Abstract

Two-dimensional QCD with adjoint fermions has many attractive features, yet its single-particle content remains largely unknown. To lay the foundation for a crucially improved approximation of the theory’s spectrum, we developed a method to find the basis of eigenstates using the symmetry structure of the asymptotic theory where pair production is disallowed. This method produces complete sets of multi-dimensional harmonic functions for the massless and the massive theory. Previously only part of such a basis was known. The method presented here should be applicable to other theories and has the promise of factoring out the long-range Coulomb-type part of interactions. The role of pair production and implications for the bosonized theory in the case of adjoint QCD\textsubscript{2} are discussed.
1 Introduction

Two-dimensional adjoint quantum chromodynamics, QCD$_{2A}$, is a non-abelian Yang-Mills theory coupled to fermions in the adjoint representation, and based on the Lagrangian

$$\mathcal{L} = Tr\left[ -\frac{1}{4g^2} F_{\mu\nu} F^{\mu\nu} + i\bar{\Psi} \gamma^{\mu} D^\mu \Psi \right],$$

(1)

where $\Psi = 2^{-1/4}(\psi)$, with $\psi$ and $\chi$ being $N \times N$ matrices. The field strength is $F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu + i[A_\mu, A_\nu]$, and the covariant derivative is defined as $D_\mu = \partial_\mu + i[A_\mu, \cdot]$. Throughout the paper, light-cone coordinates $x^\pm = (x^0 \pm x^1)/\sqrt{2}$ are used, where $x^+$ plays the role of a time. We will work in the light-cone gauge, $A_+ = 0$, effectively omitting fermionic zero modes. The theory is discussed extensively in the literature, so we refer the reader to Refs. [1, 2, 3, 7, 11] for details. Two main features are an asymptotic supersymmetry, and the stark contrast between the massive and the massless versions of the theory [4]. Recently, there has been interest in three- and four-dimensional versions of the theory [8, 9].

While the ultimate goal is a solution of the full theory, our aim here is much more modest. As a foundation for future work, we construct in Sec. 2 a complete set of eigenstates for the asymptotic theory based on symmetries which are broken in the full theory, thereby expanding work begun in [14]. The basis is a set of linear combinations of multi-dimensional harmonic functions subject to the symmetry constraints furnished by the light-cone Hamiltonian derived from Eq. (1). Since the asymptotic theory has disjoint sectors with different parton numbers, the basis states can be organized by parton number $r$, which results in $r - 1$ excitation numbers responsible for the multi-dimensionality of the solution. Technically, the basis will be appropriate only in the high excitation number limit. Empirically, we find that even the lowest states are well represented, probably due to their large separation in (bound state) mass. In the full theory particle pair production couples the disjoint parton sectors, and eigenfunctions of the full theory will be linear combinations of basis states of different parton numbers. Thus, the harmonic basis states can be used to discuss the role of particle creation and annihilation, as envisioned in [1]. This is done in Sec. 3.2. As applications of our method we briefly describe a program to solve the full theory with numerical methods in Sec. 3.1 and point out implications for the bosonized version of the theory in Sec. 3.3. Finally, we discuss the results and general applicability of the method in Sec. 4.

2 Constructing a Harmonic Basis

2.1 Introductory Remarks

Starting from the QCD$_{2A}$ Lagrangian, Eq. (1), the dynamics of a system of adjoint fermions interacting via a non-dynamical gluon field in two dimensions can be described by a light-cone momentum operator $P^+$ and Hamiltonian operator $P^-$. The two operators are expressed in terms of fermionic operators subject to the anti-commutation
relation

\[ \{ b_{ij}(k^+), b^\dagger_{lk}(p^+) \} = \delta(k^+ - p^+) (\delta_{il} \delta_{jk} - \frac{1}{N} \delta_{ij} \delta_{lk}) . \]  

(2)

To wit

\[ P^+ = \int_0^\infty dk \, k \, b^\dagger_{ij}(k)b_{ij}(k) , \]  

\[ P^- = \frac{m^2}{2} \int_0^\infty dk \, k \, b^\dagger_{ij}(k)b_{ij}(k) + g^2 N \int_0^\infty dk \, C(k)b^\dagger_{ij}(k)b_{ij}(k) \]  

\[ + \frac{g^2}{2\pi} \int_0^\infty dk_1dk_2dk_3dk_4 \left\{ B(k_i) \delta(k_1 + k_2 + k_3 - k_4) \right. \]  

\[ \times (b^\dagger_{k_1j_1}(k_4)b_{k_1i_1}(k_1)b_{k_2i_2}(k_2)b_{k_3i_3}(k_3) - b^\dagger_{k_1j_1}(k_4)b^\dagger_{k_2j_2}(k_2)b_{k_3i_3}(k_3)b_{k_1i_1}(k_1)) \]  

\[ + A(k_1) \delta(k_1 + k_2 - k_3 - k_4)b^\dagger_{k_1j_1}(k_4)b_{k_2i_1}(k_2)b_{k_3i_3}(k_3)b_{k_1i_1}(k_1) \]  

\[ + \frac{1}{2} D(k_1) \delta(k_1 + k_2 - k_3 - k_4)b^\dagger_{k_1j_1}(k_4)b^\dagger_{k_2j_2}(k_2)b_{k_3i_3}(k_3)b_{k_1i_1}(k_1)b_{k_2i_2}(k_2) \} , \]

with

\[ A(k_i) = \frac{1}{(k_4 - k_2)^2} - \frac{1}{(k_1 + k_2)^2} , \]  

\[ B(k_i) = \frac{1}{(k_2 + k_3)^2} - \frac{1}{(k_1 + k_2)^2} , \]  

\[ C(k) = \int_0^k dp \, \frac{k}{(p - k)^2} , \]  

\[ D(k_1) = \frac{1}{(k_1 - k_4)^2} - \frac{1}{(k_2 - k_4)^2} , \]

where the trace-splitting term \( D(k_i) \) can be omitted at large \( N_c \), and the trace-joining term is proportional to \( B(k_i) \). The structure of the Hamiltonian \( P^- \) displayed in Eq. (4) is

\[ P^- = P^-_m + P^-_{\text{ren}} + P^-_{PC,s} + P^-_{PC,ns} + P^-_{PV} + P^-_{\text{finite}N} . \]

The mass term \( P^-_m \) is dropped in the massless theory, but the renormalization operator \( P^-_{\text{ren}} \) needs to be included. Parton-number violating terms, \( P^-_{PV} \), couple blocks of different parton number. Parton-number conserving interactions \( P^-_{PC} \) are block diagonal, and may include singular(s) or non-singular(ns) functions of the parton momenta. For details see [2, 3, 14].

The problem is cast into an eigenvalue equation

\[ 2P^+ P^- |\Psi\rangle \equiv H_{LC} |\Psi\rangle = M^2 |\Phi\rangle . \]

(10)

Namely, the light-cone Hamiltonian \( H_{LC} \) acts on an eigenket \( |\Psi\rangle \) yielding the mass (squared) of a bound state as the eigenvalue. The eigenkets are in general linear combinations of states of definite parton(fermion) number \( r \)

\[ |\Phi_r\rangle = \int_0^{1/2} dx_1 \left( \prod_{i=2}^{r-1} \int_0^{1-(r-1)x_1 - \sum_{j=2}^{i-1} x_j} dx_j \right) \frac{\phi_r(x_1, x_2, \ldots, x_r)}{N_c^{r/2}} Tr[b(-x_1) \cdot b(-x_r)] |0\rangle . \]

(11)
The wavefunctions $\phi_r$ distribute momentum between the partons. Note that there are only $r-1$ integrations since total momentum can be set to unity. The integration is over the effective Hilbert space, which looks complicated due to elimination of redundant operator combinations like $\text{Tr}[b(x)b(y)b(z)] = \text{Tr}[b(y)b(z)b(x)]$. The explicit shape of the integration domain is displayed to emphasize that for $r > 3$ the wavefunction cannot be reconstructed in the region around the middle of the naive Hilbert space $[0, 1]^{r-1}$.

In the asymptotic limit, where only highly excited states are considered, both parton-violation and mass terms can be neglected. As a consequence the asymptotic theory splits into decoupled sectors with fixed parton numbers subject to ‘t Hooft-like equations

$$M^2 g^2 N \phi_r (x_1, \ldots, x_r) = - \sum_{i=1}^{r} (-1)^{(r+1)(i+1)} \int_{-\infty}^{\infty} \frac{\phi_r (y, x_i + x_{i+1} - y, x_{i+2}, \ldots, x_{i+r-1})}{(x_i - y)^2} dy.$$ (12)

The total momentum is set to unity, and thus the momentum fractions $x_i$ add up to one, $\sum x_i = 1$. Clearly, the number of partons $r$ is even (odd) for bosonic (fermionic) states. In [1, 14], additionally the approximation

$$\int_{0}^{1} dy \frac{1}{(x-y)^2} \phi(y) \approx \int_{-\infty}^{\infty} dy \frac{1}{(x-y)^2} \phi(y)$$ (13)

was used. Mathematically this is helpful because the solutions of the eigenvalue problem then are harmonic functions, see Eq. (15). The approximation makes sense physically, because for the highly excited states the integral is dominated by the interval around $x = y$ which is associated with the long-range Coulomb-type force.

In [14] we showed that the integral equation (12) can be solved algebraically using the ansatz

$$|n_1, n_2, \ldots, n_{r-1}\rangle = \prod_{j} e^{i\pi n_j x_j} = \phi_r (x_1, x_2, \ldots, x_r),$$ (14)

where $x_r = 1 - \sum_{j}^{r-1} x_j$. The ansatz is motivated by its simplest ($r = 2$) version, which solves the ‘t Hooft equation of fundamental QCD$_2$ [10]

$$\frac{M^2}{g^2 N} e^{i\pi n x} = - \int_{-\infty}^{\infty} dy \frac{1}{(x-y)^2} e^{i\pi ny} = \pi |n| e^{i\pi n x},$$ (15)

where the excitation number $n$ is integer. We thus use the single-particle states of a Hamiltonian appropriate for the problem to construct a Fock basis, inspired by [6].

Since the integral equation (12) is more involved than the ‘t Hooft equation, we have to symmetrize the ansatz (14) to comply with the constraints inherent in the Hamiltonian (10). Namely, the solutions of the adjoint ‘t Hooft problem have to be (pseudo-)cyclic,

$$\phi_r (x_1, x_2, \ldots, x_r) = (-1)^{r+1} \phi_r (x_2, x_3, \ldots, x_r, x_1),$$ (16)

1Meaning we cannot determine the wavefunction in this region from symmetries and its values close to the domain boundaries. For $r = 2$ we can: knowing $\phi_2 (x)$ in $[0, \frac{1}{2}]$ and $\phi_2 (x) = -\phi (1 - x)$ is obviously enough.
since the fermions are real. To implement this constraint we introduce the cyclic permutation operator
\[ \mathcal{C} : (x_1, x_2, \ldots, x_r) \rightarrow (x_2, x_3, \ldots, x_r, x_1). \]

Since the Hamiltonian is unchanged by a color index reversal of its operators, the string or trace of fermionic operators in the states \([11]\) can be reversed at will. The solutions can therefore be organized into sectors of definite parity under the orientation symmetry,
\[ \mathcal{T} : b_{ij} \rightarrow b_{ji}. \]

The two symmetry operators act on the ansatz, Eq. (14), as follows.
\[ \mathcal{C} : |n_1, n_2, \ldots, n_{r-1}\rangle \rightarrow (-1)^{n_{r-1}} | n_{r-1} - n_1, n_1 - n_{r-1}, n_2 - n_{r-1}, \ldots, n_r - n_{r-1}\rangle, \]
\[ \mathcal{T} : |n_1, n_2, \ldots, n_{r-1}\rangle \rightarrow (-1)^{n_1} | n_1, n_{r-1} - n_1, n_2 - n_{r-1} - n_1, \ldots, n_2 - n_1\rangle. \]

In \([14]\) we constructed eigenfunctions in the two- and three-parton sectors \((r = 2, 3)\) for both the massive and the massless theory, with bound-state masses
\[ M^2 = g^2 N \pi \left( |n_1| + |n_{r-1}| + \sum_{k=1}^{r-2} |n_k - n_{k+1}| \right). \]

The crucial ingredient of the method is the symmetrization due to \(\mathcal{C}\),
\[ |n_1, n_2, \ldots, n_{r-1}\rangle_{\text{sym}} \equiv \frac{1}{\sqrt{r}} \sum_{k=1}^{r} (-1)^{(r-1)(k-1)} C^{k-1} |n_1, n_2, \ldots, n_{r-1}\rangle, \]
where \(C^0 = 1\), because only the symmetrized states reflect the (pseudo)cyclic structure of the Hamiltonian.

While the \(r = 2, 3\) wavefunctions reproduce known (DLCQ) solutions of the theory remarkably well down to the lowest states, the ansatz fails to work for \(r > 3\) in general. In \([14]\), we were able to express a subset of the \(r = 4\) solutions as a linear combination of the symmetrized four-parton states. These solutions coincide with the ones derived earlier \([1]\). To introduce notation and show the complexity of the problem, we display a five-parton state symmetrized under \(\mathcal{C}\) and \(\mathcal{T}\), i.e. of definite \(C\) and \(T\) quantum numbers:\footnote{While \(T\) is an ordinary quantum number reflecting a symmetry of the Hamiltonian, \(C\) (or rather the set of \(C_i\)) is fixed by the constraint that the state has an (anti-)cyclic wavefunction, Eq. (16), as required by the structure of the Hamiltonian as a sum over permutations of the parton momenta.}

Note that the state consists of \(4r = 20\) statelets, characterized by an \((r-1)\)-tuple of (ordered) excitation numbers \(n_i\) (here: \((n, m, l, k)\))
\[ |\phi_5, n, m, l, k\rangle; M^2 = |n| + |n - m| + |m - l| + |l - k| + |k| \]
\[ + (-1)^k |k, n-k, m-k, l-k\rangle + (-1)^l |l, n-l, m-l, k\rangle + (-1)^m |m, n-m, l-n, k\rangle \]
\[ + T \left[ (-1)^n |n, k-n, l-n, m-n\rangle + |k, l, m, n\rangle + (-1)^k |k-l, m-k, n-k, -k\rangle \right. \]
\[ + (-1)^l |m-l, n-l, -l, k\rangle + (-1)^m |m-n, -m, k-m, l-m\rangle \right]. \]

Typically, these states are paired with a partner state of negative excitation numbers to create a real wavefunction, i.e. a sine or cosine. It is convenient to do so with an additional symmetry in mind, which we’ll introduce in the next section.
2.2 Exhaustive Symmetrization

As is well known, the eigenfunctions of the massive theory have to vanish when one parton momentum is zero to guarantee hermiticity of the Hamiltonian $[10]$

$$\phi_n(0, x_2, \ldots, x_n) = 0.$$  \hspace{1cm} (22)

This is sometimes called a boundary condition because it behaves as one, but this is misleading — after all, we are trying to solve an integral and not a differential equation. In the massive two-parton sector (or the simpler fundamental theory $QCD_2$ $[10]$) this leads to sine eigenfunctions, and to cosine eigenfunctions in the massless theory. Clearly, the general verdict is that the Hilbert space of the theory splits into two disjoint sets of functions: one even and the other one odd. It seems that the consequences of this straightforward observation have not been fully realized. This is not surprising, since the answer to the simple question — under which transformation or symmetry the eigenfunctions are odd or even — is trivial for few partons, and fairly complicated for many. Indeed, the symmetry in question is manifest only in the parton sectors with $r \geq 4$, because it is redundant with $C$ and $T$ otherwise. To get a handle on it, note that while physically it is true that we need to manage the behavior of the wavefunctions at the boundaries of the domain of integration, mathematically boundary conditions are not the right tool. Rather, we have to implement symmetries that will result in the desired behavior of the wavefunctions at the boundary — just like the $C$ symmetrization assures that the state so constructed is an eigenstate of the Hamiltonian. We alluded to such a symmetry in $[14]$, but the general method is more involved.

For massive fermions, we need the wavefunctions to vanish on the hyperplanes characterized by $x_i = 0$ for at least one $x_i$. Since our wavefunction ansatz $[14]$ is modular, we can simply add for every term of the form $e^{i\pi \sum j n_j x_j}$ another term with opposite sign that is the same for $x_i = 0$ but different for $x_i \neq 0$. This idea can be realized by introducing $r - 1$ symmetry operators $S_i$ which we might call lower-dimensional inversions, because they invert all but one of the excitation numbers

$$S_i : |n_1, n_2, \ldots, n_i, \ldots, n_r-1\rangle \rightarrow | -n_1, -n_2, \ldots, n_i - n_{i+1} - n_{i-1}(1 - \delta_{ii}), \ldots, -n_{r-1}\rangle. \hspace{1cm} (23)$$

The replacement of the $i$th excitation number is such that the mass (squared) of the state remains invariant, see Eq. $[19]$. This symmetry is hidden in the three-parton sector $r = 3$ because the low-dimensional inversion can be expressed in terms of the other symmetry operations $[4]$ ($S = TC^2$, see Eq. (26) of $[14]$), so that $r = 4$ is the lowest parton sector in which the full symmetry unfolds$[4]$.

In Sec. 2.4 we will see that additional $S$ operators creep in, so let’s call the set of lower-dimensional inversions $E = \{S_1, S_2, \ldots, S_{N(r)}\}$. For a given parton number $r$, the maximal number $N(r)$ of independent $S$ operators can be determined from a group theoretical argument. In practice, the argument boils down to combinatorics:

$^3$Because the wavefunction would otherwise be identically zero, of course.

$^4$At $r = 2$ the situation is fully degenerate with $C = T = S$ up to signs.

$^5$This has to be taken with a grain of salt, since at $r = 4$ we have $S_1 TC^2 = S_2 S_1$, so there are only two independent $S$ operators, not $N(r) = \frac{1}{2}(r - 1)! - 1$, see below.
the number of operators of the permutation group of order \( r \) with inversion is \( 2r! \). We derive the full symmetry group \( G \) in Sec. 2.4 and use only its generic properties here. The group choice is intuitive as we will see, since in the \( r \) parton sector, we are in essence permuting \( r \) objects. That the objects (the partons) carry different momenta is irrelevant here. We are thus symmetrizing the wavefunctions under the set of \( N(r) \) \( S \)-symmetries. Later we will see that there is only one common multiplicative \( Z_2 \) quantum number \( S \). Tentatively, we write

\[
|r\rangle_{sym} = (1 + \sum_i N_i S_i) |r\rangle_{sym},
\]

where \( |r\rangle_{sym} \) is the ansatz state \( |n_1, n_2, \ldots, n_{r-1}\rangle \) symmetrized under the cyclic group \( \langle C \rangle \), Eq. (20).

To include all symmetries in our approach, it is convenient to make the inversion of excitation numbers explicit with the operator

\[
I : |n_1, n_2, \ldots, n_{r-1}\rangle \rightarrow | - n_1, - n_2, \ldots, - n_{r-1}\rangle.
\]

Clearly, \( I \) is a \( Z_2 \) operator, and states even and odd under \( I \) simply represent cosine and sine wavefunctions, respectively. We can then write down an orthonormal set of basis states in all sectors of the theory, characterized by their \( Z_2 \) quantum numbers \((T, I, S)\) under the symmetry transformations \( T, I, \) and \( S \), and their excitation numbers \( n_i \) collected in \( |r\rangle \)

\[
|r\rangle_{FullSym} \equiv G|r\rangle = \left\{ \frac{(1 + TT)(1 + IT)}{\sqrt{2r!N}} \sum_{k=0}^{r-1} (-)^{(r-1)k} C_k^k \left( 1 + \sum_i N_i S_i |r\rangle \right) \right\},
\]

where \( N \) is the volume of the Hilbert space in the \( r \) parton sector,

\[
N = \int_0^{1/2} dx_1 \prod_{i=2}^{r-1} /_{x_1} \int_{-\sum_{j=2}^{r-1} x_j}^{1-(r-1)x_1} dx_i = \frac{1}{r!},
\]

cf. Appendix of Ref. [14]. The excitation numbers can, in general, be even or odd integers. Since the states, Eq. (25), are by construction eigenstates of the light-cone Hamiltonian with masses given by Eq. (19), they furnish, in principle, a full solution \(6 \) of asymptotic QCD\(_{2A}\) — keeping in mind that we made the approximation, Eq. (13).

### 2.3 Classification of States

In practice, most sectors prescribed by Eq. (25) are empty. As can be gleaned from the symmetry operations, Eqs. (18), (23), and (24), only two sets of quantum numbers

---

\(^6\)This construction should also settle the issue raised by 't Hooft in the footnote of his seminal paper [10]: since the “boundary conditions” are really symmetrizations, they must hold order by order in \( N_c \).
lead to viable states. Namely, only states with all even excitation numbers, and states with alternating odd and even numbers give rise to *bona fide* states. In the latter case, the first and last excitation numbers must be odd, so that these states only exist in the even parton sectors. Even so, most of these excitation number combinations are not viable due to cancellations of terms. For example, *bona fide* states are only found in the \((T\pm, I\pm)\) four-parton sectors and in the \((T\pm, I\pm)\) five-parton sectors, see Table \[1\] In the odd parton sectors, these four sectors (for both \(S\pm\)) are indeed the four sectors necessary to describe the two \(T\)-sectors of the massive and the massless theory, respectively. For an even number of partons, the addition of the mixed excitation number states (\(|\text{odd, even, odd}\rangle \equiv |\text{oeo}\rangle\) for \(r = 4\)) does, of course, not lead to more sectors. Rather, two even excitation number sectors do not yield *bona fide* states. For an explanation, see Appx. \[A\] For instance, in the four parton sector, only \((T\pm, I\mp, S\pm)\) in the even excitation number sector and \((T\pm, I\mp, S\mp)\) with mixed even and odd \(n_i\) are viable; the former are the two sectors of the massive theory, and the latter represent the two massless sectors. This is a straightforward generalization from the earlier findings \[14\] that in the two-parton sectors cosines with odd excitation number represent the massless and sines with even excitation number the massive theory, whereas all excitation numbers in the three-parton sector are even.

To check our musings, we make contact with known results. Our solution \[25\] reproduces the results of Ref. \[1\] Eq. (4.13) and classifies them as \(|\text{eee}; T - I + S\rangle\) states. The wavefunctions (4.13) of \[1\] exhibit only two (not three) excitation numbers,
Figure 2: Lowest eigenfunctions of the massive theory in the four-parton sectors. Solid lines represent numerical results as emulated in DLCQ by letting \( \mu = 4 \), dashed lines the algebraic eigenfunctions. Note that for \( \mu = 1 \), the theory is supersymmetric. Left (a): \( T \) even eigenfunctions. Right (b): \( T \) odd eigenfunctions.

because they represent a subset of the full set of wavefunctions. We thus find that there are more states than anticipated, and that the counting of states is more involved; it does not seem to lend itself to a string-motivated parametrization. Note that the solution (4.13) in [1] is much more compact and looks differently (double sines versus triple cosines), but this is a superficial disagreement and the price one has to pay for generality: 12 terms\(^7\) of (4.13) in [1] vs. 48 terms in Eq. (25) at \( r = 4 \). Next we check how accurate our algebraic solution is by comparing to a numerical (DLCQ) calculation, see Fig. 1. Some masses are degenerate at \( r = 4 \) as opposed to \( r < 4 \), and the agreement is not as good as in the three-parton sector [14], due to considerable mixing of states of equal mass. Recall that the algebraic eigensolutions were derived by making the approximation Eq. (13); using the correct limits of the integral evidently induces interactions between the algebraic basis states. As can be gleaned from Fig. 1, the discrepancy between algebraic and numerical solutions is noticeable even in the massless sector, where the masses are \textit{not} degenerate. This heralds the worsening of our approximation at large parton number \( r \). Namely, the effective volume of the Hilbert space decreases as \( 1/\!r! \), see Eq. (26). As a consequence, the integral looks less and less like \( (\int_{-\infty}^{\infty} dx)^{r-1} \), although the core motivation for the approximation (that the region around the singularity is the most important) remains valid.

What do the exact wavefunctions tell us? First off, the massless and massive sectors show significant differences. The massive sector is more straightforward, perhaps due to the more stringent constraint of wavefunctions vanishing on the \( x_i = 0 \) hyperplanes.

\(^7\)Obviously, a sine has \textit{two} exponential terms.
Even the lowest states exhibit degenerate masses in the massive, but not the massless theory. Also, the bound-state masses are much lower in the massless sector. This is more surprising than it sounds, since we are omitting the mass term in the asymptotic limit! The difference in bound-state mass is thus generated by symmetry alone. The lowest four states are in the massive theory ($\mu \neq 0$)

$$|1\rangle_{\mu\neq 0}^{++} = |4, -2, 0\rangle_{12}, \quad |1\rangle_{\mu\neq 0}^{--} = |4, 0, 2\rangle_{12},$$

$$|2\rangle_{\mu\neq 0}^{++} = |6, -2, 0\rangle_{16}, \quad |2\rangle_{\mu\neq 0}^{--} = |4, -2, 0\rangle_{12},$$

$$|3\rangle_{\mu\neq 0}^{++} = \frac{1}{\sqrt{2}} \left(|6, 10, 10\rangle_{20} + |8, 10, 6\rangle_{20}\right), \quad |3\rangle_{\mu\neq 0}^{--} = |6, 4, 6\rangle_{16},$$

$$|4\rangle_{\mu\neq 0}^{++} = |8, 10, 10\rangle_{20}, \quad |4\rangle_{\mu\neq 0}^{--} = |6, -2, 0\rangle_{16}. \quad (27)$$

In the massless theory they look like

$$|1\rangle_{\mu=0}^{++} = |1, 2, 3\rangle_{6}, \quad |1\rangle_{\mu=0}^{--} = |1, 0, 1\rangle_{4},$$

$$|2\rangle_{\mu=0}^{++} = |3, -2, -1\rangle_{10}, \quad |2\rangle_{\mu=0}^{--} = |1, -2, -1\rangle_{6},$$

$$|3\rangle_{\mu=0}^{++} = |3, -2, -3\rangle_{12}, \quad |3\rangle_{\mu=0}^{--} = |3, 0, 1\rangle_{8},$$

$$|4\rangle_{\mu=0}^{++} = |5, -2, -1\rangle_{14}, \quad |4\rangle_{\mu=0}^{--} = |3, -2, -1\rangle_{10}. \quad (28)$$

where the indices represent the TIS quantum numbers on the right-hand states, and the mass (squared in units $g^2N\pi$) on the left-hand states. Note that the excitation numbers $n_i$ are not unique. For instance, at $r = 4$ each state has up to $2r! = 48$ different tuples. One way of classifying the state is to pick one statelet’s numbers to represent the entire state, e.g. by choosing the lowest positive number for $n_i$ followed by the smallest absolutes $|n_i|$ as in Eq. ($28$).

### 2.4 Some Group Theory

The solutions ($25$) are right cosets of the subgroup $B$ of transformations associated with the full domain of integration (the “bulk”). Namely $B$ is the direct product of inversions $I$, reorientations $T$ and cyclic permutations $C$

$$B = \{1, C, C^2, \ldots C^{r-1}, T, TC, \ldots TC^{r-1}, I, IC, \ldots, ITC^{r-1}\}. \quad (29)$$

We can construct a partition of the full group $G$ of symmetry transformations of QCD$_{2A}$ by acting on all elements of $B$ with the lower-dimensional inversions $S$ concerning symmetrization on the hyperplanes forming the boundary of the integration domain collected in the set$^8$ $\mathcal{E}$ alluded to in Sec. (27)

$$\mathcal{E} = \{S_1, S_2, \ldots S_{1/2(r-1)!-1}\}. \quad$$

In general, we find $N(r) = \frac{1}{2}(r - 1)! - 1$ independent lower-dimensional inversions. We work with the right cosets here, because we want to make explicit the symmetrization of

---

$^8$We refer to it as the exhaustive set $\mathcal{E}$, because its elements are exhausting the “symmetrization space”. It is not a group, because it is not closed under composition of its members which may produce elements of $B$.

Table 1: Characteristics of the lowest states in the first few parton sectors of the asymptotic theory including their quantum numbers TIS. The sectors are labeled with a subscript indicating behavior under $T$ ($\mp$) and superscripts signifying massless ($^0$) and massive fermions ($^\mu$). For an explanation of the discrepancy between the $T$ quantum number and the $T$ sector see Appx. B.

The state under the cyclic subgroup $\langle C \rangle$, as required by the structure of the Hamiltonian, as implicitly defined in Eq. (12). Since the order of $B$ is $|B| = 2_T \times 2_T \times r_C$ and its operators act on all elements of $E$ plus the identity, a fully symmetrized state contains $2r!$ “statelets” owing to the $2r!$ independent automorphisms that can be formed on a set of $r$ objects (here: momentum fractions).

The general theme is hard to prove, so we simply checked with a computer algorithm that the order of $G$ is indeed $|G| = 2r!$ — in particular, that it is finite. This is expected because permutations form subgroups of the symmetric group. From a physical point of view, permutations are re-orderings which leave the bound-state masses invariant, and thus symmetries of the Hamiltonian.

To check the order of $G$ we proceeded as follows. By acting on all $4r$ statelets $B_r$ with the fundamental operator $S = S_1$ we produced the left coset $S_1B$. To keep the symmetry of the Hamiltonian manifest, we need however the right coset $BS_1$. Recall that terms of odd $C$-parity must be negative in the even $r$ sectors to ensure the alternating signs of the permutations in the Hamiltonian Eq. (1). Since in general the cosets are not normal, $S_1B \neq BS_1$, we do not off-hand know which $C$-parity the members of a left coset of $B$ might have. In general, both the left and the right coset will therefore contain new operators, which we’ll have to include in our growing set of operators to move towards group closure. We must also act with these new operators on $B$ as well as on the existing right cosets, which in turn will yield new operators, right and left cosets. This process continues until no new operators arise — if the group is finite. It is
thus a non-trivial test of our hypothesis. We find that the algorithm always converges on the expected number of operators or statelets, namely $2r! = 240, 1440, 10080, 80640$ for $r = 5, 6, 7, 8$ and beyond.

To construct an actual eigenfunction, we need to solve one more problem. It is the assignment of $S$ parity to the individual statelets, in the sense that some of them will carry an odd power of $S$ quantum number, and some an even power. Recall that $S^2 = 1$ since $S$ is a $Z_2$ operation. To do so it is convenient to introduce the notion of a primary operator. Of the $\frac{1}{2}(r - 1)!$ $S$ operators in the $r$ partron sector, initially only $r - 1$ (associated with the $r - 1$ excitation numbers) seem necessary to ensure that the wavefunction is vanishing (maximal) on the hyperplanes $x_i = 0$ in the massive (massless) theory, respectively. We call those $r - 1$ operators together with an additional operator $S_i$, the primary operators. They form a conjugacy class under $\langle C \rangle$ and have similar properties, since

$$S_i = C^{i - 1} S C^{r - i + 1}.$$  \hspace{1cm} (30)

It is not hard to show that the primary operator fulfill the following pseudo-commutation relations

$$C^j S_i = S_{\text{mod}_r'(i + j)} C^j \quad \text{and} \quad (TC^j) S_i = S_{\text{mod}_r'(r - i + j + 1)} (TC^j),$$  \hspace{1cm} (31)

where $\text{mod}_r'$ is congruence modulo $r$ shifted by one, so that $S_0 = S$, and $S_{r + 1} = S_1$. In other words, the $S$ operators commute with the members of the normal subgroup $B$ under loss of their identity: they transmute into a different primary operator. But then we are done! These relations allow us to compute all other operators in the symmetry group $G$, which is in essence the remainder of the subset $E$ of lower-dimensional inversions. In fact, we must keep adding operators until the $2r!$ slots in the full symmetry group are exhausted. For instance, the product of two primary operators can be evaluated as follows due to the associativity group axiom:

$$S_k (C^i S_i) = (S_k C^j) S_i = C^j (S_{\text{mod}_r'(k - j)} S_i) = (S_k S_{\text{mod}_r'(i + j)}) C^j \quad \text{for} \quad 1 \leq i, j, k \leq r.$$  \hspace{1cm} (32)

The second half is the commutation relation for the secondary operator $S_{\text{mod}_r'(k - j)} S_i$. A complete multiplication table of the group can be iteratively constructed. Finding independent operators essentially reduces to the word problem of abstract algebra. We display part of such a table for $r = 5$ in Table 2. As a corollary we note that these identities show that the Hamiltonian symmetrization constraint (fixed signs under $\langle C \rangle$) is intact. Namely, the $TC^j$ component of a right coset of $B$ of any $S_k$ (whether primary or not) is mapped onto the $T C^j$ component of a right coset of some other operator $S_k'$. 

So what are the relative signs of the individual terms? The signs within the $B$-blocks ($4r$ statelets of the right cosets $BS_i$) are fixed by the Hamiltonian and the $T$ and $I$ quantum numbers. At $r = 4$ the assignment of the $S$ quantum number is simple if counter-intuitive: both the $S_1$ and the $S_2$ block carry an additional $S$ sign (32 statelets); only the identity block’s eight statelets do not acquire a sign. This seems

---

\(^9\)While not intuitive, the last operator is necessary to complete the map $S_i \times \langle C \rangle \to \langle C \rangle S_i$, since the cyclic subgroup $\langle C \rangle$ is of order $r$, not $r - 1$.

\(^{10}\)This relation is not unique, for instance $S_{-1} = (TC)S(TC)$ also.

\(^{11}\)The $T$ version of this relation is $S_k (TC^j S_i) = TC^j (S_{\text{mod}_r'(r - k + j + 1)} S_i) = (S_k S_{\text{mod}_r'(r - i + j + 1)}) TC^j$.  

11
unbalanced, but works due to sign-cancellations unique to the four-parton sector. At $r = 5$ the orders of group and subgroups are such that we get an even split into two “half-groups”. Namely, the five secondary operators plus the identity are $S$ even and the primary operators plus a peculiar secondary operator $S_9$ are odd and carry an $S$ sign. This makes $r! = 120$ statelets with an $S$ sign, and 120 without. For an algorithm that is more universally applicable, see Appx. A.

This completes our construction of the most general solution in all parton sectors. As a cross-check we construct the eigenfunctions in the five-parton sector and compare them to numerical solutions in Fig. 3. Fig. 4(a) shows the comparison for some six-parton eigenfunctions. We used the rather low harmonic resolutions $K = 23$ and $K = 20$, because otherwise the plots get too “crowded”; agreement is just as good at higher $K$ of course. As we glean from Fig. 3 the agreement is near-perfect for the lowest $T$ even state in the massive theory, good in the massive theory in general, and fair in the massless theory. This might be due to the fact that the density of states is much higher in the massless theory. Apparently, the condition that the wavefunction vanish for zero parton momenta is quite restrictive. Given that the number of statelets rises to 1440 at $r = 6$ the agreement between algebraic eigenfunctions and numerical solution seems surprisingly good in Fig. 4(a).

It is indeed quite remarkable how perfectly the features of the theory are represented by the properties of the harmonic basis. It is tempting to speculate that this approach — which one might call “exhaustively-symmetrized Light-Cone Quantization (eLCQ)” — applies to other theories, at least in two dimensions where light-cone coordinates are the natural language. Hopefully, the treatment of the present toy model is a harbinger of wider applicability.

3 Applications

3.1 Using “eLCQ”: Some Suggestions

Since we have found a complete set of basis states for the asymptotic theory in Sec. 2, we can systematically approximate the full theory in a basis-function approach. This should be pretty straightforward, but implementing the algorithm in the higher parton-sectors is too tedious to be presented here, so we only sketch the general idea. Namely, we can use the set of coupled integral equations derived in [3] from the Hamiltonian Eq. (4) for the full wavefunctions $f_r$ in the $r$-parton sectors. The full equation couples sectors of different parton number; $f_r$ and $f_{r\pm2}$ appear in the equation.

We expand the full eigenfunctions $f_r(x_1, x_2, \ldots, x_r)$ into a complete set of asymptotic eigenfunctions $\phi_{r,\vec{n}}$

$$f_r(x_1, x_2, \ldots, x_r) = \sum_{\vec{n}} c_{r,\vec{n}} \phi_{r,\vec{n}}(x_1, x_2, \ldots, x_r),$$

\footnote{It commutes with the $B$ subgroup, i.e. $BS_9 = S_9B$, which does not imply commutation of individual subgroup elements $B_i$ with $S_9$: $B_iS_9 \neq S_9B_i$ in general.}
Figure 3: Lowest eigenfunctions in all five-parton sectors. Solid lines represent numerical (DLCQ) results, dashed lines the algebraic eigenfunctions. Left (a): Massless theory ($\mu = 0$). Right (b): Massive theory ($\mu = 4$). The lowest two eigenfunctions are $T$ even, the upper two $T$ odd.

where $\vec{n}$ represents a tuple of $r - 1$ excitation numbers. Formally, the integral equation looks like

$$M^2 f_r = M^2 \sum_{\vec{n}} c_{r, \vec{n}} \phi_{r, \vec{n}}(x_1, x_2, \ldots, x_r) = 2P^+P^- \sum_{\vec{n}} c_{r, \vec{n}} \phi_{r, \vec{n}}(x_1, x_2, \ldots, x_r).$$

If we project onto the asymptotic eigenfunctions characterized by $(s, \vec{m})$, we get an equation for the associated coefficient

$$M^2 \int d^r x f^*_{s, \vec{m}}(\vec{x}) f_r(\vec{x}) = M^2 \sum_{r, \vec{n}} \int d^r x c_{r, \vec{n}} f^*_{s, \vec{m}} f_{r, \vec{n}} = M^2 \sum_{r, \vec{n}} c_{r, \vec{n}} \delta_{s, r} \delta_{\vec{n}, \vec{m}} = M^2 c_{s, \vec{m}},$$

where $\vec{x}$ represents the $r$ momentum fractions $x_i$, and $\int d^r x$ the integration over the appropriate domain subject to the constraint $\sum_i x_i = 1$ and the removal of cyclic redundancies, cf. Eq. (11). We assumed the asymptotic eigenfunctions to be orthonormal and complete. On the left hand side, we have to evaluate the Hamiltonian matrix elements and multiply the matrix with the column vector of coefficients. In other words, we have to solve an eigenvalue problem for the coefficient vectors. Diagonalizing the full Hamiltonian clearly will yield the coefficients to express the full eigenfunctions as linear combinations of the asymptotic eigenfunctions.

Now, the number of statelets in a state is equal to the order of the group $|G| = 2r!$ and grows exponentially. This limits the practical value of the approach. However, it is in some sense the worst case scenario. Often, accidental symmetries arise due to
special combinations of excitations numbers \( n_i \). For instance, the four-parton eigenfunctions, Eq. (4.13) in Ref. [1], can be generated by symmetrizing the statelet \(|n_1, 0, n_2\rangle\). Most of its statelets will not exhibit a vanishing excitation number, yet the state as a whole is more symmetric than the generic four-parton eigenstate. To wit, it possesses an additional \( Z_2 \) symmetry\(^{13}\), so that the 24 independent statelets can be cast into 12 sinusoidal functions, or into the 6 double-sines of Eq. (4.13) in Ref. [1]. Analogous symmetries seem to exist in all higher parton-sectors, e.g. six-parton states \(|n_1, 0, n_2, 0, n_3\rangle\) generating states\(^{14}\) of the form Eq. (4.15) in Ref. [1]. All symmetries will reduce the eigenvalue problem further by block-diagonalizing the Hamiltonian and may give an intuitive understanding of the bosonization process, by which trivial multi-particle states are projected out \([20]\).

So far the emphasis has been on symmetries of the set of excitation numbers. This is natural, since the \( S \) symmetries were introduced exactly for this purpose in Eq. (23). A wavefunction symmetrized with respect to its excitation numbers is clearly also symmetrized with respect to its arguments, i.e. momentum fractions. What kind of momentum space symmetries do the \( N(r) \) \( S \) operators represent? It should be enough to explicitly look at only two, since all others can be derived from them. Namely, \( S_1 \) and \( S_2 \) can be considered stereotypical single- and double-neighbor permutations, respectively, since in the latter case \( n_2 \to n_2 - n_1 - n_3 \) is affected by both of the neighboring excitation numbers. It is clear that the shift in excitation numbers comes from the following shift in momentum fractions

\[
S_1 : \quad x_1 \to -x_1 - x_2, x_2 \to x_2, x_3 = -x_3 - x_1, \ldots, x_{r-1} \to -x_{r-1}, x_r \to -x_r - x_1,
\]

\[
S_2 : \quad x_1 \to x_1, x_2 \to -x_2 - x_1, x_3 = -x_3, \ldots, x_r \to -x_r.
\]

Apparently there is only one operation in momentum space: all (except one) momentum fractions are inverted, and the fractions next to the invariant one are shifted by the invariant fraction. This shows that the condition that the Hamiltonian be hermitian, and hence that its eigenfunctions are invariant under \( S \), generates a set of momentum space symmetries that grows exponentially with the parton number. Since these generated symmetries are not obvious, the general method may be useful to determine a full set of symmetries of a given Hamiltonian in other theories.

### 3.2 The Role of Pair Production

With the asymptotic solution Eq. (25) at hand, what can we say about the effect of pair production, i.e. parton number violation? The first observation is that the subsequent parton sectors with the same \( T \) parity have opposite \( I \) parity. In other words, the Hamiltonian is sandwiched between a cosine and a sine wavefunction. The simplest case is the matrix element between the two and four massless parton \( T \) even sectors\(^{15}\)

\[
-\langle r = 2; 1|P_{PV}|r = 4; 1\rangle_{+-},
\]

\(^{13}\)Its identity and \( S_1 \) statelets fulfill \( TZ|r\rangle = Z|r\rangle \), whereas for the \( S_2 \) statelets we have \( C|2\rangle = I|r\rangle \), so that half the statelets are redundant.

\(^{14}\)Note that this works in the massless \(|oeoeo\rangle\) sector, too.

\(^{15}\)The subscripts here are the \( TI(S) \) quantum numbers, consistent with Table [11]
where
\[ |r = 2; 1 \rangle_{+-} = \cos \pi x, \]
\[ |r = 4; 1 \rangle_{+-} = \sin (x_1 + 2x_2 + 3x_3) - \sin (3x_1 + 2x_2 + x_3) \]
\[ + \sin (x_1 - 2x_2 - x_3) + \sin (x_1 + 2x_2 - x_3), \]
and the latter wavefunction has an interesting “disappearance” symmetry under \( x_2 \leftrightarrow x_4 \). In general, we will have to evaluate a matrix element of the form
\[ -\langle \bar{n} | P_{PV} | n, m, l \rangle_{+-}, \]
where \( \bar{n} \) and \( n, m, l \) represent the excitation numbers of the two- and four-parton states, respectively, and \( P_{PV} \) is defined in Eqs. (9) and (11). Owing to the definition of Hamiltonian and states, Eqs. (4) and (11), we have to do eight integrations over momenta (one plus three for the states, and four for the Hamiltonian), and have one momentum conserving delta-function, as well as five more appearing when we commute through annihilation operators. So we are left with two integrations over a trigonometric function divided by a quadratic function of the momenta. The structure of the final expression is therefore
\[ -\langle \bar{n} | P_{PV} | n, m, l \rangle_{+-} \sim \int \int \frac{\sin \pi (n'x + m'y)}{(x + y)^2} dxdy, \]
where the integers \( n' \) and \( m' \) will depend on all excitation numbers \( \bar{n}, n, m, l \) of the two and four-parton states. This integral can be expressed in terms of cosine and sine integrals \( (Ci(x), Si(x)) \), and is not divergent. There will be several terms, and cancellations are possible. Thus for specific states, or in certain sectors\(^{16}\) the matrix element may vanish.

This in turn raises the question whether it is systematically possible to find linear combinations of the asymptotic eigenstates for which the annihilation matrix elements are zero. These would then be states with a definite parton number. In other words, we would have succeeded in summing all pair creation effects, effectively “renormalizing” the theory, i.e. formulating it in terms of effective degrees of freedom. This program is beyond the scope of the present note, but it seems to be viable — judging from previous work. Namely, in \([2, 3]\) it was shown that many of the bound states are very pure in parton number. An open question is whether this behavior is generic or due to the finite discretization used in \([2, 3]\).

### 3.3 Implications for the Bosonized Theory

QCD\(_{2A}\) can be bosonized by rewriting the Hamiltonian in terms of current operators \( J(-p) \sim \int dq b(q)b(p - q) \) subject to a Kac-Moody algebra, see e.g. Refs. \([12, 13]\). Bosonization is in essence a basis transformation, so the eigenfunctions will change while the eigenvalues, i.e. the bound state masses, remain invariant. Straightforward

\(^{16}\)Of course, the \( T \) sector is fixed, but the result can be different in the massive and massless sectors of the theory.
bosonization generates a non-orthonormal basis, with states consisting of color traces of adjoint current operators acting on a vacuum state\footnote{Either the traditional vacuum state or an “adjoint vacuum”, represented by a fermionic operator of zero momentum acting on the vacuum.}. Numerical approaches\footnote{Numerical approaches such as DLCQ use different bases for the fermionic and bosonic sectors.} produce orthonormal solutions, i.e. the coordinate vectors associated with a chosen basis (whether orthonormal or not) are mutually orthogonal and of unit length. In this sense a basis of symmetrized harmonics as produced by our “eLCQ” method will be orthonormal.

To get a handle on the bosonized theory, current-number changing operators can be omitted at first\footnote{We used $\phi_{2B} = \sin(\pi x_1)$ and $\phi_{3B} = -\frac{1}{\sqrt{3}}[\cos(\pi x_1) + \cos(\pi x_2) + \cos(\pi x_3)]$ to describe the generic features of the two wavefunctions. Note that the cosines in the higher parton sectors are consistent with our earlier finding that wavefunctions of same $T$ have opposite $I$ at subsequent $r$.}, and one arrives at an integral equation for the bosonized eigenfunctions $\phi_{rB}$

$$
\frac{M^2}{g^2 N} \phi_{rB}(x_1, \ldots, x_r) = -\sum_{i=1}^{r} \int_{-\infty}^{\infty} \frac{\phi_{rB}(y, x_i + x_{i+1} - y, x_{i+2}, \ldots, x_{i+r-1})}{(x_i - y)^2} dy,
$$

where we have used the subscript $B$ to stress that the partons in the bosonized theory are currents and not fermions. The equation is virtually identical with Eq. (12) save for the non-alternating signs. These signs stemming from anti-commuting fermionic operators are clearly absent in the bosonized theory. We should therefore be able to describe the bosonized wavefunctions with our “eLCQ” ansatz, Eq. (25). We cannot hope for a perfect match, because we cannot decouple sectors of different current number. A consistent asymptotic theory does not exist due to the nature of the Kac-Moody algebra of the current operators. There is an associated problem. Namely, the full theory contains uninteresting non-trivial multi-particle states which interact with the single-particle states of interest at any finite resolution in discretized versions of the theory\footnote{We used $\phi_{2B} = \sin(\pi x_1)$ and $\phi_{3B} = -\frac{1}{\sqrt{3}}[\cos(\pi x_1) + \cos(\pi x_2) + \cos(\pi x_3)]$ to describe the generic features of the two wavefunctions. Note that the cosines in the higher parton sectors are consistent with our earlier finding that wavefunctions of same $T$ have opposite $I$ at subsequent $r$.}. Indeed, only a few single-particle states have hitherto been identified as such. Furthermore, bosonization only works for massless fermions, so there is no massive sector. Hence, our comparison of numerical and algebraic wavefunctions will be rather limited. Of course, in the bosonized theory there is a bosonic and also a fermionic sector. In the latter, the basis states are different owing to the elimination of cyclic symmetry due to the existence of a unique fermionic operator (the “adjoint vacuum”). Here, we will focus on the bosonic sector of the bosonized theory. This is a real test of our ansatz, since the symmetrization clearly cannot be the same as in the theory with fermions. The “eLCQ” ansatz\footnote{We used $\phi_{2B} = \sin(\pi x_1)$ and $\phi_{3B} = -\frac{1}{\sqrt{3}}[\cos(\pi x_1) + \cos(\pi x_2) + \cos(\pi x_3)]$ to describe the generic features of the two wavefunctions. Note that the cosines in the higher parton sectors are consistent with our earlier finding that wavefunctions of same $T$ have opposite $I$ at subsequent $r$.} for the two-current wavefunction $\phi_{2B}$ is

$$
\phi_{2B} = e^{inx} + (-1)^n e^{-inx}
$$

(compare to Eq. (40) which has a minus sign between the terms). Therefore we “predict” that the massless states with odd $n$ will be sines in the bosonized theory, not cosines as in the fermionic theory. This is consistent with Ref. [12], and also the numerical bosonized eigenfunctions in Fig. 4(b) are consistent with our ansatz\footnote{We used $\phi_{2B} = \sin(\pi x_1)$ and $\phi_{3B} = -\frac{1}{\sqrt{3}}[\cos(\pi x_1) + \cos(\pi x_2) + \cos(\pi x_3)]$ to describe the generic features of the two wavefunctions. Note that the cosines in the higher parton sectors are consistent with our earlier finding that wavefunctions of same $T$ have opposite $I$ at subsequent $r$.}. Note that numerical approaches such as DLCQ use different bases for the fermionic and
bosonized theories. The fermionic theory is approximated using anti-periodic boundary conditions (odd half-integer momentum fractions), whereas the bosonized theory uses periodic boundary conditions (integer momentum fractions). Of course, regardless of the basis used, they should be decent approximations to the algebraic wavefunction.

In sum, we find that the “eLCQ” ansatz is compatible with the known solutions of the theory in a significantly different representation. This hints at a wider applicability of our method. What seems crucial is that the structure of the Hamiltonian be of the form

$$P^− \sim \int \frac{dp}{p^2} J_{ij}(-p)J_{ji}(p).$$

In other words, the “eLCQ” ansatz is poised to solve the long-range Coulomb-type part of a strongly interacting system. This is akin to the DLCQ ansatz which was shown in Ref. [6] to decouple the center of mass motion of a system from its more interesting physics.

4 Conclusion and Discussion

The goal of this paper was to find a complete set of eigenfunctions of QCD_{2A}. We succeeded in constructing a basis of the asymptotic theory without pair-production, consisting of multi-dimensional harmonic functions. In order to completely and exhaustively symmetrize the wavefunctions in the r parton sector, a group of operators of order 2r! is necessary and sufficient. This finite group of abstract symmetries is defined by the relations between the generators Eqs. (30)–(32). Paradoxically, this rather complicated arithmetic is based on the simple observation that “boundary conditions” on the wavefunctions have to be implemented as symmetries in a Hamiltonian approach (which leads to an integral equation for the eigenfunctions). Our finding that the eigenfunctions can be constructed largely algebraically with group theory arguments is
corroborated by comparison with numerical solutions of the theory.

At first glance our method of exhaustively symmetrizing a system quantized on the light-cone (“eLCQ”) applies to a specific family of systems, namely theories with adjoint degrees of freedom in one spatial dimension with a Coulomb-type long-range interaction. It seems likely, though, that the method presented here is more widely applicable due to its generality. In particular, exhaustive symmetrization deals with momentum as an abstract entity, i.e. it deals with it regardless of its Lorentz structure. There might well be requirements due to the Poincaré group, but this is not the point here. Rather, the fact that we have $r$ momenta requires us to symmetrize on purely abstract grounds, rather as a preconditioning of the wavefunctions akin to the Slater determinant implementing the anti-symmetrization requirement of the Pauli principle.

We presented evidence that “eLCQ” is a useful method at least for theories exhibiting similar integral equations as QCD$_{2A}$ like its bosonized version as discussed in Sec. 3.3. Other theories to which “eLCQ” can be straightforwardly applied include two-dimensional Yang-Mills theory coupled to adjoint scalars [2] and a theory with adjoint Dirac fermions tackled in [16]. Also, many of the supersymmetric models with adjoint particles (for instance [19]) could be re-evaluated with the present method.

We did not have the space to fully exploit the fact that the asymptotic spectrum of QCD$_{2A}$ is now completely mapped out, so there are several opportunities for future projects. For instance, the interaction of asymptotic states and the formation of multi-particle states can be studied. In Sec. 3.2 we laid down an initial plan how to proceed. And while the exponential rise of terms in the eigenfunctions presents some difficulty, one might be able to improve the precision of numerical solutions enough by using “eLCQ” basis functions to positively identify the single-particle content of the theory. Accidental symmetries described in Sec. 3.1 will help in this regard. Also, the structure of the asymptotic solutions may help to disentangle salient features of this and other theories. For instance, the “topological sector” of the theory, introduced in [7] to explain the appearance of fermion-fermion multi-particle states in the fermionic sectors, might be an artifact of finite group theory. As long as parton number is finite, there is a clear separation of group properties according to their (finite) order. Some combination rules for multi-particle states in terms of $T$ quantum numbers found in [7] might just be the result of such “artificial” group theoretical relations.

Acknowledgments

I thank Otterbein University for providing a work environment which made it possible to see this long-term project through to completion. The hospitality of the Ohio State University’s Physics Department, where most of this work was completed, is gratefully acknowledged.

The method of exhaustive symmetrization was conceived ten years after Hans-Christian Pauli’s passing. I’d like to dedicate the present paper, which I believe was done in the spirit of his work starting with [6], to his memory.
A Derivation of the Group Multiplication Table

To fully understand why there is only one quantum number $S$ associated with the large subgroup $E$ of $S$ operators, we work out the details here. We start with the simplest case $r = 4$. We need to show that the fully symmetrized wavefunction $\mathcal{G}(r)$ is an eigenstate to all three $S$ operators associated with its three excitations numbers $(n, m, l)$. Note that de facto there are only two independent $S$ operators at $r = 4$, which we also have to explain, along with the fact that two thirds — not half — of a state’s statelets carry an $S$ sign.

First we observe that the 4 members of the subgroup $B$ naturally split into four subsets, namely the cosets of the cyclic subgroup $\langle C \rangle$ under $T$, $I$, $T$, and $I T$. But $I$ is in the center of $G$, and therefore can be largely ignored. The cyclic structure of the Hamiltonian means that there is a conserved quantity which we might call $T C$-parity. Odd and even powers of the cyclic group carry different signs in general. Therefore an even(odd) power has to be mapped under any $S$ operation onto an even(odd) power of $C$. When we act with $T$, then the combined power has to be the same modulo two, e.g. $C_{mod2} \leftrightarrow TC_{mod2(j-1)}$. There is a twist. Namely, for states with mixed even and odd excitation numbers like $|\text{even} \rangle$, there is an additional sign, which shifts the relative power under $T$, so we have $C_{mod2} \leftrightarrow TC_{mod2}$. So the subgroup $B$ has two subsets even and odd under $T C$-parity, $B^e$ and $B^o$. We call their members (i.e. combinations like $T^i T^j \langle C \rangle$) $Z^e_j$ and $Z^o_j$. At $r = 4$ we have the pseudo-commutation relations:

$$S_i Z^e_j = Z^e_j S_i, \quad (\text{identity preserving}) \quad (34)$$
$$S_i Z^o_j = Z^o_j S_{mod2(i+1)}, \quad (\text{identity swapping}) \quad (35)$$

Note that

$$S_i B^e = B^e S_i \quad \text{and} \quad S_i B^o = B^o S_{mod2(i+1)},$$

i.e. while the individual operators do not pseudo-commute, they remain in the same subset. At $r = 4$ the following additional identities hold

$$S_1 S_2 = T Z^o_k S_1 = TS_2 Z^o_k, \quad (36)$$
$$S_2 S_1 = T Z^o_k S_2 = TS_1 Z^o_k.$$
for some $k$, so that $Z_k^o \in B^o$. In fact, $Z_k^o = T C^2$. In other words, the product of the two $S$-operators can be reduced to the leading one, but an odd $Z$ operator appears as well as an additional $T$ operator which switches the $T$ sign. We are now ready to calculate the action of $S_1$ on the totally symmetrized state. There are two versions of that state. If focusing on $S$ symmetry properties, it is natural to write the state in terms of *left* coset statelets $SB|r\rangle$

$$G|r = 4\rangle = (B^e + B^o)\ |r\rangle + SS_1 (B^e + B^o) \ |r\rangle + SS_2 (B^e + B^o) \ |r\rangle.$$  

On the other hand, we have to preserve cyclical properties due to the structure of the Hamiltonian, in which case we should use *right* coset statelets $BS|r\rangle$.

$$G|r = 4\rangle = (B^e + B^o)\ |r\rangle + S (B^e + B^o) S_1 |r\rangle + S (B^e + B^o) S_2 |r\rangle.$$  

Both requirements lead to the same constraint on the quantum numbers. In the latter case we have

$$S_1 G|r = 4; eee\rangle = S_1 (B^e + B^o) |r\rangle + SS_1 (B^e + B^o) S_1 |r\rangle + SS_2 (B^e + B^o) S_2 |r\rangle$$

$$= (B^e S_1 + B^o S_2) |r\rangle + S (B^e + B^o S_2 S_1) |r\rangle + S (B^e S_1 S_2 + B^o) |r\rangle$$

$$= S (B^e + B^o) |r\rangle + (B^e + STB^o) S_1 |r\rangle + (STB^e + B^o) S_1 |r\rangle$$

$$= SG|r = 4; eee\rangle \quad (if \ ST = 1),$$  

(37)

where we used Eq. (36) in the last step. The calculation goes analogously for $S_2$. We thus proved that a symmetrized state is an eigenstate of $S_1$ (and $S_2$) in the $|eee; T \pm S\pm\rangle$ sector of the theory. In the mixed sector, the $C^j$ and $T C^{j-1}$ terms get an extra sign for odd $j$ due to $(-1)^n = (-1)^l = -1$. This effectively reverses $T$, therefore the viable sectors are $|oeo; T \mp S\pm\rangle$.

If we organize in terms of the left cosets we come to the same conclusion. To wit

$$S_1 G|r = 4; eee\rangle = S_1 (B^e + B^o) |r\rangle + S (B^e + B^o) |r\rangle + SS_1 S_2 (B^e + B^o) |r\rangle$$

$$= S_1 (B^e + B^o) |r\rangle + S (B^e + B^o) |r\rangle + ST S_2 Z^o (B^e + B^o) |r\rangle$$

$$= S [(B^e + B^o) |r\rangle + SS_1 (B^e + B^o) |r\rangle + TS_2 (B^e + B^o) |r\rangle]$$

$$= SG|r = 4; eee\rangle \quad (if \ S = T).$$  

(38)

The $I$ quantum number is necessarily the opposite of $T$. The reason is that in the four-parton sector the pseudo-commutation relations are such that $T I$-parity $(-1)^{t+i}$ is conserved: commuting a (primary) $S$-operator with a $B$ operator will yield a different $B$ operator with equal $t + i$ (modulo two). This essentially links the identity and $T$.

---

20If this seems inconsistent, recall that the fully symmetrized state is symmetrized both in $B$ and in $S$. Hence, though parts of the state will appear to be symmetrized with respect to only one symmetry, the state as a whole has to be symmetric with respect to both operations. In general, this is only possible for certain combinations of quantum numbers. This is the reason why many sectors of the theory do not give rise to proper states.
statelets of $S_1$ to the $I T$ and $I$ statelets of $S_2$, respectively. Therefore $T$ and $I$ have to be different\(^{21}\) because otherwise the wavefunction is identically zero.

The higher parton sectors, $r > 4$, are harder to analyze because the pseudo-commutation relations are more complicated. In particular, there is no identity preserving relation akin to Eq. (34). Rather, we have to use Eqs. (31). Here $I$ is decoupled, and $I$-parity thus independently conserved. So we have to come up with an “operator calculus” that allows us to evaluate the $S$ sign of a combination of operators. As it turns out, $r = 5$ is not the most general case, but tractable and yielding clues for the generic case $r > 5$, so we discuss it here.

The exhaustively symmetrized state in terms of left coset elements can formally be written as

$$G|r⟩ = B|r⟩ + \sum_{j=1}^{N(r)} S_j S_j B|r⟩ = \left(1 + \sum_{j=1}^{N(r)} S_j S_j \right) B|r⟩,$$

where the $r$ primary operators $S_j$ carry an $S$ sign, so $S_j = S$ for $j \leq r$. The non-primary operators $S_j$ carry an unknown sign $S_j = \pm S$. As before, $N(r) = \frac{1}{2}(r-1)! - 1 = 11, 59, 359, \ldots$ The action of a primary operator $S_k$ on an exhaustively symmetrized state is then

$$S_k G|r⟩ = \left(S_k + \sum_{j=1 \atop j \neq k}^{N(r)} S_j S_k S_j \right) B|r⟩ = S \left(1 + SS_k + S \sum_{j=1 \atop j \neq k}^{N(r)} S_j S_k S_j \right) B|r⟩,$$

where we have used $S_k = S$ for primary operators. Due to the group axioms, the bi-operators $S_k S_j$ can be expressed in terms of a single $S$ operator followed by operators of the $B$ subgroup, to wit

$$S_k S_j = S_l I^i T^t C^c,$$

where the index $l$ and the powers $i, t, c$ can be looked up in a table like Table 2. But to reproduce the exhaustively symmetrized state $G|r⟩$, we need to have

$$SS_j I^i T^t C^c = S_l,$$

since the $B$ operators can be absorbed into $B|r⟩$, whence only the quantum numbers $I, T, C$ re-emerge. This is the condition we can use to identify the $S$ signs of the non-primary operators.

As an example, consider $r = 5$, where we can formally set $C = 1$, since cyclic permutations at odd $r$ do not carry signs. Acting with $S_1$, say, on $G[5]$ yields the operator indices and powers displayed in the $S_1$ column of Table 2. Since $I^i T^t = 1$ for all of them, Eq. (39) simplifies to $SS_j = S_1$, so that $S_6 = S_7 = S_8 = S_{10} = S_{11} = S^2$ and $S_9 = S$. Note the interplay between $S_9$ and $S_{10}$: since $S_l S_9 \propto S_{10}$ and $S_l S_{10} \propto S_9$, one operator gets an $S$ sign, and the other does not. Which one it is has actually to be decided by acting with another primary operator on the exhaustively symmetrized state or by writing the state in terms of right coset statelets.

\(^{21}\)In fact, this yields exactly two sectors, which makes sense in the even $r$ sectors, since here we have two excitation number sectors (even and mixed) for the required four (two massive and massless sectors. In the odd $r$ sectors there is only one condition due to the fact that there is no sign due to relative $C$ operators; at odd $r$ all cyclic permutations enter with a positive sign.
Table 2: The $\mathcal{E}$ part of the group multiplication table in the five-parton sector organized as left coset elements. Since there is a small number of primary operators, the table has been transposed, in the sense that the column-heading operators act on the row-leading operators, e.g. $S_1 S_2 = S_6$. It is obvious that $\mathcal{E}$ is not a subgroup of $G$; multiplying $S$ operators generates $\mathcal{B}$ operators.

The general algorithm is then as follows. Initially, we produce an exhaustive list of operators by acting with primary operators on primary operators until no new operators arise. This leads to a group multiplication table, such as Table 2 for $r = 5$ which can be used to write down consistent expressions for primary operators acting on the generic state (with yet undetermined $S$ signs) in terms of left or right coset statelets. The condition that the emerging state has to be an eigenstate of the primary operators determines the signs, and may lead to a further condition on $I$ as a function of $T$. Using the sign condition Eq. (39) we start with the $r$ known signs $S_j$ of the primary operators to get another $r$ signs $S_l$, and iterate the process. The only time this goes bad is when both $S_j$ and $S_l$ are unknown, as in the case of $S_9$ and $S_{10}$ at $r = 5$. Then we go on to the next $S_k$. Another constraint arises from the different powers of $I$ and $T$ in the group multiplication table. It will lead to a condition which determines one of these quantum numbers in terms of the other, e.g. $I = T$ at $r = 5$. At even $r$ there will be another condition linking (the value of) $S$ and $T$, leading to two viable sectors per (even or mixed) excitation number sector, which is what we need to produce exactly four sectors of bound states at every $r$.

B Sectors, Signs, and Sines

The assignment of symmetry sectors can be confusing due to several signs and quantum numbers involved. Let’s straighten things out by considering the simplest case, $r = 2$. Here, we have $\phi_2(x_1, x_2) \equiv \langle n \rangle$, so we think of the wavefunction $\phi_2$ depending on two momentum fractions $x_k$, as being represented by an abstract vector $\langle n \rangle$ labeled by one excitation number. The orientation symmetry $\mathcal{T}$ of the Hamiltonian acts on states only via their fermionic operators $b_{ij}(-x_k)$. By flipping color indices, $\mathcal{T}$ effectively reverses
the order of the operators and thus the order of momentum fractions. To compensate, also the wavefunction must be rewritten with the last momentum fraction now being first. Wavefunctions might be even or odd under this reversal, and the trace of operators might or might not acquire a sign under $T$. To assign a state to a sector, we have to take into account both behaviors. For example, a two-parton state looks like

$$|\Phi_2\rangle = \frac{1}{N_c} \int_{0}^{1/2} dx \phi_2(x, 1-x) \text{Tr}[b(-x)b(1-x)] |0\rangle.$$ 

Since

$$T b_{ij}(-x)b_{ji}(1-x) = b_{ji}(-x)b_{ij}(1-x) = \text{Tr}[b(-x)b(1-x)]$$

is $T$ even without the need to reverse the arguments, this state belongs to the $T$ even sector, even though the wavefunction $\phi_2$ is odd under reversal of its arguments. Technically, the wavefunction is represented as

$$|\phi_2\rangle = |n\rangle + TT |n\rangle + I(I|n\rangle + TT |n\rangle)$$

$$= |n\rangle + T(-1)^n |n\rangle + |1| - n\rangle + IT(-1)^n |n\rangle,$n$$

and also as

$$|\phi_2\rangle = |n\rangle + (-1)^{r+1} C |n\rangle = |n\rangle - (-1)^n |n\rangle,$n$$

where we recalled that $T|n\rangle = C|n\rangle = (-1)^n |n\rangle$. So for even $n$ we need $T = I$ and the vanishing of the wavefunction at $x = 0$ is guaranteed by the latter equation which produces a sine wavefunction with $I = -1$. Clearly, the even $n$ states constitute the massive sector. If $n$ is odd, on the other hand, we get cosines with $I = 1$. In both cases $T = -1$ even though the states are $T$ even, $T|\phi_2\rangle = |\phi_2\rangle$. In sum, its quantum number $T$ does not directly give away the $T$ sector of a state, but a negative(positive) $I$ quantum number always results in a wavefunction made of sines(cosines).

22The integral only runs to $\frac{1}{2}$ (in general) since operator products with flipped momentum fractions are redundant under the trace. The relative sign between the two Fock states $\text{Tr}[b(-x)b(1-x)]|0\rangle = -\text{Tr}[b(1-x)b(x)]|0\rangle$ will give rise to a wavefunction odd under argument reversal here, but not in general.

23Of course, we can also flip the $b$ operators and the wavefunction arguments, with the same result.

24We are deliberately sloppy here with normalization, which will be taken care of by the Hilbert space integral, Eq. (26).

25But almost, since $T b_{b_1}b_2 \cdots b_r = (-1)^{(r - \text{mod } 2r)/2} b_r b_{r-1} \cdots b_1$, we have $T G|r\rangle = T(-1)^{(r - \text{mod } 2r)/2} G|r\rangle$, so a state with $T = +1$ is a $T$ even state in the 4,5,8,9,12,13,\ldots parton sectors.
