-error hypothesis can be produced solely from target data;
2. if $\alpha = 0$, the only way to produce a low-error classifier on the target domain is to find a good hypothesis in the source domain while minimizing the $\mathcal{H}\mathcal{H}$-divergence between the domains. In this case, one has also to assume that $\lambda$ is low, so that the adaptation is possible.

Additionally, Theorem 11 can provide some insights about the optimal mixing value of $\alpha$ depending on the quantity of labeled instances in the source and target domains. In order to illustrate it, the right-hand side of Equation (4) can be rewritten as a function of $\alpha$ in order to understand when it is minimized. This gives

$$f(\alpha) = 2B \sqrt{\frac{\alpha^2}{\beta} + \frac{(1 - \alpha)^2}{1 - \beta}} + 2(1 - \alpha)A,$$

where

$$B = \sqrt{\frac{2 \text{VC}(\mathcal{H}) \log(2(m + 1)) + 2 \log(\frac{8}{\delta})}{m}},$$

is a complexity term that approximately equals $\sqrt{\text{VC}(\mathcal{H})/m}$ and

$$A = \frac{1}{2} d_{\mathcal{H}\mathcal{H}}(S_u, T_u) + 4 \sqrt{\frac{2 \text{VC}(\mathcal{H}) \log(2m') + \log(\frac{8}{\delta})}{m'}} + \lambda$$

is the total divergence between the two domains.

It then follows that the optimal value $\alpha^*$ is a function of the number of target examples $m_T = \beta m$, the number of source examples $m_S = (1 - \beta)m$, and the ratio $D = \sqrt{\text{VC}(\mathcal{H})/A}$:

$$\alpha^*(m_S, m_T, D) = \begin{cases} 1, & m_T \geq D^2 \\ \min(1, \nu), & m_T \leq D^2 \end{cases}$$

where

$$\nu = \frac{m_T}{m_T + m_S} \left( 1 + \frac{m_S}{\sqrt{D^2(m_S + m_T) - m_S m_T}} \right).$$
As mentioned in [Ben-David et al., 2010a], this reformulation offers a couple of interesting insights. First, if \( m_T = 0 \) (\( \beta = 0 \)) then \( \alpha^* = 0 \) and if \( m_S = 0 \) (i.e., \( \beta = 1 \)) then \( \alpha^* = 1 \). As mentioned above, it implies that if we have only source or only target labeled data, the most appropriate choice is to use them for learning directly. Second, if the divergence between two domains equals zero then the optimal combination is to use the training data with uniform weighting of the examples. On the other hand, if there is enough target data, i.e., \( m_T \geq D^2 = \text{VC}(\mathcal{H})/A^2 \), then no source data is required for efficient learning and using it will hurt the overall performance. This is due to the fact that the possible error decrease brought by using additional source data is always subject to its increase due to the increasing divergence between the source and target data. Second, for few target examples, we may not have enough source data to justify its use. In this case, the source domain’s sample can be simply ignored. Finally, once we have enough source instances combined with few target instances, the value for \( \alpha^* \) takes intermediate values. This analysis is illustrated by Figure 5.

![Figure 5: Illustration of the optimal value for \( \alpha \) as function of the number of source and target labeled instances.](image)

### 3.3 Generalization bounds based on a discrepancy distance

One important limitation of the \( \mathcal{H}\Delta\mathcal{H} \)-divergence is its explicit dependence on a particular choice of a loss function which is taken to be \( 0 - 1 \) loss. In general, however, one would like to have generalization results for a more general domain adaptation setting where any arbitrary loss function \( \ell \) with some reasonable properties can be considered. In this section, we present a series of results that allow to extend the first theoretical analysis of domain adaptation presented in the previous section to any arbitrary loss function. As we will show, the new divergence measure considered in this section is not restricted to be used exclusively for the task of binary classification but also for large families of regularized classifiers and regression. Moreover, the results of this section use the concept of the Rademacher complexity recalled in Section 2. This particular improvement will lead to data-dependent bounds that are usually tighter than the bounds obtained using the VC theory.

**Discrepancy distance** We start with the definition of the new divergence measure first introduced in [Mansour et al., 2009a]. As mentioned by the authors, its name, the discrepancy distance, is due to the relationship of this notion with the discrepancy problems arising in combinatorial contexts.

**Definition 12 ([Mansour et al., 2009a]).** Given two domains \( S \) and \( T \) over \( X \times Y \), let \( \mathcal{H} \) be a hypothesis class, and let \( \ell : Y \times Y \to \mathbb{R}_+ \) define a loss function. The discrepancy distance \( \text{disc}_\ell \) between the two marginals \( S_X \) and \( T_X \) over \( X \) is defined by

\[
\text{disc}_\ell(S_X, T_X) = \sup_{(h, h') \in \mathcal{H}^2} \left| \mathbb{E}_{x \sim S_X} [\ell(h'(x), h(x))] - \mathbb{E}_{x \sim T_X} [\ell(h'(x), h(x))] \right|.
\]

We note that the \( \mathcal{H}\Delta\mathcal{H} \)-divergence and the discrepancy distance are related. First, for the \( 0 - 1 \) loss, we have

\[
\text{disc}_{01}(S_X, T_X) = \frac{1}{2} d_{\mathcal{H}\Delta\mathcal{H}}(S_X, T_X),
\]

showing that in this case, the discrepancy distance coincides with the \( \mathcal{H}\Delta\mathcal{H} \)-divergence that appears in Theorems 10 and 11, and suffers from the same computational restrictions as the latter. Furthermore, their tight connection is illustrated by the following proposition.

**Proposition 12 ([Mansour et al., 2009a]).** Given two domains \( S \) and \( T \) over \( X \times Y \), let \( \mathcal{H} \) be a hypothesis class, and let \( \ell : Y \times Y \to \mathbb{R}_+ \) define a loss function that is bounded, \( \forall (y, y') \in Y^2, \ell(y, y') \leq M \) for some \( M > 0 \). Then, for any hypothesis \( h \in \mathcal{H} \), we have

\[
\text{disc}_\ell(S_X, T_X) \leq M d_1(S_X, T_X).
\]
This proposition establishes a link between the seminal results [Ben-David et al., 2010a] presented in the previous section, and shows that for a loss function bounded by $M$, the discrepancy distance can be upper-bounded in terms of the $L^1$-distance.

Learning bounds In order to present a generalization bound, we first need to understand how the discrepancy distance can be estimated from finite samples. To this end, the authors in [Mansour et al., 2009a] proposed the following lemma that bounds the discrepancy distance using the Rademacher complexity (see Section 2.4) of the hypothesis class.

**Lemma 13 ([Mansour et al., 2009a]).** Let $\mathcal{H}$ be a hypothesis class, and let $\ell : Y \times Y \to \mathbb{R}_+$ define a loss function that is bounded, $\forall (y, y') \in Y^2$, $\ell(y, y') \leq M$ for some $M > 0$ and let $L_{\mathcal{H}} = \{ x \to \ell(h'(x), h(x)) : h, h' \in \mathcal{H} \}$. Let $D_X$ be a distribution over $X$ and let $\hat{D}_X$ denote the corresponding empirical distribution for a sample $S = (x_1, \ldots, x_m)$. Then, for any $\delta \in (0, 1)$, with probability at least $1 - \delta$ over the choice of sample $S$, we have

$$disc_{\ell}(D_X, \hat{D}_X) \leq \mathcal{R}_S(L_{\mathcal{H}}) + 3M \sqrt{\frac{\log \frac{2}{\delta}}{2m}},$$

where $\mathcal{R}_S(L_{\mathcal{H}})$ is the empirical Rademacher complexity of $L_{\mathcal{H}}$ based on the observations from $S$.

One may notice that this lemma looks very much alike the usual generalization inequalities obtained using the Rademacher complexities presented in Section 2.4. Using this result, we can further prove the following corollary for the case of more general loss functions defined as $\forall (y, y') \in Y^2$, $\ell_q(y, y') = |y - y'|^q$ for some $q$. This parametric family of functions is a common choice of a loss function for a regression task.

**Corollary 14 ([Mansour et al., 2009a]).** Let $S$ and $T$ be the source and the target domain over $X \times Y$, respectively. Let $\mathcal{H}$ be a hypothesis class, and let $\ell_q : Y \times Y \to \mathbb{R}_+$ be a loss function that is bounded, $\forall (y, y') \in Y^2$, $\ell_q(y, y') \leq M$ for some $M > 0$, and defined as $\forall (y, y') \in Y^2$, $\ell_q(y, y') = |y - y'|^q$ for some $q$. Let $S_u$ and $T_u$ be samples of size $m_u$ and $m_t$ drawn independently from $S_X$ and $T_X$. Denote by $\hat{S}_X, \hat{T}_X$ the empirical distributions corresponding to $S_X$ and $T_X$. Then, for any $\delta \in (0, 1)$, with probability at least $1 - \delta$ over the random choice of the samples, we have

$$disc_{\ell_q}(S_X, T_X) \leq disc_{\ell_q}(\hat{S}_X, \hat{T}_X) + 4q(\mathcal{R}_{S_u}(\mathcal{H}) + \mathcal{R}_{T_u}(\mathcal{H})) + 3M \left( \sqrt{\frac{\log \frac{4}{\delta}}{2m_u}} + \sqrt{\frac{\log \frac{4}{\delta}}{2m_t}} \right).$$

This result highlights one of the major differences between the approach of [Ben-David et al., 2010a] and the one of [Mansour et al., 2009a] that lies in the way how they estimate the introduced distance. While Theorem 10 relies on the VC dimension to bound the true $\mathcal{H}\Delta\mathcal{H}$-divergence by its empirical counterpart, $\text{disc}_\ell$ is estimated using the quantities based on the Rademacher complexity. In order to illustrate what it implies for the generalization guarantees, we now present the analogue of Theorem 10 that relates the source and target error function using the discrepancy distance and compare it to the original result.

**Theorem 15 ([Mansour et al., 2009a]).** Let $S$ and $T$ be the source and the target domain over $X \times Y$, respectively. Let $\mathcal{H}$ be a hypothesis class, and let $\ell : Y \times Y \to \mathbb{R}_+$ be a loss function that is symmetric, obeys the triangle inequality and is bounded, $\forall (y, y') \in Y^2$, $\ell(y, y') \leq M$ for some $M > 0$. Then, for $h^*_S = \arg\min_{h \in \mathcal{H}} R^\ell_S(h)$ and $h^*_T$ denoting the ideal hypotheses for the source and target domains, we have

$$\forall h \in \mathcal{H}, R^\ell_T(h) \leq R^\ell_S(h, h^*_S) + disc_{\ell}(\hat{S}_X, \hat{T}_X) + \epsilon,$$

where $R^\ell_S(h, h^*_S) = \mathbb{E}_{x \sim \hat{S}_X} \ell(h(x), h^*_S(x))$ and $\epsilon = R^\ell_T(h^*_T) + R^\ell_S(h^*_T, h^*_S)$.

**Comparison with the $\mathcal{H}\Delta\mathcal{H}$-divergence** As pointed out by the authors, this bound is not directly comparable to Theorem 10, but involves similar terms and reflects a very common trade-off between them. Indeed, the first term of this bound stands for the same source risk function as the one found in the work of [Ben-David et al., 2010a]. The second term here captures the deviation between the two domains through the discrepancy distance similar to the $\mathcal{H}\Delta\mathcal{H}$-divergence used before. Finally, the last term $\epsilon$ can be interpreted as the capacity to adapt and is very close in spirit to the $\lambda$ term seen previously.

Despite these similarities, a closer comparison made in [Mansour et al., 2009a] revealed that the bound based on the discrepancy distance can be tighter in some plausible scenarios. For instance, in a degenerate case where there is only
one hypothesis \( h \in \mathcal{H} \) and a single target function \( f_T \), the bounds of Theorem 15 and that of Theorem 10 with true distributions give \( R_T^2(h, f) + disc_S(S_X, T_X) \) and \( R_T^2(h, f) + 2R_S^2(h, f) + disc_S(S_X, T_X) \), respectively. In this case, the latter expression is obviously larger when \( R_S^2(h, f) \leq R_T^2(h, f) \). The same kind of result can be also shown to hold under the following plausible assumptions:

1. When \( h^* = h^*_S = h^*_T \), the bounds of Theorems 15 and 10 respectively boil down to

\[
R_T^2(h) \leq R_T^2(h^*) + R_S^2(h, h^*) + disc_S(S_X, T_X), \tag{5}
\]

and

\[
R_T^2(h) \leq R_T^2(h^*) + R_S^2(h^*) + R_S^2(h) + disc_S(S_X, T_X), \tag{6}
\]

where the right-hand side of Equation 6 includes the sum of three errors and is always larger than the right-hand side of Equation 5 due to the triangle inequality.

2. When \( h^* = h^*_S = h^*_T \) and \( disc_S(S_X, T_X) = 0 \), Theorems 15 and 10 give

\[
R_T^2(h) \leq R_T^2(h^*) + R_S^2(h, h^*) \quad \text{and} \quad R_T^2(h) \leq R_T^2(h^*) + R_S^2(h^*) + R_S^2(h),
\]

where the former coincides with the standard generalization bound while the latter does not.

3. Finally, when \( f_T \in \mathcal{H} \), Theorem 10 simplifies to

\[
|R_T^2(h) - R_S^2(h)| \leq disc_{tot}(S_X, T_X),
\]

which can be straightforwardly obtained from Theorem 15.

All these results show a tight link that can be observed in different contributions of the domain adaptation theory. This relation illustrates that the results of [Mansour et al., 2009a] strengthen the previous contributions on the subject but keep a tight connection to them.

### 3.4 Generalization bounds based on the discrepancy distance for regression

As mentioned in the beginning of this section, the discrepancy distance not only extends the first theoretical results obtained for domain adaptation, but also allows to derive new point-wise guarantees for other learning scenarios such as, for instance, the regression task where, contrary to classification, the output variable \( Y \) is continuous. The domain adaptation problem for regression is illustrated in Figure 6.

To address this scenario, another type of theoretical results based on the discrepancy distance was proposed in [Cortes and Mohri, 2011]. The authors considered the case where the hypothesis set \( \mathcal{H} \) is a subset of the reproducing kernel Hilbert space (RKHS) \( \mathbb{H} \) associated to a positive definite symmetric (PDS) kernel \( K : \mathcal{H} \times \mathcal{H} \rightarrow \mathbb{R} \) where \( \| \cdot \|_K \) denotes the norm defined by the inner product on \( \mathbb{H} \) and \( \Lambda \geq 0 \). We shall assume that there exists \( R > 0 \) such that

\[
K(x, x) \leq R^2 \text{ for all } x \in X.
\]

By the reproducing property, for any \( h \in \mathcal{H} \) and \( x \in X \), \( h(x) = \langle h, K(x, \cdot) \rangle_K \), thus this implies that \( |h(x)| \leq \| h \|_K \sqrt{K(x, x)} \leq AR \).

In this setting, the authors further present point-wise loss guarantees in domain adaptation for a broad class of kernel-based regularization algorithms. Given a learning sample \( S \), where \( \forall (x, y) \in S, x \sim D_X, y = f_D(x) \), these algorithms are defined by the minimization of the following objective function:

\[
F_{D_X}(h) = R_{D_X}(h, f_D) + \beta\| h \|_K^2,
\]

where \( \beta > 0 \) is a trade-off parameter. This family of algorithms includes support vector machines (SVM), support vector regression (SVR) [Vapnik, 1995], kernel ridge regression (KRR) [Saunders et al., 1998] and many other methods. Finally, the loss function \( \ell \) is also assumed to be \( \mu \)-admissible following the definition given below.

**Definition 13** (\( \mu \)-admissible loss). A loss function \( \ell : Y \times Y \rightarrow \mathbb{R} \) is \( \mu \)-admissible if it is symmetric and convex with respect to both of its arguments, and for all \( x \in X \) and \( y \in Y \) and \( (h, h') \in \mathcal{H}^2 \), it verifies the following Lipschitz condition for some \( \mu > 0 \):

\[
|\ell(h'(x), y) - \ell(h(x), y)| \leq \mu |h'(x) - h(x)|.
\]
The family of $\mu$-admissible losses includes the hinge loss and all $\ell_q(y, y') = |y - y'|^q$ with $q \geq 1$, in particular the squared loss, when the hypothesis set and the set of output labels are bounded.

With the assumptions made previously, the following results can be proved.

**Theorem 16** ([Cortes and Mohri, 2011, Cortes and Mohri, 2014]). Let $\mathcal{S}$ and $\mathcal{T}$ be the source and the target domain on $X \times Y$, let $\mathcal{H}$ be a hypothesis class, and let $\ell$ be a $\mu$-admissible loss. We assume that the target labeling function $f_T$ belongs to $\mathcal{H}$, and let $\eta$ denote $\max \{ \ell(f_S(x), f_T(x)) : x \in \text{supp}(\mathcal{S}_X) \}$. Let $h'$ be the hypothesis minimizing $F_{\mathcal{T}_X}$ and $h$ the one returned when minimizing $F_{\mathcal{S}_X}$. Then, for all $(x, y) \in X \times Y$ we have

$$|\ell(h'(x), y) - \ell(h(x), y)| \leq \mu R \sqrt{\frac{\text{disc}_\ell(\mathcal{S}_X, \mathcal{T}_X) + \mu \eta}{\beta}}.$$  

This theorem shows that the difference between the errors achieved by the optimal hypotheses learned on the source and target samples is proportional to the distance between the samples plus a term reflecting the worst value that a loss function can achieve for some instance belonging to the support of $\mathcal{S}_X$.

A similar theorem can be proven when not $f_T$ but $f_S \in \mathcal{H}$ is assumed. Moreover, the authors mention that these theorems can be extended to the case where neither the target function $f_T$ nor $f_S$ belong to $\mathcal{H}$ by replacing $\eta$ in the statement of the theorem with

$$\eta' = \max_{x \in \text{supp}(\mathcal{S}_X)} \{ \ell(h^*_T(x), f_S(x)) \} + \max_{x \in \text{supp}(\mathcal{T}_X)} \{ \ell(h^*_T(x), f_T(x)) \},$$

where $h^*_T \in \text{argmin}_{h \in \mathcal{H}} \ell(h(x), f_T)$. In both cases, when $\eta$ is assumed to be small, i.e. $\eta \ll 1$, the key term of the obtained bound is the empirical discrepancy distance $\text{disc}_\ell(\mathcal{S}_X, \mathcal{T}_X)$. In the extreme case when $f_T = f_S = f$, we obtain $\eta = 0$ and the problem reduces to the covariate shift adaptation scenario characterized by the same labeling function in both domains and analyzed more in detail in the following section. In general, one can draw a parallel between the $\eta$ term that appears in this bound and the other so-called adaptation capacity terms as the $\lambda$ term in the bound of Ben-David et al. from Theorem 10.

The result given by Theorem 16 can be further strengthen when the considered loss function is assumed to be the squared loss $\ell_2 = (y - y')^2$ for some $(y, y') \in Y^2$ and when the kernel-based regularization algorithm described above coincides with the Kernel Ridge Regression (KRR). In what follows, the term $\eta$ will be replaced by a finer quantity defined as

$$\delta_H(f_S, f_T) = \inf_{h \in \mathcal{H}} \| E_{x \sim \mathcal{S}_X} [\Delta(h, f_S)] - E_{y \sim f_T} [\Delta(h, f_T)] \|,$$

where $\Delta(h, f) = (f(x) - h(x))\Phi(x)$ with $\Phi(x)$ being the associated to the kernel $K$ feature vector so that $K(x, x') = \langle \Phi(x), \Phi(x') \rangle$. Using this quantity the following guarantee holds.

**Theorem 17** ([Cortes and Mohri, 2014]). Let $\ell$ be a squared loss bounded by some $M > 0$ and let $h'$ be the hypothesis minimizing $F_{\mathcal{T}_X}$ and $h$ the one returned when minimizing $F_{\mathcal{S}_X}$. Then, for all $(x, y) \in X \times Y$, we have:

$$|\ell(h(x), y) - \ell(h'(x), y)| \leq \frac{R \sqrt{M}}{\beta} \left( \delta_H(f_S, f_T) + \sqrt{\delta_H^2(f_S, f_T) + 4 \beta \text{disc}_\ell(\mathcal{S}_X, \mathcal{T}_X)} \right).$$

As pointed out by the authors, the main advantage of this result is its expression in terms of $\delta_H(f_S, f_T)$ instead of $\eta_H(f_S, f_T)$. One may note that $\delta_H(f_S, f_T)$ is defined as a difference and thus it becomes zero for $\delta_X = \delta_T$, which does not hold for $\eta_H(f_S, f_T)$. Furthermore, when the covariate-shift assumption holds for some shared labeling function $f$ such that $f_S = f_T = f$, $\delta_H(f, f)$ can be upper-bounded using the following result.

**Theorem 18** ([Cortes and Mohri, 2014]). Assume that for all $x \in X$, $K(x, x) \leq R^2$ for some $R > 0$. Let $A$ denote the union of the supports of $\mathcal{S}_X$ and $\mathcal{T}_X$. Then, for any $p > 1$ and $q > 1$, with $1/p + 1/q = 1$,

$$\delta_H(f, f) \leq d_p(f, A, H, A) \rho_p(\mathcal{S}_X, \mathcal{T}_X),$$

where for any set $A \subseteq X$, $f \mid A$ (resp. $H \mid A$) denote the restriction of $f$ (resp. $h$) to $A$ and $d_p(f, A, H, A) = \inf_{h \in H} \| f - h \|_p$.
In particular, the authors show that for a labeling function $f$ that belongs to the closure of $\mathcal{H}_A$, $\delta_\mathcal{H}(f) = 0$ when the KRR algorithm is used with normalized Gaussian kernels. For this specific algorithm often deployed in practice, the bound of the theorem then reduces to the simpler expression:

$$|\ell(h(x), y) - \ell(h'(x), y)| \leq 2R \sqrt{\frac{M_{disc}(\hat{S}_X, \hat{T}_X)}{\beta}}.$$  

Generalized discrepancy The above-mentioned results can be further strengthen using a recently proposed notation of the generalized discrepancy introduced by [Cortes et al., 2015]. In order to introduce this distance, we may first note that a regression task in the domain adaptation context can be seen as an optimal approximation of an ideal hypothesis $h_\tau^* = \arg\min_{h \in \mathcal{H}} R_{\mathcal{X}}(h, f_T)$ by another hypothesis $h$ that ensures the closeness of the losses $R_{\mathcal{X}}(h^*, f_T)$ and $R_{\mathcal{X}}(h, f_T)$. As we do not have access to $f_T$ but only to the labels of the source sample $S$, the main idea is to define, for any $h \in \mathcal{H}$, a reweighing function $Q_h : S \rightarrow \mathbb{R}$ such that the objective function $G$ defined for all $h \in \mathcal{H}$ by

$$G(h) = R_{\mathcal{X}}(h) + \beta\|h\|_K^2,$$

remains uniformly close to $F_{\mathcal{X}}(h)$ defined over the target sample $T_\tau$. As pointed out by the authors, this idea introduces a different learning concept as instead of reweighing the training sample with some fixed set of weights, the weights are allowed to vary as a function of the hypothesis $h$ and are not assumed to sum to one or to be non-negative. Based on this construction, the optimal reweighing can be obtained by solving:

$$Q_h = \arg\min_{q \in \mathcal{F}(\hat{S}_X, \mathbb{R})} |R_{\mathcal{X}}^T(h, f_T) - R_q(h, f_S)|,$$

where $\mathcal{F}(\mathcal{S}_X, \mathbb{R})$ is the set of real-valued functions defined over $\text{supp}(\mathcal{S}_X)$.

We can notice that, in practice, we may not have access to target labeled samples, that implies that we cannot estimate $f_T$. To solve this problem, the authors propose to consider a non-empty convex set of candidate hypotheses $\mathcal{H}' \subseteq \mathcal{H}$ that could contain a good approximation of $f_T$. Using $\mathcal{H}'$ as a set of surrogate labeling functions, the previous optimization problem becomes:

$$Q_h = \arg\min_{q \in \mathcal{F}(\mathcal{S}_X, \mathbb{R})} \max_{h' \in \mathcal{H}'} |R_{\mathcal{X}}^T(h, h') - R_q(h, f_S)|.$$

The risk obtained using the solution of this optimization problem given by $Q_h$ can be equivalently expressed as follows:

$$R_{Q_h}(h, f_S) = \frac{1}{2} \left( \max_{h' \in \mathcal{H}'} R_{\mathcal{X}}^T(h, h') + \min_{h' \in \mathcal{H}'} R_{\mathcal{X}}^T(h, h') \right).$$

This, in its turn, allows us to reformulate $G(h)$ that now becomes:

$$G(h) = \frac{1}{2} \left( \max_{h' \in \mathcal{H}} R_{\mathcal{X}}^T(h, h') + \min_{h' \in \mathcal{H}} R_{\mathcal{X}}^T(h, h') \right) + \beta\|h\|_K^2.$$

The proposed optimization problem should have the same point-wise guarantees as the ones established in Theorem 17 but based on a new notation of the distance between the probability distributions that can be seen as a generalization of the discrepancy distance used before. In order to introduce it, we now define $A(\mathcal{H})$ as a set of functions $U : h \rightarrow U_h$ that map $\mathcal{H}$ to $\mathcal{F}(\mathcal{S}_X, \mathbb{R})$ such that for all $h \in \mathcal{H}$, $h \rightarrow \ell_{U_h}(h, f_S)$ is a convex function. The set $A(\mathcal{H})$ contains all constant functions $U$ such that $U_h = q$ for all $h \in \mathcal{H}$, where $q$ is a distribution over $\mathcal{S}_X$. The definition of the generalized discrepancy can thus be given as follows.

**Definition 14.** For any $U \in A(\mathcal{H})$, the generalized discrepancy between $U$ and $\hat{T}_X$ is defined as

$$\text{DISC}(\hat{T}_X, U) = \max_{h \in \mathcal{H}, h' \in \mathcal{H}'} \left| R_{\mathcal{X}}^T(h, h') - R_{U_h}(h, f_S) \right|.$$  

In addition, the authors also defined the following distance of $f$ to $\mathcal{H}'$ over the support of $\hat{T}_X$:

$$d_{\mathcal{X}}^T(f_T, \mathcal{H}') = \min_{h_0 \in \mathcal{H}', h_0 \in \text{supp}(\hat{T}_X)} \max_{x \in \text{supp}(\hat{T}_X)} |h_0(x) - f_T(x)|.$$  

Using the above-defined quantities, the following point-wise guarantees can be given.
**Theorem 19** ([Cortes et al., 2015]). Let $h^*$ be a minimizer of $R^*_{T_{\mathcal{X}}}(h, f_T) + \beta\|h\|_K^2$ and $h_Q$ be a minimizer of $R^*_{Q,h}(h, f_S) + \beta\|h\|_K^2$. Then, for $Q : h \rightarrow Q_h$ and $\forall x \in X$, $y \in Y$ the following holds:

$$|\ell(h_Q(x), y) - \ell(h^*(x), y)| \leq \mu R(\frac{1}{\beta})^\frac{1}{\mu d_{\mathcal{X}}(f_T, H'')} + DISC(Q, \tilde{T}_X).$$

Furthermore, this inequality can be equivalently written in terms of the risk functions as

$$R_T^T(h_Q, f_T) \leq R_T^T(h^*, f_T) + \mu R(\frac{1}{\beta})^\frac{1}{\mu d_{\mathcal{X}}(f_T, H'')} + DISC(Q, \tilde{T}_X).$$

The result of Theorem 19 suggests selecting $H''$ to minimize the right-hand side of the last inequality. In particular, the authors provide further evidence that if the space over which $H''$ is searched is the family of all balls centered in $f_S$ defined in terms of $l_q$, i.e., $H'' = \{h'' \in H | l_q(h'', f_Q) \leq r\}$ for some distribution $q$ over the space of the reweighed source samples, then the proposed algorithm based on the generalized discrepancy gives provably better results compared to the original one.

**Semi-supervised case** When labeled sample $T$ from target domain is available, one can actually use part of it to find an appropriate value of $r$. In order to prove this latter statement, let us consider the following set $S' = S \cup T$ and an empirical distribution $\hat{S}_X$ over it and denote by $q''$ the distribution minimizing the discrepancy between $\hat{S}_X$ and $\tilde{T}_X$. Now since $\text{supp}(\hat{S}_X)$ is included in that of $\text{supp}(\tilde{T}_X)$ the following inequality can be obtained

$$\text{disc}_\ell(\tilde{T}_X, q'') = \min_{\text{supp}(g) \subseteq \text{supp}(\hat{S}_X)} \text{disc}_\ell(\tilde{T}_X, q) \leq \min_{\text{supp}(g) \subseteq \text{supp}(\tilde{T}_X)} \text{disc}_\ell(\tilde{T}_X, q) = \text{disc}_\ell(\tilde{T}_X, q^*).$$

Consequently, in view of Theorem 19, for an appropriate choice of $H''$, the learning guarantee for adaptation algorithms based on the generalized discrepancy is more favorable when using some labeled data from the target domain. Thus, using the limited amount of labeled points from the target distribution can improve the performance of their proposed algorithm.

### 3.5 Other relevant contributions

**[Mansour et al., 2008]** In this paper, the authors considered the multi-source domain adaptation problem and introduced the learning bounds in two different adaptation settings. For the first one, they assumed that $T_X = \sum_{i=1}^N \alpha_i S_X^i$ and studied the performance of a hypothesis defined as $h_{\alpha} = \sum_{i=1}^N \alpha_i h_i$, where $S_X^i$ is the marginal distributions of the $i^{\text{th}}$ source domain and $\forall i, \alpha_i \geq 0$, $\sum_{i=1}^N \alpha_i = 1$. In this scenario, the authors proved that there exists a domain adaptation problem such that $R_T(h_{\alpha}) = \frac{1}{2}$ even when $\forall i$, $R_{S_X^i}(h_i) = 0$. This prompted them to consider a different combined hypothesis defined as

$$h_D^\alpha = \sum_{i=1}^N \frac{\alpha_i S_X^i}{\sum_{i=1}^N \alpha_i S_X^i} h_i.$$

In this case, the authors proved that $R_T(h_D^\alpha) \leq \varepsilon$ when $\forall i$, $R_{S_X^i}(h_i) \leq \varepsilon$.

**[Mansour et al., 2009b]** This work extends the contribution of [Mansour et al., 2008] by analyzing arbitrary target distributions that are not necessarily represented by a weighted mixture of source distributions. The authors propose a domain adaptation learning bounds having the following form:

$$R_T(h_D^\alpha) \leq (\varepsilon d_{\alpha}(T_X | S_X))^\frac{1}{\varepsilon d_{\alpha}(T_X | S_X)} M^\frac{1}{\varepsilon d_{\alpha}(T_X | S_X)},$$

where $d_{\alpha}(T_X | S_X) = \left( \int_{S_X} \frac{T_X}{S_X} \right)_{\alpha}^{\frac{1}{\alpha - 1}}$ is the exponential of the $\alpha$-Rényi divergence, $R_{S_X^i}(h_i) \leq \varepsilon$ and $M \geq 0$ is a constant bounding the loss function used in the definition of $R_D$.

**[Hoffman et al., 2018]** In this work, the authors extend the analysis of [Mansour et al., 2009b] to account for cross-entropy and other similar losses not considered in previous work. They also propose a principal way of determining the coefficients $\alpha_i$ ensuring efficient adaptation and extend their analysis to the scenario of non-deterministic labeling.
In this work, the authors proposed a learning bound for hypotheses associated to a general family of similarity functions introduced in [Balcan et al., 2008]. The proposed bounds rely on $L^1$ and $\chi^2$ divergences and similar to [Mansour et al., 2009b] present a multiplicative dependence of the source error on the divergence term.

Finally, in this work the authors introduced a bound for the multi-source domain adaptation based on the discrepancy of [Mansour et al., 2009a] for the target shift scenario where the inequality between $S$ and $T$ is due to the drift between the marginal distributions of $Y$ in each domain.

3.6 Summary

This section presents several cornerstone results of the domain adaptation theory including those proposed by Ben-David et al. based on the $H\Delta H$-divergence and a variety of results based on the discrepancy distance proposed by Mansour et al. and Cortes et al. for the tasks of classification and regression. As one may note, the general ideas used to prove generalization bounds for domain adaptation are based on the definition of a relation between the source and the target domain through a divergence allowing us to upper-bound the target risk by the source risk and on the theoretical results presented in Section 2 and their properties. Unsurprisingly, this trend is usually maintained regardless the considered domain adaptation scenario or analyzed learning algorithm. The overall form of the presented generalization bound on the error of a hypothesis calculated with respect to the target distribution appears to contain inevitably the following important terms:

1. The source error of the hypothesis measured with respect to some loss function;
2. The divergence term between the marginal distributions of the source and target domains. In the case of Ben-David et al. this term is explicitly linked to the hypothesis space inducing a complexity term related to its Vapnik-Chervonenkis dimension; in the case of Mansour et al. and Cortes et al. the divergence term depends on the hypothesis space but the complexity term is data-dependent and is linked to the Rademacher complexity of the hypothesis space;
3. The non-estimable term that reflects the a priori hardness of the domain adaptation problem. This latter usually requires at least some target labeled data in order to be quantified.

The terms appearing in the bounds show us that in case where two domains are almost indistinguishable, the performance of a given hypothesis across them will remain largely similar. When this is not the case, the divergence between the source and target domains marginal distributions starts to play a crucial role in assessing the proximity of two domains. For both presented results, the actual value of this divergence can be consistently calculated using the available finite (unlabeled) samples thus providing us with a first estimate of the potential success of adaptation. Finally, the last term tells us that even bringing the divergence between the marginal distributions to zero across two domains may not suffice for efficient adaptation. This last point can be summarized by the following statement made by Ben-David in [Ben-David et al., 2010a]:

“When the combined error of the ideal joint hypothesis is large, then there is no classifier that performs well on both the source and target domains, so we cannot hope to find a good target hypothesis by training only on the source domain.”

This statement brings us to another important question regarding the conditions that one needs to verify in order to make sure that the adaptation can be successful. This question spurs a cascade of other relevant inquiries such as what is the actual size of the source and target unlabeled samples needed for the adaptation to be efficient? Are target labeled data needed for an efficient adaptation and if yes can we prove formally that it leads to better results? And finally, what are the pitfalls of domain adaptation when even strong prior knowledge regarding the adaptation problem does not guarantee it to have a solution? All these question are answered by the so-called “hardness theorems” that we present in the following section.

4 Hardness results for domain adaptation

This section is devoted to a series of results that prove the so-called “hardness or impossibility theorems” for domain adaptation. These latter statements show the extent to which the domain adaptation problem can be hard to solve or the conditions when it is provably unsolvable under some common assumptions. These theorems are very important as they highlight that in some cases one cannot hope to adapt well even with a prohibitively large amount of data from both domains or when the adaptation task may be trivial.
4.1 Problem setup

Before presenting main theoretical results, we first introduce the necessary preliminary definitions that formalize the concepts used afterwards. These definitions are then followed by a set of assumptions that are commonly considered to have a direct influence on the potential success of domain adaptation.

**Definitions** We have seen from the previous sections that the adaptation efficiency is directly correlated with two main terms that inevitably appear in almost all analyses: one term depicting the divergence between the domains while the other one stands for the existence and the error achieved by the best hypothesis across the source and target domains. The authors of [Ben-David et al., 2010b] proposed to analyze the presence of these two terms in the bounds by answering the following questions:

1. Is the presence of these two terms inevitable in the domain adaptation bounds?
2. Is there a way to design a more intelligent domain adaptation algorithm that uses not only the labeled training sample but also the unlabeled sample of the target data distribution?

These two questions are very important as answering them can help us to obtain an exhaustive set of conditions that theoretically ensure efficient adaptation with respect to a given domain adaptation algorithm. Before proceeding to the presentation of the main results, the authors first defined several quantities that are used later. The first one is the formalization of an unsupervised domain adaptation algorithm [Ben-David et al., 2010a].

**Definition 15** (Domain adaptation learner). A domain adaptation learner is a function

\[ A : \bigcup_{m=1}^{\infty} \bigcup_{n=1}^{\infty} (X \times \{0, 1\})^m \times X^n \rightarrow \{0, 1\}^X. \]

As before, the standard notation for the performance of the learner is given by the used error function. When the error is measured with respect to the best hypothesis in some hypothesis class \( \mathcal{H} \), we use the notation \( R_D(\mathcal{H}) = \inf_{h \in \mathcal{H}} R_D(h) \). Using this notation, the authors further define the learnability as follows.

**Definition 16** (\((\varepsilon, \delta, m, n)\)-learnability). Let \( S \) and \( T \) be distributions over \( X \times \{0, 1\} \), \( \mathcal{H} \) a hypothesis class, \( A \) a domain adaptation learner, \( \varepsilon > 0, \delta > 0, \) and \( m, n \) positive integers. We say that \( A(\varepsilon, \delta, m, n) \)-learns \( T \) from \( S \) relative to \( \mathcal{H} \), if when given access to a labeled sample \( S \) of size \( m \), generated i.i.d. by \( S \), and an unlabeled sample \( T_u \) of size \( n \), generated i.i.d. by \( TX \), with probability at least \( 1 - \delta \) (over the choice of the samples \( S \) and \( T_u \)), the learned classifier does not exceed the error of the best classifier in \( \mathcal{H} \) by more than \( \varepsilon \), i.e.,

\[
\Pr_{S \sim (S)^m, T_u \sim (T_X)^n} \left[ R_T(A(S, T_u)) \leq R_T(\mathcal{H}) + \varepsilon \right] \geq 1 - \delta.
\]

This definition gives us a criterion that we can use in order to judge if a particular algorithm has strong learning guarantees that consists in finding an optimal trade-off between both \( \varepsilon \) and \( \delta \) in the above definition. We further introduce two alternative definitions of domain adaptation learnability for proper learning setting and when the best error of a classifier in \( \mathcal{H} \) is scaled by an additional constant \( c \).

**Definition 17** \((c, \varepsilon, \delta, m, n)\)-proper learnability). With the notations from Definition 16, we say that \( A(c, \varepsilon, \delta, m, n) \)-solves a proper domain adaptation for the class \( W \) relative to \( \mathcal{H} \), if \( A \) outputs an element \( h \) of \( \mathcal{H} \) with

\[
\Pr_{S \sim (S)^m, T_u \sim (T_X)^n} \left[ R_T(A(S, T_u)) \leq cR_T(\mathcal{H}) + \varepsilon \right] \geq 1 - \delta.
\]

In other words, this definition says that proper solving of the domain adaptation problem is achieved when the error of the returned hypothesis from a fixed hypothesis class w.r.t. the target distribution is bounded by \( c \) times the error of the best hypothesis on the target distribution plus a constant \( \varepsilon \). Obviously, efficient solving of the proper domain adaptation is characterized by small \( \delta \), \( \varepsilon \) and \( c \) close to 1. We also note that for both definitions given above, the inequality event can be reduced to \( R_T(A(S, T_u)) \leq \varepsilon \) when the hypothesis class \( \mathcal{H} \) contains a zero-error hypothesis, i.e., \( R_T(\mathcal{H}) = 0 \).

Finally, we will also need a definition introduced in [Ben-David and Urner, 2012] that expresses the capacity of a hypothesis class to produce a zero-error classifier with margin \( \gamma \).
Definition 18. Let $X \subseteq \mathbb{R}^d$, $D_X$ a distribution over $X$ and $h : X \to \{0, 1\}$ a classifier and $B_r(x)$ be the ball of radius $\gamma$ around some domain point $x$. We say that $h$ is a $\gamma$-margin classifier with respect to $D_X$ if for all $x \in X$ whenever $D_X(B_r(x)) > 0$ then $h(y) = h(z)$ holds for all $y, z \in B_r(x)$.

In [Ben-David and Urner, 2012], it is also noted that $h$ being a $\gamma$-margin classifier with respect to $D_X$ is equivalent to $h$ satisfying the Lipschitz-property with Lipschitz constant $\frac{1}{\gamma}$ on the support of $D_X$. Thus, we may refer to this assumption as the Lipschitzness assumption. For the sake of completeness, we present the original definition of the probabilistic Lipschitzness below.

Definition 19. Let $\phi : \mathbb{R} \to [0, 1]$. We say that $f : X \to \mathbb{R}$ is $\phi$-Lipschitz with respect to a distribution $D_X$ over $X$ if, for all $\lambda > 0$, we have

$$P_{\mathbf{x} \sim D_X} \left[ \exists \mathbf{x}' : |f(x) - f(x')| > \lambda \mu(x, x') \right] \leq \phi(\lambda),$$

where $\mu : X \times X \to \mathbb{R}^+$ is some metric over $X$.

Common assumptions in domain adaptation We now proceed to recalling the most common assumptions that were considered in the literature as those that can ensure efficient adaptation.

1. **Covariate shift.** This assumption is among the most popular ones and has been extensively studied in a series of theoretical works on the subject (see, for instance, [Sugiyama et al., 2008] and the references therein). While in domain adaptation we generally assume $S \neq T$, this can be further understood as $S_X(X) \neq T_X(X)$ where $S(Y | X) = T(Y | X)$ while $S_X \neq T_X$ is generally called covariate shift assumption.

2. **Similarity of the (unlabeled) marginal distributions.** [Ben-David et al., 2010b] considered the $\mathcal{H}$-distance between the $S_X$ and $T_X$ in order to assess the impossibility of domain adaptation and assumed that it remains low between the two domains. This is the most straightforward assumption that directly follows from all proposed generalization bounds for domain adaptation. We refer the reader to Section 3 for the details.

3. **Weight-ratio of the (unlabeled) marginal distributions.** The weight-ratio assumption was introduced in [Cortes et al., 2010] and further studied in [Ben-David and Urner, 2012] as a stronger notion of similarity between two marginal distributions. It is defined as:

$$C_B(S_X, T_X) = \inf_{b \in B, b \neq 0} \frac{S_X(b)}{T_X(b)}$$

with respect to a collection of input space subsets $B \subseteq 2^X$.

3. **Ideal joint error.** Finally, the last important assumption is the one stating that there should exist a low-error hypothesis for both domains. As explained in Section 3, this error can be defined as a so-called $\lambda_H$ term as follows:

$$\lambda_H = \min_{h \in \mathcal{H}} R_S(h) + R_T(h).$$

These three assumptions are at the heart of the impossibility theorems where they are usually analyzed in a pair-wise fashion.

### 4.2 Constructive impossibility theorems

In what follows, we present a series of so-called impossibility results related to the domain adaptation problem. These results are then illustrated based on some concrete examples that highlight the pitfalls of domain adaptation algorithms.

To proceed, we present a theorem showing that some of the intuitive assumptions presented above do not suffice to guarantee the success of domain adaptation. More precisely, among the three assumptions that have been quickly discussed – covariate shift, small $\mathcal{H}$-distance between the unlabeled distributions and the existence of a hypothesis that achieves a low error on both the source and target domains (small $\lambda_H$) – the last two are both necessary (and, as we know from previous results, are also sufficient).

**Theorem 20** (Necessity of a small $\mathcal{H}$-distance [Ben-David et al., 2010b]). Let $X$ be some domain set, and $\mathcal{H}$ a class of functions over $X$. Assume that, for some $A \subseteq X$, we have that $\{h^{-1}(1) \cap A : h \in \mathcal{H}\}$ contains more than two sets and is linearly ordered by inclusion. Then, the conditions “covariate shift” plus “small $\lambda_H$” do not suffice for domain adaptation. In particular, for every $\epsilon > 0$ there exists probability distributions $S$ over $X \times \{0, 1\}$, and $T_X$ over $X$ such that for every domain adaptation learner $A$, every integers $m > 0, n > 0$, there exists a labeling function $f : X \to \{0, 1\}$ such that
1. \( \lambda_\mathcal{H} \leq \varepsilon \) is small;

2. \( \mathcal{S} \) and \( \mathcal{T}_f \) satisfy the covariate shift assumption;

3. \[
\Pr_{\substack{S \sim (\mathcal{S})^m \\ T_u \sim (\mathcal{T}_u)^n}} \left[ R_{\mathcal{T}_f} (\mathcal{A}(S, T_u)) \geq \frac{1}{2} \right] \geq \frac{1}{2},
\]

where the distribution \( \mathcal{T}_f \) over \( \mathbf{X} \times \{0, 1\} \) is defined as \( \mathcal{T}_f \{1| \mathbf{x} \in \mathbf{X}\} = f(\mathbf{x}) \).

This result highlights the importance of the need of a small divergence between the marginal distributions of the domains as even when the covariate shift assumption is satisfied and \( \lambda_\mathcal{H} \) is small, the error of the classifier returned by a domain adaptation learner can be larger than \( \frac{1}{2} \) with probability exceeding this same value. We now proceed to the symmetric result that shows the necessity of a small joint error between the two domains expressed by the \( \lambda_\mathcal{H} \) term.

**Theorem 21** (Necessity of a small \( \lambda_\mathcal{H} \) [Ben-David et al., 2010b]). Let \( \mathbf{X} \) be some domain set, and \( \mathcal{H} \) a class of functions over \( \mathbf{X} \) whose VC dimension is much smaller than \( |\mathbf{X}| \) (for instance any \( \mathcal{H} \) with a finite VC dimension over an infinite \( \mathbf{X} \)). Then, the conditions covariate shift plus small \( \mathcal{H} \Delta \mathcal{H} \)-divergence do not suffice for domain adaptation. In particular, for every \( \varepsilon > 0 \) there exists probability distributions \( S \) over \( \mathbf{X} \times \{0, 1\} \), \( \mathcal{T}_\mathbf{X} \) over \( \mathbf{X} \) such that for every domain adaptation learner \( \mathcal{A} \), every integers \( m, n > 0 \), there exists a labeling function \( f : \mathbf{X} \rightarrow \{0, 1\} \) such that

1. \( d_{\mathcal{H} \Delta \mathcal{H}} (\mathcal{T}_\mathbf{X}, \mathcal{S}_\mathbf{X}) \leq \varepsilon \) is small;

2. The covariate shift assumption holds;

3. \[
\Pr_{\substack{S \sim (\mathcal{S})^m \\ T_u \sim (\mathcal{T}_u)^n}} \left[ R_{\mathcal{T}_f} (\mathcal{A}(S, T_u)) \geq \frac{1}{2} \right] \geq \frac{1}{2}.
\]

Once again, this theorem shows that a small divergence combined with a satisfied covariate shift assumption may lead to an error of the hypothesis returned by a domain adaptation learner that exceeds \( \frac{1}{2} \) with high probability. Consequently, the main conclusion of these two theorems can be summarized as follows: among the studied assumptions neither the assumption combination 1. and 3. nor 2a. and 3. suffice for successful domain adaptation in the unsupervised case. Another important conclusion that should be underlined here is that all generalization bounds for domain adaptation a with distance term and a joint error term introduced throughout this survey indeed imply learnability even with the most straightforward learning algorithm. On the other hand, the covariate shift assumption is rather unnecessary: it cannot replace any of the other assumptions, and it becomes redundant when the other two assumptions hold. This study, however, needs a further investigation as in the case of semi-supervised domain adaptation the situation can be drastically different.

**Case of proper domain adaptation learning**  Below, we turn out attention to impossibility results established in [Ben-David et al., 2012] for the case where the output of the given domain adaptation algorithm should be a hypothesis belonging to some predefined hypothesis class. This particular constraint easily justifies itself in practice where one may want to find a hypothesis as quickly as possible from a predefined set of hypotheses at the expense of having a higher error rate. The following result was obtained in [Ben-David and Urner, 2012] in this setting.

**Theorem 22** ([Ben-David et al., 2012]). Let domain \( \mathbf{X} = \{0, 1\}^d \), for some \( d \). Consider the class \( \mathcal{H} \) of half-spaces as the target class. Let \( \mathbf{x} \) and \( \mathbf{z} \) be a pair of antipodal points on the unit sphere and let \( \mathcal{W} \) be a set that contains two pairs \( (\mathcal{S}, \mathcal{T}) \) and \( (\mathcal{S}', \mathcal{T}') \) of distributions with:

1. both pairs satisfy the covariate shift assumption;

2. \( f(\mathbf{x}) = f(\mathbf{z}) = 1 \) and \( f(\mathbf{0}) = 0 \) for their common labeling function \( f \);

3. \( S_\mathbf{x}(\mathbf{x}) = T_\mathbf{x}(\mathbf{z}) = S_\mathbf{x}(\mathbf{0}) = \frac{1}{2} \); 

4. \( T_\mathbf{x}(\mathbf{x}) = T_\mathbf{x}(\mathbf{0}) = \frac{1}{2} \) or \( T_\mathbf{z}(\mathbf{z}) = T_\mathbf{z}(\mathbf{0}) = \frac{1}{2} \).

Then, for any number \( m \), any constant \( c \), no proper domain adaptation learning algorithm can \((c, \varepsilon, \delta, m, 0)\) solve the domain adaptation learning task for \( \mathcal{W} \) with respect to \( \mathcal{H} \), if \( \varepsilon < \frac{1}{2} \) and \( \delta < \frac{1}{2} \). In other words, every learner that ignores unlabeled target data fails to produce a zero-risk hypothesis with respect to \( \mathcal{W} \).

This theorem shows that having some amount of data generated by the target distribution is crucial for the learning algorithm to estimate whether the support of the target distribution is \( \mathbf{x} \) and \( \mathbf{0} \) or \( \mathbf{z} \) and \( \mathbf{0} \). Surprisingly, there is no
possible way of obtaining this information without having access to a sample drawn from the target distribution event if the point-wise weight-ratio is assumed to be as large as $\frac{1}{3}$. Thus, no amount of labeled source data can compensate for having a sample from the target marginal distribution.

**Illustrative examples** Now as the main impossibility theorems are stated, it can be useful to give an illustrative example of situations where different assumptions and different learning strategies may fail or succeed. To this end, [Ben-David et al., 2010b] considered several examples that show the inadequacy of the covariate shift assumption explained above as well as the limits of the reweighing scheme.

In what follows, the considered hypothesis class is restricted to the space of threshold functions on $[0, 1]$ where a threshold function $h_U(x)$ is defined for any $t \in [0, 1]$ as $h_U(x) = 1$ if $x < t$ and 0 otherwise. In this case, the set $\mathcal{H}_U$ becomes the class of half-open intervals.

**Inadequacy of the covariate shift.** Let us consider the following construction: for some small fixed $\xi \in \{0; 1\}$, let $\mathcal{T}$ be a uniform distribution over $\{(2k+1)\xi : k \in \mathbb{N}, (2k+1)\xi \leq 1\} \times \{0\}$ and let the source distribution $\mathcal{S}$ be the uniform distribution over $\{(2k+1)\xi : k \in \mathbb{N}, (2k+1)\xi \leq 1\} \times \{1\}$. The illustration of these distributions are given in Figure 7.

Figure 7: The scheme illustrates the considered source and target distributions satisfying the covariate shift assumption with $\xi = \frac{2}{3}$.

For this construction, the following holds.

1. The covariate shift assumption holds for $\mathcal{T}$ and $\mathcal{S}$;
2. The distance $d_{\mathcal{H}_U}(\mathcal{S}, \mathcal{T}) = \xi$ and thus can be arbitrary small;
3. The errors $R_{\mathcal{S}}(\mathcal{H})$ and $R_{\mathcal{T}}(\mathcal{H})$ are zero;
4. $\lambda_{\mathcal{H}}(\mathcal{S}, \mathcal{T}) = 1 - \xi$ and $R_{\mathcal{T}}(h^*_U) \geq 1 - \xi$ are large.

From this example one can instantly see that the covariate shift assumption even combined with a small $\mathcal{H}_U$-divergence between domains still results in a large joint error and consequently in a complete failure of the best source classifier when applied to the target distribution.

**Reweighing method.** A reweighing method in domain adaptation consists in determining a vector of weights $w = \{w_1, w_2, \ldots, w_m\}$ that are used to reweight the unlabeled source sample $S_u$ generated by $\mathcal{S}_X$ in order to built a new distribution $\mathcal{T}^{S_u}$ such that $d_{\mathcal{H}_U}(\mathcal{T}^{S_u}, \mathcal{T}_X)$ would be as small as possible. In what follows, we denote this reweighed distribution $\mathcal{T}^{S_u}$.

This new sample is then fed to any available supervised learning algorithm at hand in order to produce a classifier that is expected to have a good performance when applied subsequently in the target domain. As this method plays a very important role in the domain adaptation, the authors also gave two intrinsically close examples that show both its success and failure under the standard domain adaptation assumptions.

We first consider the following scheme: for some small $\epsilon \in (0, \frac{1}{3})$, we assume that the covariate shift assumption holds, i.e., for any $x \in \mathcal{X}$, $\mathcal{T}(y = 1|x) = \mathcal{S}(y = 1|x) = f(x)$. We define $f : \mathcal{X} \rightarrow [0, 1]$ as follows: for $x \in [1 - 3\epsilon, 1 - \epsilon]$ we set $f(x) = 0$ and otherwise we set $f(x) = 1$. In order to define $\mathcal{S}$ and $\mathcal{T}$, we have only to specify their marginals $\mathcal{S}_X$ and $\mathcal{T}_X$. To this end, we let $\mathcal{S}_X$ be the uniform distribution over $[0, 1]$ and we let $\mathcal{T}_X$ be the uniform distribution over $[1 - \epsilon, 1]$. This particular setting is depicted in Figure 8.

Figure 8: Illustration for the reweighing scenario. The source and target distributions satisfy the covariate shift assumption where $f$ is their common conditional distribution. The marginal $\mathcal{S}_X$ is the uniform distribution over $[0, 1]$ and the marginal $\mathcal{T}_X$ is the uniform distribution over $[1 - \epsilon, 1]$.

The following observations follow from this construction.
1. For the given construction, the best joint hypothesis that defines $\lambda_H$ is given by the function $h_{t=1}$; This function commits 0 errors on the target distribution and $2\epsilon$ errors on the source distribution thus giving $\lambda_H(S, T)$ equal to $2\epsilon$.

2. From the definition of $H\Delta H$-divergence, we get that $d_H(\mathcal{S}_X, \mathcal{T}_X) = 1 - \epsilon$.

3. $R_T(h_S^*) = 1$, $R_T(H) = 0$ and $R_S(H) = \epsilon$ achieved by threshold functions $h_{t=1-3\epsilon}$, $h_{t=1}$ and $h_{t=1-3\epsilon}$, respectively.

On the other hand, one can find a reweighing distribution that will produce a sample such that $R_T(h_{\tau,S}) \to 0$ in probability when $m$ and $n$ tend towards infinity and $h_{\tau,S} = \arg\min_{h \in H} R_T(h_{\tau,S})$. This happens along with the probability of the source error tending to 1 when $m$ grows to infinity. This example is a clear illustration when simple reweighing scheme can be efficient for adaptation. This however, is not the case when we consider a different labeling of the target data points. Let us now assume that the source distribution remains the same while for the target distribution $f(x) = 1$ for any $x \in X$. This slight change gives the following results:

1. $\lambda_H(S, T) = \epsilon$;
2. $d_H(\mathcal{S}_X, \mathcal{T}_X) = 1 - \epsilon$;
3. $R_T(h_S^*) = 0$, $R_T(H) = 0$ and $R_S(H) = \epsilon$.

We can observe that now the $\lambda_H$ term became smaller and that the best source hypothesis achieves a 0 error on the target distribution. However, the result that we obtain with the reweighing method is completely different: it is not hard to see that $R_T(h_{\tau,S}) \to 1$ in probability when $m$ and $n$ tend towards infinity while the error of $h_S^*$ will tend to zero.

We conclude by saying that the bound from [Ben-David et al., 2010a] recalled in Section 3 implies that $R_T(h_S^*)$ is bounded by $R_T(H) + \lambda_H(S, T) + d_H(\mathcal{S}_X, \mathcal{T}_X)$ and thus one could have hoped that, by reweighing the sample $S$ to reflect the distribution $\mathcal{T}_X$, the term $d_H(\mathcal{S}_X, \mathcal{T}_X)$ in that bound would be diminished. The last example, however, shows that this may not be the case as $R_{\tau,S}$ may be as bad as that bound allows.

### 4.3 Impossibility theorems based on sample complexity

We now present several results that assess the hardness of the domain through the lens of its sample complexity usually defined as a number of training instances required to achieve a low-error classifier for a certain distribution $D$. This setting in the context of the adaptation problem was studied by Ben-David and Urner [Ben-David and Urner, 2012] with their first theorem establishing the sample complexity of solving a domain adaptation problem formulated as follows.

**Theorem 23** ([Ben-David and Urner, 2012]). For every finite domain $X$, for every $\epsilon$ and $\delta$ with $\epsilon + \delta < \frac{1}{2}$, no algorithm can $(\epsilon, \delta, |S_u|, |T_u|)$-solve the domain adaptation problem for the class $W$ of triples $(S_X, T_X, f)$ with $C_W(S_X, T_X) \geq \frac{1}{2}$, $d_H(S_X, T_X) = 0$ and $R_T(H) = 0$ if

$$|S_u| + |T_u| < \sqrt{(1 - 2(\epsilon + \delta))|X|},$$

where $H$ is the hypothesis class that contains only the all-1 and the all-0 labeling functions and $R_T(H) = \min_{h \in H} R_T(h, f)$.

This result is interesting in many ways. First, the assumptions done in the theorem are extremely simplified, which means that the a priori knowledge about the target task is so strong that a zero error classifier for the given hypothesis class can be obtained using only one labeled target instance. Second, we may also note that the considered setting is extremely favorable for adaptation as the marginal distributions of the source and target domains are close both in terms of the $H\Delta H$-divergence and the weight-ratio $C_W(S_X, T_X)$. For the latter, it roughly means that the probability to encounter a source point is at least half of the probability of finding it in the target domain. These assumptions further spur the following surprising conclusions:

1. The sample complexity of domain adaptation cannot be bounded only in terms of the VC dimension of the class that can produce a hypothesis achieving a zero error on it. This statement agrees well with the previous results showing the necessity of the existence of a good hypothesis for both domains;
2. Some data drawn from the target distribution should be available in order to obtain a bound with an exclusive dependency on the VC dimension of the hypothesis class.
3. This result implies that the sample sizes needed to obtain useful approximations of weight-ratio is prohibitively high.
We now provide another result provided by Ben-David and Urner that shows that the same lower bound can be obtained using the Lipschitz assumption imposed on the labeling function $f$.

**Theorem 24 ([Ben-David and Urner, 2012]).** Let $X = [0, 1]^d$, $\varepsilon > 0$ and $\delta > 0$ be such that $\varepsilon + \delta < \frac{1}{2}$, let $\lambda > 1$ and let $\mathcal{W}_\lambda$ be the set of triples $(S_X, T_X, f)$ of distributions over $X$ with $R_T(\mathcal{H}) = 0$, $C_B(S_X, T_X) \geq \frac{1}{2}$, $d_{\text{Lipschitz}}(S_X, T_X) = 0$ and $\lambda$-Lipschitz labeling functions $f$. Then no domain adaptation-learner can $(\varepsilon, \delta, |S_u| + |T_u|)$-solve the domain adaptation problem for the class $\mathcal{W}_\lambda$ unless

$$|S_u| + |T_u| \geq \sqrt{(\lambda + 1)^d(1 - 2(\varepsilon + \delta))}.$$

**4.4 Hardness results for sample complexity**

So far we presented theorems that show what conditions provably lead to the failure of domain adaptation. These results showed that even in some extremely simple settings successful adaptation may require an abundant number of labeled source data or at least a reasonable amount of labeled target data. In spite of this, a natural question that one may ask is to what extent target domain’s unlabeled data can help to adapt when traded against some labeled source domains’ data. Before answering this question, we first turn our attention to sample complexity results presented by [Ben-David et al., 2012] that investigate the existence of a learning method capable of efficiently learning a good hypothesis for a target task provided that the target sample from its corresponding probability distribution is replaced by a (possibly larger) generated sample from a different probability distribution. The efficiency of such a learning method requires from it not to worsen the generalization guarantee of the learned classifier in the target domain. As an example of the considered classifer, we can take a popular nearest-neighbor classifier $h_{\text{NN}}(x)$ that given a metric $\mu$ defined over the input space $X$ assigns a label to a point $x$ as $h_{\text{NN}}(x) = y(N_S(x))$, with $N_S(x) = \arg\min_{z \in S} \mu(x, z)$ being the nearest neighbor of $x$ in the labeled source sample $S$, and $y(N_S(x))$ is the label of this nearest neighbor. The obtained theorems are proved under the covariate shift condition and assuming a bound on the weight-ratio between the two domains as explained before. We now present the first theorem proved for this case below.

**Theorem 25 ([Ben-David et al., 2012]).** Let domain $X = [0, 1]^d$ and for some $C > 0$, let $\mathcal{W}$ be a class of pairs of source and target distributions $\{(S, T)|C_B(S_X, T_X) \geq C\}$ with bounded weight-ratio and their common labeling function $f : X \to [0, 1]$ satisfying the $\phi$-probabilistic-Lipschitz property with respect to the target distribution, for some function $\phi$. Then, for all $\lambda$,

$$\mathbb{E}_{S \sim S_m} \left[ R_T(h_{\text{NN}}) \right] \leq 2R_T(\mathcal{H}) + \phi(\lambda) + 4\lambda \sqrt{\frac{d}{C}} m^{-\frac{1}{m-1}}.$$

This theorem suggests that under covariate shift and bounded weight-ratio assumptions, the expected target error of a NN classifier learned on a sample drawn from the source distribution is bounded by twice the optimal risk over the whole considered hypothesis space plus several constants related to the nature of the labeling function and the dimension of the input space. Regarding these latter, one may note that if the labeling function is $\lambda$-Lipschitz in the standard sense of Lipschitzness and the labels are deterministic, then we have $R_T(\mathcal{H}) = 0$ and $\phi(\alpha) = 0$ for all $\alpha \geq \lambda$. Applying Markov’s inequality then yields the following corollary on the sample size bound which further strengthens the previous result.

**Corollary 26.** Let domain $X = [0, 1]^d$ and for some $C > 0$, let $\mathcal{W}$ be a class of pairs of source and target distributions $\{(S, T)|C_B(S_X, T_X) \geq C\}$ with bounded weight-ratio and their common labeling function $f : X \to [0, 1]$ satisfying the $\phi$-probabilistic-Lipschitz property with respect to the target distribution, for some function $\phi$. Then, for all $\varepsilon > 0$, $\delta > 0$, $m \geq \left( \frac{4\lambda \sqrt{d}}{C\varepsilon} \right)^{d+1}$ the nearest neighbor algorithm applied to a sample of size $m$, has, with probability at least $1 - \delta$, error of at most $\varepsilon$ w.r.t. the target distribution for any pair $(S, T) \in \mathcal{W}$.

This corollary provides the first positive result establishing the number of samples required for efficient adaptation in case when no target data is available to the learner. A natural question that arises is then to quantify the utility of the additional unlabeled target data in the adaptation process and the conditions required for it to succeed. To answer this question, the authors of [Ben-David and Urner, 2012] considered a particular adaptation algorithm $\mathcal{A}$ summarized below.

The following theorem provides lower bounds for both the size of the source labeled and the target unlabeled samples required by algorithm $\mathcal{A}$ to learn well when a prior knowledge is assumed to be available to the learner in the form of a hypothesis class that realizes $T_X$ with margins as in the definition above.
Theorem 28 ([Ben-David and Urner, 2012]). Let $X = [0, 1]^d$, $\gamma > 0$ a margin parameter, $\mathcal{H}$ be a hypothesis class of finite VC dimension and $\mathcal{W}$ be the set of triples $(\mathcal{S}_X, \mathcal{T}_X, f)$ of source distribution, target distribution and labeling function with

1. $C_I(\mathcal{S}_X, \mathcal{T}_X) \geq \frac{1}{2}$ for the class $I = (\mathcal{H}\Delta\mathcal{H}) \cap \mathcal{B}$, where $\mathcal{B}$ is a partition of $[0, 1]^d$ into boxes of sidelength $\frac{2}{\sqrt{d}}$;
2. $\mathcal{H}$ contains a hypothesis that has $\gamma$-margin on $\mathcal{T}$;
3. the labeling function $f$ is a $\gamma$-margin classifier with respect to $\mathcal{T}$.

Then there is a constant $c > 1$ such that, for all $\varepsilon > 0$, $\delta > 0$, and for all $(\mathcal{S}_X, \mathcal{T}_X, f) \in \mathcal{W}$, when given an i.i.d. sample $S_u$ from $\mathcal{S}_X$, labeled by $f$ of size

$$|S_u| \geq c \left[ \frac{\text{VC}(\mathcal{H}) + \log \frac{1}{\delta}}{C_I(\mathcal{S}_X, \mathcal{T}_X)(1 - \varepsilon)\varepsilon} \log \left( \frac{\text{VC}(\mathcal{H})}{C_I(\mathcal{S}_X, \mathcal{T}_X)(1 - \varepsilon)\varepsilon} \right) \right],$$

and an i.i.d. sample $T_u$ from $\mathcal{T}_X$ of size

$$|T_u| \geq \frac{1}{\varepsilon} \left( \frac{2\sqrt{d}}{\gamma} \right)^d \ln \left( \frac{3\sqrt{d}}{\gamma} \right),$$

then $A$ outputs a classifier $h$ with $R_T(h, f) \leq \varepsilon$ with probability at least $1 - \delta$.

It is worth noticing that these bounds follow the standard bounds from the statistical learning theory where the size of the learning sample required for successful learning is given as a function of the VC dimension of the hypothesis class. In domain adaptation, this dependency is further extended to the weight-ratio and the accuracy parameters of the learnability model. Moreover, we observe that this theorem considers the input space that may contain an infinite number of points. This assumption can lead to a vacuous bound as in reality the input space often presents a finite domain and the dependency of the sample size should be given in its terms. The following theorem covers this case.

Theorem 29. Let $X$ be some finite domain, $\mathcal{H}$ be a hypothesis class of finite VC dimension and $\mathcal{W} = \{(\mathcal{S}_X, \mathcal{T}_X, f) | R_T(h, f) = 0, C(\mathcal{S}_X, \mathcal{T}_X) \geq 0 \}$ be a class of pairs of source and target distributions with bounded weight-ratio where $\mathcal{H}$ contains the zero-error hypothesis on $\mathcal{T}$. Then there is a constant $c > 1$ such that, for all $\varepsilon > 0$, $\delta > 0$, and all $(\mathcal{S}_X, \mathcal{T}_X, f) \in \mathcal{W}$, when given an i.i.d. sample $S_u$ from $\mathcal{S}_X$, labeled by $f$ of size

$$|S_u| \geq c \left[ \frac{\text{VC}(\mathcal{H}) + \log \frac{1}{\delta}}{C(\mathcal{S}_X, \mathcal{T}_X)(1 - \varepsilon)\varepsilon} \log \left( \frac{\text{VC}(\mathcal{H})}{C(\mathcal{S}_X, \mathcal{T}_X)(1 - \varepsilon)\varepsilon} \right) \right],$$

and an i.i.d. sample $T_u$ from $\mathcal{T}_X$ of size

$$|T_u| \geq \frac{1}{\varepsilon} \left( \frac{2|X| \ln 3|X|}{\delta} \right),$$

then algorithm $A$ outputs a classifier $h$ with $R_T(h, f) \leq \varepsilon$ with probability at least $1 - \delta$.

To conclude, we note that both hardness results that state under which conditions domain adaptation fails, as well as the results of the analysis of the samples’ sizes required from the source and target domains for the adaptation to succeed, fall into the category of the so-called impossibility theorems. They essentially draw the limits of the domain adaptation problem under various common assumptions and provide insights into the hardness of solving it.

Case of agnostic proper domain adaptation Before, we presented an impossibility result for proper domain adaptation showing that a conservative learner that is fed with a large labeled sample from the source domain may fail to produce a low-error classifier in the target domain even under high weight-ratio and covariate shift assumptions. Below, we recite a two-stage paradigm suggested in [Ben-David et al., 2012] that allows to enable successful learning in this
scenario. The proposed two-stage procedure consists of 1) using labeled source sample to learn an arbitrary hypothesis with decent performance on the target domain and 2) applying the learned hypothesis to the unlabeled examples from the target domain and feeding them to a standard agnostic learner. For the sake of clarity, the definition of an agnostic learning is given below.

**Definition 20** ([Ben-David et al., 2012]). For $\varepsilon > 0, \delta > 0, m \in \mathbb{N}$ we say that an algorithm $(\varepsilon, \delta, m)$ (agnostically) learns a hypothesis class $\mathcal{H}$, if for all distributions $\mathcal{D}$, when given an i.i.d. sample of size at least $m$, it outputs a classifier of error at most $R_D(\mathcal{H}) + \varepsilon$ with probability at least $1 - \delta$. If the output of the algorithm is always a member of $\mathcal{H}$, we call it a agnostic proper learner for $\mathcal{H}$.

This definition can now be used to prove the following theorem for the proposed two-stage procedure.

**Theorem 29** ([Ben-David et al., 2012]). Let $X$ be some domain and $\mathcal{W}$ be a class of pairs $(S, T)$ of distributions over $X \times \{0,1\}$ with $R_T(\mathcal{H}) = 0$ such that there is an algorithm $A$ and functions $m : (0,1)^2 \to \mathbb{N}, n : (0,1)^2 \to \mathbb{N}$ such that $A(0, \varepsilon, \delta, m(\varepsilon, \delta), n(\varepsilon, \delta))$-solves the domain adaptation learning task for $\mathcal{W}$ for all $\varepsilon, \delta > 0$. Let $\mathcal{H}$ be some hypotheses class for which there exists an agnostic proper learner. Then, the $\mathcal{H}$-proper domain adaptation problem can be $((0,\varepsilon,\delta,m(\varepsilon/3,\delta/2),n(\varepsilon/3,\delta/2)) + m'(\varepsilon/3,\delta/2))$-solved with respect to the class $\mathcal{W}$, where $m'$ is the sample complexity function for agnostically learning $\mathcal{H}$.

As in the previous case, one can consider the algorithm $A$ in the statement of this theorem to be the nearest neighbor classifier $NN(S)$, if the class $\mathcal{W}$ satisfies the conditions from the theorem. To summarize, the presented theorems for the proper domain adaptation learning show that with a domain adaptation algorithm, that takes into account the unlabeled instances from the target marginal distribution, one may hope to solve the proper domain adaptation problem while in the contrary case, it is provably unsolvable.

### 4.5 Other relevant contributions

- **Redko et al., 2019b** In this work, the authors provide a first analysis for consistent estimation of the adaptability term $\lambda$ when some target label data is available. The main construction used in their work is to express the ideal joint hypothesis $h^* = \arg\min_{h \in H} R_S(h, f_S) + R_T(h, f_T)$ as a barycenter of source and target labeling functions $f_S$ and $f_T$. These latter are then considered to be probability measures over $X$ so that the barycenter is defined over the space of probability distributions without requiring a hypothesis space to be picked in advance.

- **Zhao et al., 2019** In this paper, the authors provide an example similar to that given in [Ben-David et al., 2010b] to show that small $\mathcal{H}$-divergence between marginal distributions and low source error do not guarantee a good performance in the target domain. They further argue that this is mainly explained by the shift in the conditional distributions over the two domains that is accounted for by the inestimable adaptability term.

- **Johansson et al., 2019** This paper proceeds in the spirit similar to that of [Zhao et al., 2019] by first showing an example where finding an invariant representation decreasing the shift between the two domains while minimizing the source error leads to poor performance in the target domain. This is attributed to the unobserved adaptability term and lack of invertability of the learned representation and dealt with by taking into account the performance of a hypothesis in the source domain in regions where the source density is sufficiently high. The authors then provide a tight learning bound based on a weighted source error, a support discrepancy and an unobservable term characterizing the invertability of the invariant representation.

- **Hanneke and Kpotufe, 2019** In this paper, the authors consider a semi-supervised setting where the goal is to learn a hypothesis from a mixture of labeled source and target samples and to bound the excess risk of such hypothesis, i.e., $R_D(h) - R_D(\mathcal{H})$ in each domain. The paper further introduces a novel notion of discrepancy between the two domains called “transfer-exponents” and provides first minimax-rates in terms of both source and target sample size and of the latter divergence similar to the work of [Ben-David and Urner, 2012].

### 4.6 Summary

In this section, we covered a series of results that establish necessary conditions required to make a domain adaptation problem solvable. As it was shown, these necessary conditions may take different forms and depend on the value of certain terms presented in the generalization bound and on the size of the available source and target learning samples. The take-away messages of this section can be summarized as follows:

1. Solving a domain adaptation problem requires two independent conditions to be fulfilled. First, one has to properly minimize the divergence between the source and target marginal distributions. Second, one has to
As mentioned by [Müller, 1997], the quantity

All these conclusions provide us with a more general view on the learning properties of the adaptation phenomenon and thus a theoretical analysis of domain adaptation problem with it is of high scientific interest.

From a practical point of view, we observe that numerous domain adaptation and transfer learning approaches are based on MMD minimization [Pan et al., 2009, Geng et al., 2011, Huang et al., 2006, Pan et al., 2008, Chen et al., 2009] and associated kernel

Maximum mean discrepancy Let

From a practical point of view, we observe that numerous domain adaptation and transfer learning approaches are based on MMD minimization [Pan et al., 2009, Geng et al., 2011, Huang et al., 2006, Pan et al., 2008, Chen et al., 2009] and thus a theoretical analysis of domain adaptation problem with it is of high scientific interest.

All these conclusions provide us with a more general view on the learning properties of the adaptation phenomenon and essentially give a list of conditions that one has to verify in order to make sure that the adaptation problem at hand can be solved efficiently. Apart from that, the established results also provide us with an understanding that some adaptation tasks are harder when compared to others and that this hardness can be quantified by not one but several criteria that take into account both data distribution and the labeling of instances. Finally, they also show that successful adaptation requires a certain amount of data to be available during the adaptation step and that this amount may directly depend on the proximity of the marginal distributions of the two domains. This last feature is quite important as it is added to the dependence on the complexity of the hypothesis class considered previously in the standard supervised learning described in Section 2.

5 Learning bounds with integral probability metrics

In the previous sections, we presented several seminal results regarding the generalization bounds for domain adaptation and the impossibility theorems for some of them. We have shown that the basic shape of generalization bounds in the context of domain adaptation remains more or less the same and principally differs only in the divergence used to measure the distance between the source and the target marginal distributions. In this section, we consider a large family of metrics on the space of probability measures called Integral Probability Metrics (IPMs) that present a well-studied topic in the probability theory. We particularly show that depending on the chosen functional class some instances of IPMs can have interesting properties that are completely different from those exhibited by both the $\mathcal{H}$-$\Delta\mathcal{H}$-divergence and the discrepancy distance see previously.

5.1 Problem setup

IPMs present a large class of distances defined on the space of probability measures that found their application in many machine learning algorithms. Their general definition of IPMs can be given as follows.

**Definition 21 ([Zolotarev, 1984])**. Given two probability measures $\mathcal{S}_X$ and $\mathcal{T}_X$ defined on a measurable space $X$, the integral probability metric (IPM) is defined as

\[
D_F(\mathcal{S}_X, \mathcal{T}_X) = \sup_{f \in \mathcal{F}} \left| \int_X f d\mathcal{S}_X - \int_X f d\mathcal{T}_X \right|,
\]

where $\mathcal{F}$ is a class of real-valued bounded measurable functions on $X$.

As mentioned by [Müller, 1997], the quantity $D_F(\mathcal{S}_X, \mathcal{T}_X)$ is a semimetric, and it is a metric if and only if the functional class $\mathcal{F}$ separates the set of all signed measures with $\mu(X) = 0$. It then follows for any non-trivial function class $\mathcal{F}$ that the quantity $D_F(\mathcal{S}_X, \mathcal{T}_X)$ is equal to zero if $\mathcal{S}_X$ and $\mathcal{T}_X$ are the same. Several important special cases of IPMs can be obtained by specifically choosing the functional class $\mathcal{F}$. We present the ones that were used for the analysis of the domain adaptation problem below.

**Maximum mean discrepancy** Let $\mathcal{F} = \{ f : \| f \|_{\mathcal{H}_k} \leq 1 \}$ where $\mathcal{H}_k$ is a Reproducing Kernel Hilbert Space with its associated kernel $k$. Then, the maximum mean discrepancy (MMD) distance is defined as follows:

\[
d_{\text{MMD}}(\mathcal{S}_X, \mathcal{T}_X) = \sup_{\| f \|_{\mathcal{H}_k} \leq 1} \left| \int_X f d(\mathcal{S}_X - \mathcal{T}_X) \right| = \left\| \int_X k(x, \cdot) d(\mathcal{S}_X - \mathcal{T}_X) \right\|_{\mathcal{H}_k}.
\]

From a practical point of view, we observe that numerous domain adaptation and transfer learning approaches are based on MMD minimization [Pan et al., 2009, Geng et al., 2011, Huang et al., 2006, Pan et al., 2008, Chen et al., 2009] and thus a theoretical analysis of domain adaptation problem with it is of high scientific interest.
Wasserstein distance. Let $\mathcal{F} = \{ f : \|f\|_L \leq 1 \}$ where
\[
\|f\|_L = \sup_{x \neq x' \in \mathbf{X}} \frac{|f(x) - f(x')|}{c(x, x')}
\]
is the Lipschitz semi-norm for real-valued continuous $f$ on $\mathbf{X}$ and some metric $c(\cdot, \cdot) : \mathbf{X} \times \mathbf{X} \to \mathbb{R}_+$. In this case, the Kantorovich-Rubinstein theorem [Dudley, 2002] yields the following result defining the Wasserstein distance $W_1$ as follows:
\[
W_1(\mathcal{S}_X, \mathcal{T}_X) = \sup_{\|f\|_L \leq 1} \left| \int f d(\mathcal{S}_X - \mathcal{T}_X) \right| = \inf_{\gamma \in \Pi(\mathcal{S}_X, \mathcal{T}_X)} \int_{\mathbf{X} \times \mathbf{X}} c(x, x') d\gamma(x, x'),
\]
where $\Pi(\mathcal{S}_X, \mathcal{T}_X)$ is a space of all joint probability measures on $\mathbf{X} \times \mathbf{X}$ with marginals $\mathcal{S}_X$ and $\mathcal{T}_X$.

The original optimal transportation problem has been introduced in [Monge, 1781] to study the problem of resource allocation. Its modern formulation, that led to the introduction of the Wasserstein distance, is due to [Kantorovich, 1942] who proposed a relaxation of the Monge’s problem allowing to prove the existence of a unique minimizer for it. Despite being a very powerful tool for comparing and aligning probability distributions, the Wasserstein distance has become an emerging topic in machine learning only recently due to [Cuturi, 2013] where an efficient regularization scheme allowing to solve the optimal transportation problem has been introduced.

### 5.2 Generalization bound with IPMs

We start this section with a general result that introduces IPMs to the domain adaptation generalization bounds provided in [Zhang et al., 2012]. In this paper, the authors consider a general multi-source scenario where not one but $K \geq 2$ source domains are available. In order to be consistent with the rest of the survey, we present the main result of [Zhang et al., 2012] that introduces the IPMs in the context of domain adaptation specified for the case of one source and one target domain.

**Theorem 30.** For a labeling function $f \in \mathcal{G}$, let $\mathcal{F} = \{ (x, y) \to \ell(f(x), y) \}$ be a loss function class consisting of the bound functions with the range $[a, b]$ for a space of labeling functions $\mathcal{G}$. Let $S = \{(x_1, y_1), \ldots, (x_m, y_m)\}$ be a labeled sample drawn from $\mathcal{S}$ of size $m$. Then given any arbitrary $\xi \geq D_\mathcal{F}(S, T)$, we have for any $m \geq \frac{8(b-a)^2}{\xi^2}$ and any $\epsilon > 0$, with probability at least $1 - \epsilon$ the following holds
\[
\sup_{f \in \mathcal{F}} |R_{\hat{\mathcal{S}}}^\ell f - R_T^\ell f| \leq D_\mathcal{F}(S, T) + \left( \frac{\ln N_1(\xi', \mathcal{F}, 2m) - \ln(\epsilon/8)}{m} \right)^{1/2},
\]
where $\xi' = \xi - D_\mathcal{F}(S, T)$.

Here the quantity $N_1(\xi', \mathcal{F}, 2m)$ is defined in terms of the uniform entropy number (see Definition 8) and is given by the following equation
\[
N_1(\xi, \mathcal{F}, 2m) = \sup_{\{S^{2m}\}} \log N(\xi, \mathcal{F}, \ell_1(S^{2m})),
\]
where for the source sample $S$ and its associated ghost sample $S' = \{(x'_1, y'_1), \ldots, (x'_m, y'_m)\}$ drawn from $\mathcal{S}$ the quantity $S^{2m} = \{S, S'\}$ and the metric $\ell_1$ is a variation of the $\ell_1$ metric defined for some $f \in \mathcal{F}$ based on the following norm
\[
\|f\|_{\ell_1(S^{2m})} = \frac{1}{m} \sum_{i=1}^{m} \left( |f(x_i, y_i)| + |f(x'_i, y'_i)| \right).
\]

One may note several peculiarities related to this result. First, it is different from other generalization bounds provided before as the divergence term here is defined for the joint distributions $S$ and $T$ and not for the marginal distributions $S_X$ and $T_X$. Note that, in general, one cannot estimate the joint target distribution $T$ in the classical scenario of unsupervised domain adaptation as this can be done only when target labels are known thus making the application of this bound quite uninformative in practice. Second, the proposed bound is very general as it does not specify explicitly the functional class $\mathcal{F}$ considered in the definition of the IPM. On the one hand, this allows to adjust this bound to any instance of IPMs that can be obtained by choosing the appropriate functional class but, on the other hand, it also requires to determine the uniform entropy number for it. Finally, the authors establish a link between the discrepancy distance seen before and the $D_\mathcal{F}(S, T)$ that allows us to obtain a bound having a more “traditional” shape. More
precisely, the authors proved that the following inequality holds in the case of one source and one target domain for any ℓ and functional class \( F \):

\[
D_F(S, T) \leq \text{disc}_\ell(S_X, T_X) + \sup_{g \in \mathcal{G}} \left| \mathbb{E}_{x \sim T_X} [\ell(g(x), f_T(x))] - \mathbb{E}_{x \sim T_X} [\ell(g(x), f_S(x))] \right|.
\]

Note that the second term of the right-hand side is basically a disagreement between the labeling functions \( f_S \) and \( f_T \) that is equal to zero only when they are equal. Using this inequality, one may show that the proposed theorem can be reduced to have the following shape:

\[
\sup_{f \in \mathcal{F}} |R^\ell_S f - R^\ell_T f| \leq \text{disc}_\ell(S_X, T_X) + \lambda + \left( \frac{\ln N_1(\xi', 1/2)}{2^3/2 - 1/2} \right)^{1/2},
\]

where \( \lambda = \sup_{g \in \mathcal{G}} \left| \mathbb{E}_{x \sim T_X} [\ell(g(x), f_T(x))] - \mathbb{E}_{x \sim T_X} [\ell(g(x), f_S(x))] \right| \) and the last term is the complexity term that depends on the covering number of the space \( \mathcal{F} \) similar to the bounds based on the algorithmic robustness presented in Section 2. To this end, Equation (7) now looks pretty much like the generalization bounds from the previous sections.

In order to show that for a finite complexity term the difference between the empirical source risk and the target risk never exceeds the divergence between the two domains with the increasing number of available source examples, the authors proved the following theorem.

**Theorem 31.** For a labeling function \( f \in \mathcal{G} \), let \( \mathcal{F} = \{ (x, y) \rightarrow \ell(f(x), y) \} \) be a loss function class consisting of the bounded functions with the range \([a, b]\) for a space of labeling functions \( \mathcal{G} \). If the following holds

\[
\lim_{m \to \infty} \mathbb{P} \left\{ \sup_{f \in \mathcal{F}} \left| R^\ell_S f - R^\ell_T f \right| > \xi \right\} = 0.
\]

One may note that here the probability of event \( \left\{ \sup_{f \in \mathcal{F}} |R^\ell_S f - R^\ell_T f| > \xi \right\} \) is taken with respect to the threshold \( \xi \geq D_F(S, T) \) while in standard learning theory this guarantee is usually stated for any \( \xi > 0 \) given that \( \lim_{m \to \infty} \frac{\ln N_1(\xi, 2m)}{m} < \infty \). This highlights an important difference between the classic generalization bounds for supervised learning and the result given in Theorem 30.

As we mentioned above, the general setting for generalization bounds with IPMs proposed by Zhang et al. suffers from two major drawbacks: (1) the function class in the definition of the IPM is not specified making it intractable to compute; (2) the proposed bounds are established for joint distributions rather than marginal distributions making them not very informative in practice. To this end, we present below two different lines of research that tackle these drawbacks and establish the generalization bounds for domain adaptation by explicitly considering a particular function class with a divergence term taking into account the discrepancy between the marginal distributions of the source and target domains. These lines lead to two important particular cases of IPMs that were used to derive generalization bounds in domain adaptation that are the Wasserstein distance and the Maximum Mean Discrepancy distance (MMD). We take a closer look at both of them in what follows.

### 5.3 Learning bounds with the Wasserstein distance

Despite many important theoretical insights presented before, the above mentioned divergence measures such as the \( \mathcal{H}\Delta\mathcal{H} \)-divergence and the discrepancy do not directly take into account the geometry of the data distribution when estimating the discrepancy between two domains. Recently, [Courty et al., 2013] have proposed to tackle this drawback by solving the domain adaptation using the Wasserstein distance. In order to justify domain adaptation algorithms based on the minimization of the Wasserstein distance, the generalization bounds for the three domain adaptation settings involving this latter were presented in [Redko et al., 2017]. According to [Villani, 2009], the Wasserstein distance is rather strong and can be combined with smoothness bounds to obtain convergences in other distances. As mentioned by the authors, this important advantage of the Wasserstein distance leads to tighter bounds in comparison to other state-of-the-art results and is more computationally attractive as explained below.

To proceed, let \( \mathcal{F} = \{ f \in \mathcal{H}_k : \|f\|_{\mathcal{H}_k} \leq 1 \} \), where \( \mathcal{H}_k \) is a RKHS with its associated kernel \( k \). Let \( \ell_{h,f} : x \rightarrow \ell(h(x), f(x)) \) be a convex loss-function defined \( \forall h, f \in \mathcal{F} \) and assume that \( \ell \) obeys the triangle inequality. As before,
$h(x)$ corresponds to the hypothesis and $f(x)$ to the true labeling functions, respectively. Considering that $(h, f) \in \mathcal{F}^2$, the loss function $\ell$ is a non-linear mapping of the RKHS $\mathcal{H}_k$ for the family of $\ell_q$ losses defined previously. Using results from [Saitoh, 1997], one may show that $\ell_{h,f}$ also belongs to the RKHS $\mathcal{H}_k$, admitting the reproducing kernel $k_q$ and that its norm obeys the following inequality:

$$
\|\ell_{h,f}\|_{\mathcal{H}_k}^2 \leq \|h - f\|_{\mathcal{H}_k}^{2q}.
$$

This result gives us two important properties of $\ell_{f,h}$ that are used further:

1. the function $\ell_{h,f}$ belongs to the RKHS that allows us to use the reproducing property via some feature map $\phi(x)$ associated to kernel $k_q$;
2. the norm $\|\ell_{h,f}\|_{\mathcal{H}_k}$ is bounded.

Thus, the error function defined above can be also expressed in terms of the inner product in the corresponding Hilbert space, i.e.,

$$
R^D_\ell(h, f_D) = \mathbb{E}_{x \sim D_x} [\ell(h(x), f_D(x))] = \mathbb{E}_{x \sim D_x} [(\phi(x), \ell)_{\mathcal{H}_k}].
$$

Now the following lemma that relates the Wasserstein metric with the source and target error functions for an arbitrary pair of hypotheses can be proved.

**Lemma 32** ([Redko et al., 2017]). Let $\mathcal{S}_X, \mathcal{T}_X \in \mathcal{P}(X)$ be two probability measures on $\mathbb{R}^d$. Assume that the cost function $c(x, x') = \|\phi(x) - \phi(x')\|_{\mathcal{H}_k}$, where $\mathcal{H}$ is a Reproducing Kernel Hilbert Space (RKHS) equipped with kernel $k : X \times X \to \mathbb{R}$ induced by $\phi : X \to \mathcal{H}_k$ and $k(x, x') = \langle \phi(x), \phi(x') \rangle_{\mathcal{H}_k}$. Assume further that the loss function $\ell_{h,f} : x \to \ell(h(x), f(x))$ is convex, symmetric, bounded, obeys the triangular equality and has the parametric form $|h(x) - f(x)|^q$ for some $q > 0$. Assume also that the kernel $k_\ell$ in the RKHS $\mathcal{H}_{k_\ell}$ is square-root integrable w.r.t. both $\mathcal{S}_X, \mathcal{T}_X$ for all $\mathcal{S}_X$, $\mathcal{T}_X \in \mathcal{P}(X)$ where $X$ is separable and $0 \leq k_\ell(x, x') \leq R, \forall x, x' \in X$. If $\|\ell\|_{\mathcal{H}_{k_\ell}} \leq 1$, then the following holds

$$
\forall (h, h') \in \mathcal{H}_{k_\ell}^2, \quad R^D_\ell(h, h') \leq R^D_{\mathcal{H}_k}(h, h') + W_1(\mathcal{S}_X, \mathcal{T}_X).
$$

This lemma makes use of the Wasserstein distance to control the source and target errors. The assumption made here is to specify that the cost function $c(x, x') = \|\phi(x) - \phi(x')\|_{\mathcal{H}_k}$. While it may seem too restrictive, this assumption is, in fact, not that strong. Using the properties of the inner-product, one has

$$
\|\phi(x) - \phi(x')\|_{\mathcal{H}_k} = \sqrt{\langle \phi(x) - \phi(x'), \phi(x) - \phi(x') \rangle_{\mathcal{H}_k}} = \sqrt{k(x, x') - 2k(x, x') + k(x, x')}.
$$

As the authors noted, one may further show that for any given positive-definite kernel $k$ there is a distance $c$ (used as a cost function in our case) that generates it and vice versa (see Lemma 12 from [Sejdinovic et al., 2013]).

The following generalization bound was proved by the authors using a result showing the convergence of the empirical measure $\hat{\mu}$ to its true associated measure w.r.t. the Wasserstein metric provided in [Bolley et al., 2007].

**Theorem 33.** Under the assumptions of Lemma 32, let $S_n$ and $T_n$ be two samples of size $N_S$ and $N_T$ drawn i.i.d. from $S_X$ and $T_X$ respectively. Let $\hat{S}_\ell = \frac{1}{N_S} \sum_{i=1}^{N_S} \delta_{x^*_i}$ and $\hat{T}_\ell = \frac{1}{N_T} \sum_{i=1}^{N_T} \delta_{x^*_i}$ be the associated empirical measures. Then for any $d' > d$ and $\varsigma' < \sqrt{2}$ there exists some constant $N_0$ depending on $d'$ such that for any $d > 0$ and $\min(N_S, N_T) \geq N_0 \max(\delta^{-d' + 2}, 1)$ with probability at least $1 - \delta$ for all $h$ we have

$$
R^e_{\ell}(h) \leq R^e_{\mathcal{H}_k}(h) + W_1(\hat{S}_\ell, \hat{T}_\ell) + \sqrt{\frac{2\log \left( \frac{1}{\delta} \right)}{\varsigma'}} \left( \sqrt{\frac{1}{N_S}} + \sqrt{\frac{1}{N_T}} \right) + \lambda,
$$

where $\lambda$ is the combined error of the ideal hypothesis $h^*$ that minimizes the combined error of $R^e_{\mathcal{H}_k}(h) + R^e_{\ell}(h)$.

A first immediate consequence of this theorem is that it justifies the use of the optimal transportation in the domain adaptation context when combined with the minimization of the source error and assuming the joint error given by the $\lambda$ term is small. For the latter, [Courty et al., 2014] proposed a class-labeled regularization term added to the optimal transport formulation in order to restrict source examples of different classes to be transported to the same target example by promoting group sparsity in the matrix $\gamma$ thanks to $\| \cdot \|_{\ell_q}$ with $q = 1$ and $\rho = \frac{q}{2}$. In some way, this regularization term influences the capability term by ensuring the existence of a good hypothesis that will be able to be discriminant on both source and target domains data.

---

2 If $(h, f) \in \mathcal{F}^2$ then $h - f \in \mathcal{F}$ implying that $\ell(h(x), f(x)) = |h(x) - f(x)|^q$ is a nonlinear transform for $h - f \in \mathcal{F}$.

3 For simplicity, we further write $\ell$ meaning $\ell_{f,h}$.
Semi-supervised case  To remain consistent with the previous sections, we also provide the generalization bound for the Wasserstein distance in the semi-supervised setting below.

**Theorem 34 ([Redko et al., 2017])**. Let $S_u$, $T_u$ are unlabeled samples of size $N_S$ and $N_T$ each, drawn independently from $S_X$ and $T_X$ respectively. Let $S$ be a labeled sample of size $m$ generated by drawing $\beta m$ points from $T_X (\beta \in [0, 1])$ and $(1 - \beta) m$ points from $S_X$ and labeling them according to $f_S$ and $f_T$, respectively. If $\hat{h} \in H$ is the empirical minimizer of $R^\alpha_S(h)$ on $S$ and $h_T^* = \arg\min_{h \in H} R^\alpha_T(h)$ then for any $\delta \in (0, 1)$, with probability at least $1 - \delta$ (over the choice of samples),

$$R^\alpha_T(\hat{h}) \leq R^\alpha_S(h_T^*) + c_1 + 2(1 - \alpha)(\hat{\delta}_X, \hat{T}_X) + \lambda + c_2,$$

where

$$c_1 = 2 \sqrt{\frac{2K}{m} \left(\frac{(1 - \alpha)^2}{1 - \beta} + \frac{\alpha^2}{\beta} \right) \log(2/\delta)} + \sqrt{K/m} \left(\frac{\alpha}{m\beta\sqrt{\beta}} + \frac{(1 - \alpha)}{m(1 - \beta)\sqrt{1 - \beta}}\right),$$

$$c_2 = 2 \sqrt{2 \log \frac{1}{\delta}/\sqrt{m}} \left(\sqrt{\frac{1}{N_S}} + \sqrt{\frac{1}{N_T}}\right).$$

In line with the results obtained previously, this theorem shows that the best hypothesis that takes into account both source and target labeled data (i.e., $0 \leq \alpha < 1$) performs at least as good as the best hypothesis learned on target data instances alone ($\alpha = 1$). This result agrees well with the intuition that semi-supervised domain adaptation approaches should be at least as good as unsupervised ones.

**5.4 Generalization bound with MMD**

Based on the results with the Wasserstein distance, we now introduce learning bounds for the target error where the divergence between tasks’ distributions is measured by the MMD distance. As before, we start with a lemma that relates the source and target errors in terms of the introduced discrepancy measure for an arbitrary pair of hypotheses. Then, we show how the target error can be bounded by the empirical estimate of the MMD plus the complexity term.

**Lemma 35 ([Redko, 2015])**. Let $F = \{f \in H_k : \|f\|_{H_k} \leq 1\}$ where $H_k$ is a Reproducing Kernel Hilbert Space with its associated kernel $k$. Let $\ell : H \times F \rightarrow \ell(h(x), f(x))$ be a convex loss-function having a parametric form $|h(x) - f(x)|^q$ for some $q > 0$ and defined $\forall h, f \in F$ such that $\ell$ obeys the triangle inequality. Then, if $\|f\|_{H_{L^q}} \leq 1$, then we have:

$$\forall (h, h') \in F^2, \quad R^q_{\ell}(h, h') \leq R^q_S(h, h') + d_{\text{MMD}}(\hat{S}_X, \hat{T}_X).$$

This lemma is proved in a similar way to Lemma 32 from [Redko et al., 2017] presented before in this section. Using it and the result that relates the true and the empirical MMD distances [Song, 2008], we can prove the following theorem.

**Theorem 36.** With the assumptions from Lemma 35, let $S_u$ and $T_u$ are two samples of size $m$ drawn i.i.d. from $S_X$ and $T_X$, respectively. Then, with probability at least $1 - \delta (\delta \in (0, 1))$ for all $h \in F$ the following holds:

$$R^q_{\ell}(h) \leq R^q_S(h) + d_{\text{MMD}}(\hat{S}_X, \hat{T}_X) + \frac{2}{m} \left(\mathbf{E}_{x \sim \hat{S}_X} \left[\sqrt{\operatorname{tr}(K_S)}\right] + \mathbf{E}_{x \sim \hat{T}_X} \left[\sqrt{\operatorname{tr}(K_T)}\right]\right) + 2 \sqrt{\frac{\log(\frac{2}{\delta})}{2m}} + \lambda,$$

where $d_{\text{MMD}}(\hat{S}_X, \hat{T}_X)$ is an empirical counterpart of $d_{\text{MMD}}(S_X, T_X)$, $K_S$ and $K_T$ are the kernel functions calculated on samples from $S_X$ and $T_X$ respectively and $\lambda$ is the combined error of the ideal hypothesis $h^*$ that minimizes the combined error of $R^q_S(h) + R^q_T(h)$.

We can see that this theorem is similar in shape to Theorem 33 and Theorem 10. The main difference, however, is that the complexity term does not depend on the Vapnik-Chervonenkis dimension. In our case, the loss function between two errors is bounded by the empirical MMD between distributions and two terms that correspond to the empirical Rademacher complexities of $H$ w.r.t. the source and target samples. In both theorems, $\lambda$ plays the role of the combined error of the ideal hypothesis. Its presence in the bound comes from the use of the triangle inequality for the classification error.

This result is particularly useful as an unbiased estimate of the squared MMD distance $d_{\text{MMD}}^2(\hat{S}_X, \hat{T}_X)$ can be calculated in linear time. We also note that the obtained bound can be further simplified if one uses, for instance, Gaussian,
exponential or Laplacian kernels to calculate the kernel functions \(K_S\) and \(K_T\) as they have 1s on the diagonal thus facilitating the calculation of the trace. Finally, it can be seen that the bound from Theorem 36 has the same terms as Theorem 10 while the MMD distance is estimated as in Corollary 14.

**Semi-supervised case** Similar to the case considered in [Ben-David et al., 2010a], one can also derive similar bounds for the MMD distance in case of the combined error. To this end, we present the following analogue of Theorem 11.

**Theorem 37.** With the assumptions from Lemma 35, let \(S_u, T_u\) are unlabeled samples of size \(m'\) each, drawn independently from \(S_X\) and \(T_X\), respectively. Let \(S\) be a labeled sample of size \(m\) generated by drawing \(\beta\) \(m\) points from \(T_X\) \((\beta \in [0, 1])\) and \((1 - \beta)\) \(m\) points from \(S_X\) and labeling them according to \(f_S\) and \(f_T\), respectively. If \(\hat{h} \in \mathcal{H}\) is the empirical minimizer of \(R^\alpha(h)\) on \(S\) and \(h_T^\delta = \arg\min_{h \in \mathcal{H}} R_T^\delta(h)\) then for any \(\delta \in (0, 1)\), with probability at least \(1 - \delta\) (over the choice of samples),

\[
R_T^\delta(\hat{h}) \leq R_T^\delta(h_T^\delta) + c_1 + c_2,
\]

\[
c_1 = 2 \sqrt{\frac{2K(1 - \alpha)^2}{1 - \beta}} + \frac{\alpha^2}{\beta} \log \frac{2}{\delta} + 2 \left( \sqrt{\frac{\alpha}{\beta}} + \sqrt{\frac{1 - \alpha}{1 - \beta}} \right) \sqrt{\frac{K}{m}},
\]

\[
c_2 = \hat{d}_{\text{MMD}}(S_u, T_u) + \frac{2}{m'} \mathbb{E}_{X \sim S_X} \sqrt{\text{tr}(K_S)} + \frac{2}{m'} \mathbb{E}_{X \sim T_X} \sqrt{\text{tr}(K_T)} + 2 \sqrt{\frac{\log \frac{2}{\delta}}{2m'}} + \lambda.
\]

Several observations can be made from this theorem. First of all, the main quantities that define the potential success of domain adaptation according to [Ben-David et al., 2010a] (i.e., the distance between the distributions and the combined error of the joint ideal hypothesis) are preserved in the bound. This is an important point that indicates that the two results are not contradictory or supplementary. Second, rewriting the approximation of the bound as a function of \(\delta\) may point out the existence of a strong connection between them.

The generalization guarantees obtained for domain adaptation based on the MMD distance allow to make another step forward in domain adaptation theory and that by extending the results presented in the previous sections in two different ways. Similar to discrepancy based results, the bounds with the MMD distance allow to consider any arbitrary loss function and thus other than binary classification applications of domain adaptation can be studied. On the other hand, the MMD distance, similar to the entropic-regularized Wasserstein distance, has some very nice estimation guarantees that are unavailable for both the \(\mathcal{H}\Delta \mathcal{H}\) and disc divergences. This feature can be very important in accessing both the a priori hardness of adaptation and its a posteriori success in order to understand if a given adaptation algorithm manages to properly reduce the discrepancy between the domains.

### 5.5 Relationship between the MMD and the Wasserstein distances

At this point, we presented two results that introduced the MMD and the Wasserstein distances to the domain adaptation generalization bounds for both semi-supervised and unsupervised cases. As both results are built on the same construction, one may want to explore the link between the MMD distance and the Wasserstein distance. In order to do this, we first observe that in some particular cases the former can be bounded by the latter. Indeed, if we assume that the ground metric in the Wasserstein distance is equal to \(c(x, x') = \|\phi(x) - \phi(x')\|_\mathcal{H}\) the following results can be obtained:

\[
\left\| \int_X f d(S_X - T_X) \right\|_{\mathcal{H}} = \left\| \int_{X \times X} (f(x) - f(x')) d\gamma(x, x') \right\|_{\mathcal{H}} \leq \int_{X \times X} \|f(x) - f(x')\|_{\mathcal{H}} d\gamma(x, x') = \int_{X \times X} \|\langle f(x), \phi(x) \rangle - \langle f(x'), \phi(x') \rangle\|_{\mathcal{H}} d\gamma(x, x') \leq \|f\|_{\mathcal{H}} \int_{X \times X} \|\phi(x) - \phi(x')\|_{\mathcal{H}} d\gamma(x, x').
\]

Now taking the supremum over \(f\) w.r.t. \(F = \{f : \|f\|_{\mathcal{H}} \leq 1\}\) and the infimum over \(\gamma \in \Pi(S_X, T_X)\) gives

\[
d_{\text{MMD}}(S_X, T_X) \leq W_1(S_X, T_X).
\]

(8)
This result holds under the hypothesis that \( c(x, x') = \| \phi(x) - \phi(x') \|_{\mathcal{H}} \). On the other hand, in [Gao and Galvao, 2014], the authors showed that \( W_1(S_X, T_X) \) with this particular ground metric can be further bounded as follows

\[
W_1(S_X, T_X) \leq \sqrt{d^2_{\text{MMD}}(S_X, T_X) + C},
\]

where \( C = \| \mu(S_X) \|_{\mathcal{H}} + \| \mu(T_X) \|_{\mathcal{H}} \). This result is quite strong for multiple reasons. First, it allows to introduce the squared MMD distance to the domain adaptation bounds using [Redko et al., 2017, Lemma 1] leading to the following result for two arbitrary hypotheses \( (h, h') \in \mathcal{H}^2 \)

\[
R_T(h, h') \leq R_S(h, h') + \sqrt{d^2_{\text{MMD}}(S_X, T_X) + C}.
\]

On the other hand, the unified inequality

\[
d_{\text{MMD}}(S_X, T_X) \leq W_1(S_X, T_X) \leq \sqrt{d^2_{\text{MMD}}(S_X, T_X) + \| \mu(S_X) \|_{\mathcal{H}} + \| \mu(T_X) \|_{\mathcal{H}}} \quad (9)
\]

suggests that the MMD distance establishes an interval bound for the Wasserstein distance. This point is very interesting because originally the calculation of the Wasserstein distance (also known as the Earth Mover’s distance) requires to solve a linear programming problem which can be quite time consuming due to the computational complexity of \( O(n^3 \log(n)) \) where \( n \) is the number of instances.

This result, however, is true only under the assumption that \( c(x, x') = \| \phi(x) - \phi(x') \|_{\mathcal{H}} \). While in most applications, the Euclidean distance \( c(x, x') = \| x - x' \| \) is used as a ground metric, this assumption can represent an important constraint. Luckily, it can be circumvented due to the duality between the RKHS-based and distance-based metric representations studied in [Sejdinovic et al., 2013]). Let us first rewrite the ground metric as

\[
\| \phi(x) - \phi(x') \|_{\mathcal{H}} = \sqrt{\langle \phi(x) - \phi(x'), \phi(x) - \phi(x') \rangle_{\mathcal{H}}} = \sqrt{k(x, x) - 2k(x, x') + k(x', x')}.
\]

Now, in order to obtain the standard Euclidean distance in the expression of the ground metric, we can pick a kernel given by the covariance function of the fractional Brownian motion, i.e., \( k(x, x') = \frac{1}{2}(\| x \|^2 + \| x' \|^2 - 2\| x - x' \|^2) \). Plugging this expression into the definition of \( c(x, x') \) gives the desired Euclidean distance and thus allows to calculate the Wasserstein distance with the standard ground metric.

### 5.6 Other relevant contributions

[Zhang et al., 2019] In this work, the authors generalized the seminal bounds to the multi-class setting and introduced a classification margin \( \beta > 0 \) into their results. This is done by introducing a definition of the error function \( R_D^\beta \) that takes into account the classification margin as follows:

\[
R_D^\beta = \mathbb{E}_{x \sim D} \left[ l^\beta(h(x), f_D(x)) \right],
\]

where

\[
l^\beta(t) := \begin{cases} 
1 - \frac{t}{\beta}, & \text{if } 0 \leq t \leq \beta \\
[t < 0], & \text{otherwise}
\end{cases}
\]

Their main contribution for the case of binary classification with labels encoded in \( \{-1, 1\} \) can then be stated as follows:

\[
R_T(h) \leq R_S^\beta(h) + \sup_{h' \in \mathcal{H}} \left| R_S^\beta(\text{sgn}(h), h') - R_T^\beta(\text{sgn}(h), h') \right| + \lambda^\beta, \quad (10)
\]

where

\[
\lambda^\beta = \inf_{h \in \mathcal{H}} R_S^\beta(h) + R_T^\beta(h).
\]

The alignment term in (10) was termed the Margin Disparity Discrepancy (MDD). As one may note, it involves a supremum over one hypothesis instead of two, making it lower than \( \Delta \mathcal{H} \)-divergence defined previously that corresponds to the case of \( \beta = 0 \) with the definition of the error given above. It also offers new insights on domain adaptation problem by introducing the margin violation rate and scoring functions that give the confidence level of belonging to a class of interest rather than functions with binary output. However, as they bound the 0-1 loss on the target domain, i.e., \( c_T^0(h, f) \), their bound does not indicate the behaviour of the margin violation rate on this latter. As for \( \lambda^\beta \), it remains conceptually similar to the \( \lambda \) term of the other bounds with the only difference consisting in the definition of the error terms.
Several works presented generalization bounds for domain adaptation based on the Wasserstein distance similar to those presented in this section. To this end, [Shen et al., 2018] gave a learning bound having the exact same form as the bound in Theorem 33 but without imposing any additional assumptions on the ground metric used in the definition of the Wasserstein distance. On the other hand, [Courty et al., 2017] proposed a learning bound for an adaptation scenario between joint source and target probability distributions $S$ and $T$ similar to that of [Zhang et al., 2012]. Their bound introduced $W(S, T)$ with an additional term related to the probabilistic transfer Lipschitzness assumption introduced in the latter paper for the labeling function with respect to the optimal coupling.

Finally, we also note that the work of [Johansson et al., 2019] mentioned in the previous section also introduces learning bounds for domain adaptation based on the notion of IPM.

### 5.7 Summary

In this section, we presented several theoretical results that use IPMs as a measure of divergence between the marginal source and target domains’ distributions in the domain adaptation generalization bounds. We argued that this particular choice of a distance provides a number of advantages compared to the $\mathcal{H}\triangle\mathcal{H}$-distance and the discrepancy distances considered before. First, both the Wasserstein distance and the MMD distance can be calculated from available finite-samples in a computationally attractive way due to the existence of linear time estimators for their entropy-regularized and quadratic versions, respectively. Second, the Wasserstein distance allows to take geometrical information into account when calculating the divergence between the two domains’ distributions while the MMD distance is calculated based on the distance between the embeddings of two distributions in some (possibly) richer space. This feature is quite interesting as it provides more flexibility when it comes to incorporating the prior knowledge to the domain adaptation problem on one hand and allows to have a potentially richer characterization of the divergence between the domains on the other. This may explain the abundance of domain adaptation algorithms based on the MMD distance and some recent domain adaptation techniques developed based on the optimal transportation theory. Finally, we note that, in general, the presented bounds are similar in shape to those described in Section 3 and preserve their main terms thus remaining consistent with them. This shows that despite a large variety of ways that may be used to formally characterize the generalization phenomenon in domain adaptation, the intuition behind this process and the main factors defining its potential success remain the same.

### 6 PAC-Bayesian theory for domain adaptation

In this section, we recall the the results from [Germain et al., 2016, Germain et al., 2013, Germain et al., 2020] where the PAC-Bayesian theory was used to theoretically understand domain adaptation through the weighted majority vote learning point of view.

#### 6.1 Problem setup

In the traditional PAC-Bayesian setting, we consider a $\pi$ distribution over the hypothesis set $\mathcal{H}$, and the objective is to learn a $\rho$ distribution over $\mathcal{H}$ by taking into account the information captured by the learning sample $S$. In the domain adaptation setting, the goal is different and consists in learning the $\rho$-weighted majority vote

$$\forall x \in X, \quad B^\rho(x) = \text{sign} \left[ \mathbb{E}_{h \sim \rho} h(x) \right],$$

with the best performance on the target domain $T$. Note that, here, we consider the 0 − 1 loss function. As in the non-adaptation setting, PAC-Bayesian domain adaptation generalization bounds do not directly upper-bound $R_{T}^{\ell_{01}}(B^\rho)$, but upper-bound the expectation according to $\rho$ of the individual risks of the functions from $\mathcal{H}$: $\mathbb{E}_{h \sim \rho} R_{T}^{\ell_{01}}(h)$, which is closely related to $B^\rho$ (see Equation (2)). Let us introduce a tight relation between $R_{D}(B^\rho)$ and $\mathbb{E}_{h \sim \rho} R_{D}^{\ell_{01}}(h)$ known as the C-Bound [Lacasse et al., 2006] and defined for all distribution $D$ on $X \times Y$ as

$$R_{D}^{\ell_{01}}(B^\rho) \leq 1 - \frac{\left( 1 - 2 \mathbb{E}_{h \sim \rho} R_{D}^{\ell_{01}}(h) \right)^{2}}{1 - 2d_{X}(\rho)}, \quad (11)$$

where

$$d_{X}(\rho) = \mathbb{E}_{(h,h') \sim \rho^2} \mathbb{E}_{x \sim D_X} \ell_{01}(h(x), h'(x))$$

36
Theorem 39. For any domains $S$ and $T$ over $X \times Y$, any set of voters $\mathcal{H}$, any prior distribution $\pi$ over $\mathcal{H}$, any $\delta \in (0, 1]$, any real numbers $\omega > 0$ and $a > 0$, with a probability at least $1 - \delta$ over the random choice of $S \times T_u \sim (S \times T)^m$, for every posterior distribution $\rho$ on $\mathcal{H}$, we have

$$\mathbb{E}_{h \sim \rho} R_T^{\ell_0} (h) \leq \omega' \mathbb{E}_{h \sim \rho} R_S^{\ell_0} (h) + a' \frac{1}{2} \text{dis}_\rho (S, T_u) + \left( \frac{\omega'}{\omega} + \frac{a'}{a} \right) \frac{\text{KL}(\rho \| \pi)}{m} + \ln \frac{3}{\delta} + \lambda_\rho + \frac{1}{2} (a' - 1),$$

where $\text{dis}_\rho (S, T_u)$ is the empirical estimate of the domain disagreement; $\lambda_\rho$ is defined by Equation (13); $\omega' = \frac{\omega}{1 - e^{-\omega}}$ and $a' = \frac{2a}{1 - e^{-2a}}$.
Similarly to the bounds of Theorems 6 and 15, this bound can be seen as a trade-off between different quantities. The terms \( E_{h \sim \rho} R^\delta_{\mathcal{T}}(h) \) and \( \text{dis}_\rho(S, T) \) are akin to the first two terms of the bound of Theorem 6: \( E_{h \sim \rho} R^\delta_{\mathcal{S}}(h) \) is the \( \rho \)-average risk over \( \mathcal{H} \) on the source sample, and \( \text{dis}_\rho(S, T_u) \) measures the \( \rho \)-average disagreement between the marginals but is specific to the current model depending on \( \rho \). The last term \( \lambda_\rho \) measures the deviation between the expected joint target and source errors of the individual hypothesis from \( \mathcal{H} \) (according to \( \rho \)). A successful domain adaptation is possible if this deviation is low but when no labels in the target sample are available, this term cannot be controlled or estimated.

Despite the same underlying philosophy, the authors note that this bound is in general incomparable with the ones of Theorems 6 and 15 due to the dependence of \( \text{dis}_\rho(S, T) \) and \( \lambda_\rho \) on the learned posterior.

### 6.3 A different philosophy

In [Germain et al., 2016] the authors introduce another domains’ divergence to provide an original bound for the PAC-Bayesian setting. They take advantage of Equation (12) that expresses the risk of the Gibbs classifier in terms of two quantities:

\[
E_{h \sim \rho} R^\delta_{\mathcal{T}}(h) = \frac{1}{2} d_{\mathcal{X}}(\rho) + \epsilon_\mathcal{T}(\rho)
\]

(14)

One may note that the latter expression consists of a half of the expected disagreement, that does not require labeled data to be estimated, and the inestimable expected joint error. To deal with the latter, the authors design a divergence to link \( \epsilon_\mathcal{T}(\rho) \) to \( \epsilon_\mathcal{S}(\rho) \), called the \( \beta \)-divergence and defined by

\[
\forall q > 0, \quad \beta_q = \left[ E_{(x,y) \sim \mathcal{S}} \left( \frac{T(x,y)}{S(x,y)} \right)^q \right]^{\frac{1}{q}}
\]

(15)

The \( \beta \)-divergence is parametrized by the value of \( q > 0 \), and allows to recover well-known distributions’ divergence such as the \( \chi^2 \)-distance or the Rényi divergence mentioned in the end of Section 3. When \( q \to \infty \), we have

\[
\beta_\infty = \sup_{(x,y) \in \text{supp}(\mathcal{S})} \left( \frac{T(x,y)}{S(x,y)} \right)
\]

(16)

with \( \text{supp}(\mathcal{S}) \) denoting the support of the domain \( \mathcal{S} \). This \( \beta \)-divergence leads to the following bound.

**Theorem 40** ([Germain et al., 2016]). Let \( \mathcal{H} \) be a hypothesis space, \( \mathcal{S} \) and \( \mathcal{T} \) be the source and the target domains on \( \mathcal{X} \times \mathcal{Y} \) and \( q > 0 \) be some positive constant. Then, for all posterior distributions \( \rho \) on \( \mathcal{H} \), we have

\[
E_{h \sim \rho} R^\delta_{\mathcal{T}}(h) \leq \frac{1}{2} d_{\mathcal{X}}(\rho) + \beta_q \times [\epsilon_\mathcal{S}(\rho)]^{\frac{1}{q}} + \eta_{\mathcal{T} \setminus \mathcal{S}},
\]

where

\[
\eta_{\mathcal{T} \setminus \mathcal{S}} = \max_{(x,y) \sim \mathcal{T}} \left( \mathbb{P}_{(x,y) \sim \mathcal{T}} \left( (x,y) \notin \text{supp}(\mathcal{S}) \right) \sup_{h \in \mathcal{H}} R^\delta_{\mathcal{T} \setminus \mathcal{S}}(h) \right)
\]

with \( \mathcal{T} \setminus \mathcal{S} \) the distribution of \( (x,y) \sim \mathcal{T} \) conditional to \( (x,y) \in \text{supp}(\mathcal{T}) \setminus \text{supp}(\mathcal{S}) \).

The last term of the bound \( \eta_{\mathcal{T} \setminus \mathcal{S}} \), that cannot be estimated without target labels, captures the worst possible risk for the target area not included in \( \text{supp}(\mathcal{S}) \) similar to the idea used in [Johansson et al., 2019]. Note that we have

\[
\eta_{\mathcal{T} \setminus \mathcal{S}} \leq \max_{(x,y) \sim \mathcal{T}} \left( \mathbb{P}_{(x,y) \sim \mathcal{T}} \left( (x,y) \notin \text{supp}(\mathcal{S}) \right) \right).
\]

An interesting property of Theorem 40 is that when domain adaptation is not required (i.e., \( \mathcal{S} = \mathcal{T} \)), the bound is still sound and non-degenerate. Indeed, in this case we have

\[
R_{\mathcal{S}}(G_\rho) = R_{\mathcal{T}}(G_\rho) \leq \frac{1}{2} d_{\mathcal{X}}(\rho) + \max_{h \in \mathcal{H}} [\epsilon_{\mathcal{S}}(\rho)]^{\frac{1}{q}} + 0 = \frac{1}{2} d_{\mathcal{X}}(\rho) + \epsilon_{\mathcal{S}}(\rho) = R_{\mathcal{S}}(G_\rho).
\]

Below, we present the PAC-Bayesian generalization bound obtained from the above theorem for the case \( q \to \infty \).

**Theorem 41.** For any domains \( \mathcal{S} \) and \( \mathcal{T} \) over \( \mathcal{X} \times \mathcal{Y} \), any set of voters \( \mathcal{H} \), any prior distribution \( \pi \) over \( \mathcal{H} \), any \( \delta \in (0, 1) \), any real numbers \( b > 0 \) and \( c > 0 \), with a probability at least \( 1 - \delta \) over the random choices of \( \mathcal{S} \sim (\mathcal{S})^{m_{\mathcal{S}}} \) and \( T_u \sim (\mathcal{T}_u)^{m_{\mathcal{T}}} \), for every posterior distribution \( \rho \) on \( \mathcal{H} \), we have

\[
E_{h \sim \rho} R^\delta_{\mathcal{T}}(h) \leq c' \left( \frac{1}{2} d_{\mathcal{T}}(\rho) + b' \epsilon_{\mathcal{S}}(\rho) + \eta_{\mathcal{T} \setminus \mathcal{S}} + \left( \frac{c'}{m_{\mathcal{T}} \times c} + \frac{b'}{m_{\mathcal{S}} \times b} \right) (2 \text{KL}(\rho|\pi) + \ln \frac{2}{\delta}) \right),
\]

where \( d_{\mathcal{T}}(\rho) \) and \( \epsilon_{\mathcal{S}}(\rho) \) are the empirical estimations of the target voters’ disagreement and the source joint error, and

\[
b' = \frac{b}{1 - e^{-c}}, \quad \text{and} \quad c' = \frac{c}{1 - e^{-c}}.
\]
Similarly to the first bound, the above theorem upper-bounds the target risk by a trade-off of different terms given by the following atypical quantities:

1. The expected disagreement \( d_T(\rho) \) that captures a second degree information about the target domain;
2. The divergence between the domains, captured by the \( \beta_q \)-divergence is not anymore an additive term: it weights the influence of the expected joint source error \( e_S(\rho) \) where the parameter \( q \) allows to consider different instances of the \( \beta_q \)-divergence;
3. The term \( \eta_{T\setminus S} \) quantifies the worst feasible target error on the regions where the source domain is not informative for the target task.

### 6.4 Comparison of the two domain adaptation bounds

The main difference between the bounds of Theorems 38 and 40 lies in the estimable terms that the latter rely on. In Theorem 40, the non-estimable terms are the \( \beta_q \)-divergence \( \beta_q \) and the term \( \eta_{T\setminus S} \). Contrary to the non-controllable term \( \lambda_\rho \) of Theorem 38, these terms do not depend on the learned posterior distribution \( \rho \); for every \( \rho \) on \( \mathcal{H} \), \( \beta_q \) and \( \eta_{T\setminus S} \) are constant values measuring the relation between the domains for the considered task. Moreover, the fact that the \( \beta_q \)-divergence is not an additive term but a multiplicative one (as opposed to \( \text{dis}_q(S_X, T_X) + \lambda_\rho \) in Theorem 38) is an important contribution of this new perspective. This is similar to the work of [Mansour et al., 2009b] and [Dhouib and Redko, 2018] that also introduce such a multiplicative dependence. Consequently, \( \beta_q \) can be viewed as a hyperparameter allowing us to tune the trade-off between the target voters’ disagreement \( d_{T_X}(\rho) \) and the source joint error \( e_S(\rho) \).

Note that, when \( e_T(\rho) \geq e_S(\rho) \), we can upper-bound the term \( \lambda_\rho \) of Theorem 38 by using the same trick as in the proof of Theorem 40. This leads to

\[
e_T(\rho) \geq e_S(\rho) \implies \lambda_\rho = e_T(\rho) - e_S(\rho) \leq \beta_q \times [e_S(\rho)]^{1-\frac{q}{2}} + \eta_{T\setminus S} - e_S(\rho).
\]

Thus, in this particular case, we can rewrite Theorem 38 statement for all \( \rho \) on \( \mathcal{H} \), as

\[
\mathbb{E}_{\rho \sim \mathcal{H}} R_T^{\text{opt}}(h) \leq \mathbb{E}_{\rho \sim \rho} R_S^{\text{opt}}(h) + \frac{1}{2} \text{dis}_q(S_X, T_X) + \beta_q \times [e_S(\rho)]^{1-\frac{q}{2}} - e_S(\rho) + \eta_{T\setminus S}.
\]

It turns out that, if \( d_{T_X}(\rho) \geq d_{S_X}(\rho) \) in addition to \( e_T(\rho) \geq e_S(\rho) \), the above statement reduces to the one of Theorem 40. In all other cases, Theorem 40 is tighter thus confirming that following the seminal works of Section 3 by introducing absolute values in Theorem 38 proof leads to a very rough approximation. Finally, one of the key points of the generalization bounds of Theorems 39 and 41 is that they suggest algorithms for tackling majority vote learning in the domain adaptation context. Similarly to what was done in traditional supervised learning [Langford and Shawe-Taylor, 2002, Ambroldaze et al., 2006], [Germain et al., 2013, Germain et al., 2016, Germain et al., 2020] specialized these theorems to linear classifiers and derived adaptation algorithms based on this specialization.

### 6.5 Other relevant contributions

[McNamara and Balcan, 2017] In this work, the authors made use of the PAC-Bayesian framework to derive a generalization bound for fine tuning in deep learning in a spirit close to that of analysing a domain adaptation problem. Their considered setting corresponded to a scenario where one wants to adapt a network trained for a given domain to a similar one. The authors obtained a bound that does not directly involve the notion of divergence between the domains, but a function that measures a transferability property between the two domains.

### 6.6 Summary

In this section, we recalled the two domain adaptation analyses for the PAC-Bayesian framework presented in [Germain et al., 2013, Germain et al., 2016, Germain et al., 2020] for models taking the form of a majority vote over a set of classifiers. More precisely, the first result of this section follows the underlying philosophy of the seminal works of Ben-David et al. and Mansour et al. of Section 3 by upper-bounding the target risk by a source risk and a domains’ divergence measure suitable for the PAC-Bayesian setting. This divergence is expressed as the average deviation between the disagreement over a set of classifiers on the source and target domains contrary to \( \mathcal{H}|\Delta|\mathcal{H} \)-divergence and discrepancy distance that are defined in terms of the worst-case deviation. Then, we recalled another domain adaptation bound that takes advantage of the inherent behavior of the target risk in the PAC-Bayesian setting. The upper obtained bound is different from the original one as it expresses a trade-off between the disagreement on the target domain only,
the joint errors of the classifiers on the source domain only, and a term reflecting the worst case error in regions where the source domain is non-informative. Contrary to the first bound and those of the previous sections, the divergence is not an additive term but is a factor weighting the importance of the source information. These analyses were combined with PAC-Bayesian generalization bounds of Section 2 and involved an additional term that measures the deviation of the learned majority vote to the a priori knowledge we have on the majority vote.

7 Domain adaptation theory based on algorithmic properties

In this section we first review the work of [Mansour and Schain, 2014], where they derive a generalization bound based on the algorithm in regards to the the algorithmic robustness of [Xu and Mannor, 2010] recalled in Section 2. Then, we present the works of [Kuzborski and Orabona, 2013] and [Perrot and Habrard, 2015] based on a closely related notion of algorithmic stability. Note that these last two contributions are proved for a setting different from the domain adaptation problem considered so far as in this case one does not have access to the source examples, but rather to a hypothesis learned from them.

7.1 Robust domain adaptation

Definition of λ-shift [Mansour and Schain, 2014] used the notion of algorithmic robustness [Xu and Mannor, 2010] to define the λ-shift that encodes a prior knowledge on the deviation between the source and target domains. The goal of their definition was to capture the proximity of the loss associated to a hypothesis on the source and target domains in the regions defined by partitioning the joint space X × Y. Since one does not usually have access to target labels, the authors proposed to consider the conditional distribution of the label in a given region and the relation to its sampled value over the given labeled sample S. To proceed, let ρ be a distribution over the label space Y and denote by σ^y and σ^{-y} = 1 − σ^y the probability of a given label y ∈ Y and the total probability of the other labels, respectively. The definition of the λ-shift is then given as follows.

**Definition 23 ([Mansour and Schain, 2014]).** Let σ and ρ be two distribution over Y. ρ is λ-shift with respect to σ, denoted ρ ∈ λ(σ), if for all y ∈ Y we have ρ^y ≤ σ^y + λσ^{-y}, and ρ^y ≥ σ^y(1 − λ). If for some y ∈ Y we have ρ^y = σ^y + λσ^{-y} we say that ρ is strict-λ-shift with respect to σ.

Note that, for the sake of simplicity, for ρ ∈ λ(σ) the upper bound and the lower bound of the probability ρ^y are respectively denoted by:

\[ \lambda^y(\sigma) = \sigma^y + \lambda(1 - \sigma^y), \quad \text{and} \quad \lambda^{-y}(\sigma) = \sigma^y(1 - \lambda). \]

The above definition means that assuming the λ-shift between two distributions on Y implies a restriction on the deviation between the probability of a label on the distributions: this shift may be at most a λ portion of the probability of the other labels or of the probability of the label. Remark that λ = 1, respectively λ = 0, corresponds to the no restriction and the total restriction cases, respectively.

Learning bounds based on algorithmic robustness To analyze the domain adaptation setting, the authors assume that X × Y can be partitioned into M disjoint subsets defined as: X × Y = \bigcup_{i=1}^{M} X_i × Y_j, where the input space is partitioned as X = \bigcup_{i=1}^{M} X_i and the output space as Y = \bigcup_{j=1}^{M} Y_j, and M = M_X M_Y. Note that, a (M, ϵ)-robust algorithm outputs a hypothesis that has an ϵ variation in the loss in each region X_i × Y_j. We now present the following theorem.

**Theorem 42 ([Mansour and Schain, 2014]).** Let A be a (M, ϵ)-robust algorithm with respect to a loss function ℓ : X × Y such that 0 ≤ ℓ(h(x, y)) ≤ M_i, for all (x, y) ∈ (X × Y) and h ∈ H. If S is λ-shift of T with respect to the partition of X for any δ ∈ (0, 1], the following bound holds with probability at least 1 − δ, over the random draw of the sample S from S, and of the sample T from T of size m,

\[ \forall h ∈ H, \ R_T^A(h) ≤ \sum_{i=1}^{M_x} T(X_i) \ell^\Delta_S(h, X_i) + \epsilon + M_T \sqrt{2M \ln 2 + 2 \ln \frac{1}{\delta}} \frac{2M \ln 2 + 2 \ln \frac{1}{\delta}}{m}, \]

where \( T(X_i) = \frac{1}{m} \sum_{x \in T \cap X_i} \) is the ratio of target points in the region X_i, and

\[ \forall i \in \{1, \ldots, M_X\}, \quad \ell^\Delta_S(h, X_i) ≤ \max_{y \in Y} \left\{ \ell_i(h, y) \lambda^y(S_i) + \sum_{y' \neq y} \ell_i(h, y') \lambda^{-y'}(S_i) \right\}, \]
An hypothesis $h$ labeled target sample. The goal of HTL is then to learn a target model using a hypothesis $h$ in the same space as $w$. Consider a source hypothesis of the form $h_{src} = \{x \times y \mid x \in S, y \in S\}$. It is well-known that RLS has nice theoretical properties and its solution can be expressed in closed form. Now, we define a biased RLS algorithm for HTL.

A biased RLS algorithm for HTL. We first begin by a quick recap of the classic RLS algorithm. For a learning sample $T = \{(x_i, y_i)\}_{i=1}^m \sim (T)^m$ such that $y_i \in [-B, B]$ with $B \in \mathbb{R}$ and $x_i \in \mathbb{R}^d$ with $\|x\| \leq 1$, RLS algorithm aims at solving the following optimization problem:

$$\min_{w \in \mathbb{R}^d} \left\{ \frac{1}{m} \sum_{i=1}^m (w^T x_i - y_i)^2 + \lambda \|w\|^2 \right\}.$$  

It is well-known that RLS has nice theoretical properties and its solution can be expressed in closed form. Now, we consider a source hypothesis of the form $h_{src}(x) = x^T w_0$, where $w_0$ corresponds to the parameters of $h_{src}$ living in the same space as $w$. In [Orabona et al., 2009], the authors suggest to use a biased regularization with respect to $w_0$ as

$$\min_{w \in \mathbb{R}^d} \left\{ \frac{1}{m} \sum_{i=1}^m (w^T x_i - y_i)^2 + \lambda \|w - w_0\|^2 \right\}.$$
In this formulation, we can see that the source hypothesis represented by \( w_0 \) acts as a bias that tends to make the learned model closer to \( w_0 \) if the learning sample is compatible with it. Following the result of [Kuzborskij and Orabona, 2013], we present a more general version where the target hypothesis to be learned is defined by

\[
h_T(x) = w_C \sum_{i=1}^{m} (w_i x_i - y_i + h_{src}(x_i))^2 + \lambda ||w||^2,
\]

and the truncation function \( t_{RC}(a) \) is defined as

\[
t_{RC}(a) = \min \left[ \max (a, -C), C \right].
\]

This formulation is a generalization of the usual biased RLS algorithm that allows to consider any type of source model \( h_{src} \). In particular, we can retrieve the usual formulation when \( C = \infty \) and \( h_{src}(x) = x^T w_0 \), where \( w_0 \) and \( w_T \) belong to the same space.

From the theoretical standpoint, the authors’ goal was then to bound the expected risk associated to this algorithm in terms of the characteristics of the source model \( h_{src} \). The proposed result is based upon the leave-one-out (LOO) risk over a sample \( T \) defined as

\[
R_{LOO}^A(A, T) = \frac{1}{m} \sum_{i=1}^{m} \ell(A_{T\setminus i}, (x_i, y_i)),
\]

where \( A_{T\setminus i} \) represents the model learned by algorithm \( A \) from the sample \( T \) without the example \((x_i, y_i)\). The first result related to HTL can be now presented in the following theorem.

**Theorem 43** ([Kuzborskij and Orabona, 2013]). Set \( \lambda \geq \frac{1}{m} \). If \( C \geq B + ||h_{src}||_\infty \), then for any hypothesis learned by the algorithm presented in Equation (17), with probability at least \( 1 - \delta \) over any sample \( T \) of size \( m \) i.i.d. from \( T \) we have

\[
R_T(h_T) - R_{LOO}^T(h_T, T) = O \left( \sqrt{R_T(h_{src})t_{RC}(\sqrt{R_T(h_{src})} + R_T^2(h_{src})) \over \sqrt{m} m \delta \lambda^{3/4}} \right).
\]

If \( C = \infty \), then we have

\[
R_T(h_T) - R_{LOO}^T(h_T, T) = O \left( \sqrt{R_T(h_{src})(||h_{src}||_\infty + B) \over \sqrt{m} m \delta \lambda} \right).
\]

According to [Kuzborskij, 2018], we can draw the following implications.

1. For the null source hypothesis, i.e., \( h_{src} = 0 \), we fall in a classic supervised learning setting while for \( C = \infty \), the generalization bound is bounded by \( O \left( \frac{B}{\sqrt{m}} \right) \) similar to the results obtained for classic RLS algorithms [Bousquet and Elisseeff, 2002];

2. If \( h_{src} \neq 0 \) and \( \frac{1}{T} R_T(h_{src}) \) tends to zero, then the target true risk converges to the leave-one-out risk. This means that when the source hypothesis is good enough on the target domain, then transfer learning helps to learn a better hypothesis on the target domain even with small training samples.

3. If \( \frac{1}{T} R(h_{src}) \) is high, then one needs more target labeled data to provide a reliable hypothesis on the target. The domains are then considered to be unrelated so that the source hypothesis does not bring any useful information.

**Multi-source scenario** Here, we consider the setting of [Kuzborskij and Orabona, 2017] where the source hypothesis is expressed as a weighted combination of different source hypotheses

\[
h_{\alpha, \beta}(x) = \sum_{i=1}^{n} \beta_i h_{src}^i(x),
\]

and where the target hypothesis is defined as

\[
h_{w, \beta}(x) = \langle w, x \rangle + h_{src}^\beta(x).
\]
The relevance of the different source hypotheses is then characterized by their associated weight given by the vector \( \beta \).

Let \( \ell : Y \times Y \to \mathbb{R}_+ \) be an \( H \)-smooth loss function such that \( \forall y_1, y_2 \in Y, |\nabla_y \ell(y_1, y) - \nabla_y \ell(y_2, y)| \leq H|y_1 - y_2| \) and let \( \Omega : \mathcal{H} \to \mathbb{R}_+ \) be a \( \sigma \)-strongly convex function with respect to a norm \( \| \cdot \| \) and to a hypothesis space \( \mathcal{H} \). Given a target training set \( T = \{(x_i, y_i)\}_{i=1}^n \), \( n \) source hypotheses \( \{h_{\text{src}}^i\}_{i=1}^n \) and a parameter vector \( \beta \) verifying \( \Omega(\beta) \leq \rho \), the transfer algorithm generates a target hypothesis \( h_{\hat{w}, \beta} \) such that

\[
\hat{w} = \arg\min_{w \in \mathcal{H}} \left\{ \frac{1}{m} \sum_{i=1}^m \ell(w, x_i) + h_{\text{src}}^i(x_i, y_i) + \lambda \Omega(w) \right\}.
\]

In this formulation, the loss function is only minimized with respect to \( w \) and not specifically with respect to \( \beta \). However, it is assumed that \( \Omega(\beta) \leq \rho \) making \( \beta \) constrained by a strongly convex function which allows one to cover regularized algorithms that consider an additional regularization with respect to \( \beta \). As in the previous analysis, the key quantity \( R_T(h_{\text{src}}^i) \) measuring the relevance of the source hypothesis on the target domain will play a crucial role in the analysis of the generalization properties of \( h_{\hat{w}, \beta} \). To illustrate the types of algorithms covered by this analysis, we can consider the least-squares based regularization that given source hypotheses \( \{w_{\text{src}}^i\} \subset \mathcal{H} \), the parameters \( \beta \in \mathbb{R}^n \) and \( \lambda \in \mathbb{R}_+ \), outputs the target hypothesis

\[
h(x) = \langle \hat{w}, x \rangle,
\]

where

\[
\hat{w} = \arg\min_{w \in \mathcal{H}} \left\{ \frac{1}{m} \sum_{i=1}^m \left( \langle w, x_i \rangle - y_i \right)^2 + \lambda \| w - \sum_{j=1}^n \beta_j w_{\text{src}}^j \|^2 \right\}.
\]

The problem defined by Equation (18) presents a special case of the classic regularized ERM and can be interpreted as the minimization of the empirical error on the target sample while keeping the solution close to the (best) linear combination of source hypotheses. Note that while such a formulation is limited to a linear combination of the source hypotheses living in the same space as the target predictor, it can be generalized allowing one to treat the source hypotheses as “black boxes” predictors. The results presented below correspond to generalization bounds for such RLS multi-source algorithm.

**Theorem 44 ([Kuzborskij and Orabona, 2017]).** Let \( h_{\hat{w}, \beta} \) an hypothesis output by a regularized ERM algorithm from a \( m \)-sized training set \( T \) i.i.d. from the target domain \( T \), \( n \) source hypotheses \( \{h_{\text{src}}^i\} : \|h_{\text{src}}^i\|_\infty \leq 1 \}_{i=1}^n \), any source weights \( \beta \) obeying \( \Omega(\beta) \leq \rho \) and \( \lambda \in \mathbb{R}_+ \). Assume that the loss is bounded by \( M : \ell(h_{\hat{w}, \beta}(x), y) \leq M \) for any \( (x, y) \) and any training set. Then, denoting \( \kappa = \frac{H}{\sigma} \) and assuming that \( \lambda \leq \kappa \), we have with probability at least \( 1 - e^{-\eta} \), for all \( \eta \geq 0 \)

\[
R_T(h_{\hat{w}, \beta}) \leq R_T(h_{\hat{w}, \beta}) + O \left( \frac{R_T^{\text{src}} \kappa}{\sqrt{m \lambda}} + \frac{R_T^{\text{src}} \rho \kappa^2}{m \lambda} + \frac{M \eta}{m \log \left( 1 + \frac{M \eta}{\sqrt{m \rho}} \right)} \right)
\]

\[
\leq R_T(h_{\hat{w}, \beta}) + O \left( \frac{\kappa}{\sqrt{m}} \left( \frac{R_T^{\text{src}}}{\lambda} + \frac{R_T^{\text{src}} \rho}{\lambda} \right) \right)
\]

where \( u^{\text{src}} = \frac{R_T^{\text{src}}}{m} (m + \frac{\sqrt{m} \rho}{\lambda}) + \kappa \sqrt{\frac{R_T^{\text{src}} \rho}{\lambda}} \) and \( R_T^{\text{src}} = R_T(h_{\text{src}}^i) \) is the risk of the source hypothesis combination.

The following conclusions can be drawn from this result.

1. If \( R_T^{\text{src}} \) is high, then \( h_{\text{src}}^i \) is useless for transfer and would only hurt the performance in the target domain;
2. If \( m = O(1/R_T^{\text{src}}) \), then a small value \( R_T^{\text{src}} \) allows one to have a faster convergence rate of \( O(\sqrt{\rho} / m \sqrt{\lambda}) \) when making use of the information coming from the source hypotheses combination.

**Comparison with standard theory of domain adaptation** Recall that the seminal results presented in Section 3 have the following general form

\[
R_T(h) \leq R_{\Delta}(h) + d(S_X, T_X) + \lambda,
\]

where \( d \) is some divergence between the source and target marginal distributions and \( \lambda \) refers to the adaptation capability of the hypothesis class \( \mathcal{H} \) from where \( h \) is taken.
In general, domain adaptation bounds cannot be directly compared to the result of Theorem 44, even though the term $R_{src}$ can be interpreted as $\mathcal{H}_\mathcal{N}R$-divergence by defining $\mathcal{H} = \{x \to \langle \beta, h_{src}(x) \rangle \mid \Omega(\beta) \leq \tau \}$ where $h_{src}(x) = [h_{src}^1(x), \ldots, h_{src}^n(x)]^T$, and fixing $h = h_{src} \in \mathcal{H}$, so that one can write

$$R_{src} = R_T(h_{src}^\beta) \leq R_S(h_{src}^\beta) + d_{\mathcal{H}S}(\mathcal{S}_X, \mathcal{T}_X) + \lambda_\mathcal{H}.$$  

If we plug this inequality into the result presented above, then for any hypothesis $h$ and $\lambda \leq 1$, and $\rho \leq 1/\lambda$ we have

$$R_T(h) \leq R_S(h) + O\left(\frac{R_S(h_{src}^\beta) + d_{\mathcal{H}S}(\mathcal{S}_X, \mathcal{T}_X) + \lambda_\mathcal{H}}{\sqrt{m\lambda}} + \frac{1}{m\lambda}\right). \quad (19)$$

The two results agree on the fact that the divergence between the domains has to be small to generalize well. The divergence is actually controlled by the choice of $h_{src}$ while the complexity of the hypothesis class $\mathcal{H}$ controlled by $\tau$.

In traditional domain adaptation, a hypothesis $h$ performs well on the target domain only if it performs well on the source domain under the condition that $\mathcal{H}$ is expressive enough for ensuring adaptation or, in other words, that the $\lambda_\mathcal{H}$ term should be small. In HTL, however, this condition can be relaxed as highlighted by Equation (19) implying that a good source model has to perform well on its own domain. Additionally, while in traditional domain adaptation the $\lambda$-term is assumed to be small – otherwise there is no hypothesis able to perform well on both domains at the same time and the adaptation cannot be effective – in HTL, transfer can still be beneficial even for large $\lambda$ due to the availability of the labeled target samples.

### 7.3 Other relevant contributions

[Li and Bilmes, 2007] The authors of this work investigated HTL from the Bayesian perspective by proposing a PAC-Bayesian study of the latter and deriving bounds capturing the relationship between domains by an additive $KL$-divergence term which is classic in the PAC-Bayesian setting. In the particular case of logistic regression, they showed that the divergence term is upper-bounded by $\|h - h_{src}\|^2$, motivating the biased regularization term in logistic regression and the interest of incorporating the source hypothesis to the adaptation model. We invite the interested reader to have a look to the related publications.

[Morvant et al., 2012] As in Dhouib and Redko, 2018, the authors of this paper considered learning with a particular family of similarity functions introduced in Balcan et al., 2008 and provided a generalization bound for it using the algorithmic robustness framework.

[Habrard et al., 2013] This work studied iterative self-labeling for domain adaptation where at each iteration one learns a hypothesis $h$ from the current sample $\mathcal{S}$, pseudo-labels some target samples from $\mathcal{T}$, by $h$ and incorporates them into the source sample $\mathcal{S}$ to progressively modify the current classifier. Their analysis suggests that such a procedure theoretically solves a domain adaptation problem when the hypothesis obtained at each iteration improves upon the hypothesis obtained without self-labeling.

[Perrot and Habrard, 2015] The theoretical results of this paper make use of an extension of the notion of algorithmic stability (see Subsection 2.6) to similarity learning and provide generalization bounds for its extension to the HTL framework presented above. In particular, instead of learning a set of weights $w$ parametrizing the hypothesis function $h$, the authors learn a similarity matrix $\mathbf{M}$ that is regularized with respect to a similarity matrix $\mathbf{M}_S$ learned in a related source domain.

[Habrard et al., 2016] In this work, the authors analyzed a setting that consists in learning $N$ weak hypotheses using the labeled source sample and reweights them differently by taking into account the data from the unlabeled target domain. Their theoretical analysis proves that the proportion of target examples having a margin $\gamma$ decreases exponentially fast with the number of iterations but does not benefit from any generalization guarantees given by an upper bound on the risk with respect to the target distribution.

[Du et al., 2017] In this work, the authors consider an extension of the original HTL setting by considering a general form of transfer defined by a transformation functions that can be provided as input to the HTL algorithm. These latter include, for instance, the offset transfer and scale transfer thus generalizing the work of Kuzborskij and Orabona, 2013. Also, we note that the work of Hanneke and Kpotufe, 2019 mentioned in Section 4 also analysed the HTL-based adaptation approach and showed its efficiency in improving the target performance.

---

4A weak hypothesis for $\mathcal{D}$ is a hypothesis such that $R_{\mathcal{D}}(h) = 1/2 - \varepsilon$, where $\varepsilon > 0$ is a small constant.
7.4 Summary

In this section, we presented theoretical results that allow to take into consideration algorithmic properties of adaptation algorithms. First, we recalled how the algorithmic robustness can be extended to the domain adaptation setting where one assumes a relaxation of the covariate-shift assumption. Second, we focused on a different domain adaptation setting called hypothesis transfer learning, where one does not have access to source samples, but to source model(s) given by the learned hypotheses. In this setting, we presented theoretical results obtained in the case of regularized ERM-based algorithms relying on the algorithmic stability framework.

In general, we may highlight several important differences of this framework with respect to the results seen in the previous sections. They are the following:

1. Contrary to the divergence-based bounds, the learning guarantees presented in this section do not include a term measuring the discrepancy between the marginal distributions of the two domains. This is rather expected as in HTL scenario we do not have access to a learning sample from the source domain but only to a hypothesis learned on it;

2. The potential success of adaptation in the HTL framework depends on the performance of the source hypothesis on the target distribution and allows to learn a better hypothesis even on small samples when some assumptions are fulfilled;

3. Contrary to the majority of the results seen so far, the adaptability term is absent from the bounds related to the HTL setting as in this case the learner has access to some target labeled data.

8 Conclusions and discussions

In this survey, we presented an overview of existing theoretical guarantees that were proved for the domain adaptation problem, a learning setting that extends traditional learning paradigms to the case where the model is learned and deployed on samples coming from different yet related probability distributions. The cited theoretical results often took a shape of learning bounds where the goal is to relate the error of a model on the training (also called source) domain to that of the test (also called target) domain. To this end, we note that the presented results are highly intuitive as they explicitly introduce the dependence of the relationship between the two errors mentioned above to the similarity of their data generating probability distributions and that of their corresponding labeling functions. Consequently, this two-way relatedness between the source and target domains characterizes both unsupervised proximity of two domains by comparing their marginal distributions and the possible labelings of their samples by looking for a good model having a low-error with respect to them. This general trade-off is preserved, in one way or another, in the majority of published results on the subject and thus can be considered as a cornerstone of the modern domain adaptation theory.

As any survey that gives an overview of a certain scientific field, this one would have been incomplete without identifying those problems that remain open. In the context of domain adaptation theory, they can be arguedly split into two main categories where the first one is related to domain adaptation problem itself while the second is related to other learning scenarios similar to domain adaptation. For the first category, one important open problem is that of characterizing the a priori adaptability of the adaptation given by the joint error term. Indeed, this term is often assumed to be small for domain adaptation to be possible but only one prior work [Redko et al., 2019b] suggested an actual way for its consistent estimation from a handful of labeled target data. On the other hand, domain adaptation has been recently extended to open-set and heterogeneous settings where for the former both source and target domains are allowed to have non-overlapping classes while for the latter the input space of the two domains may differ. To the best of our knowledge, there are still no theoretical results that analyze them. This latter point brings us to the second category of open problems related to learning scenarios similar to that of domain adaptation such few-shot learning problems where one has to learn on a sample that contains no or only few example of certain classes appearing in the test data. Intuitively, this problem is tightly related to the domain adaptation and may naturally inherit some of its theoretical guarantees but no studies making this link explicit were proposed in the literature so far.

Finally, this survey has not discussed such closely related topics as multitask learning, learning-to-learn and lifelong learning to name a few. This particular choice was made in order to remain focused on one particular problem as the latter is vast enough on its own. We also admit that there are certainly other relevant papers providing guarantees for domain adaptation that were not included in this survey\(^5\). This field, however, is so large and recent advances are published at such a great pace that we are simply not able to keep up with it and to report all possible results without breaking the general structure and the narrative of our survey.

\(^5\)If your paper does not appear in this survey but seems relevant to its contents, please notify us and we will try to include it in the revised versions.
