We have studied ab initio the phase transition in PbZrO$_3$, a perovskite oxide usually presented as the prototypic anti-ferroelectric material. Our work reveals the crucial role that anti-ferrodistortive modes – involving concerted rotations of the oxygen octahedra in the structure – play in the transformation, as they select the observed anti-ferroelectric phase, among competing structural variants, via a cooperative trilinear coupling.

PACS numbers: 77.80.-e, 77.84.-s, 63.20.dk, 71.15.Mb

From a structural point of view, most ABO$_3$ perovskite oxides present phases that can be regarded as distorted versions of the cubic prototype [1–3]. Many are characterized by concerted rotations of the O$_6$ octahedra that constitute the basic building block of the lattice (e.g., SrTiO$_3$, most manganites and nickelates). A second group presents off-centering displacements of the A and B cations, which typically result in a switchable ferroelectric (FE) polarization (e.g., BaTiO$_3$ or PbTiO$_3$). Finally, these two features appear combined in some cases (e.g., BiFeO$_3$ or LiNbO$_3$). Exceptions to these typical situations are uncommon, but are attracting growing interest. In particular, materials displaying an anti-polar cation displacement pattern, i.e. the so-called anti-ferroelectric (AFE) order, are currently a focus of attention for both fundamental and applied reasons [4–6].

Many phases characterized by rotations of the O$_6$ octahedra (anti-ferrodistortive or AFD modes henceforth) also display anti-polar displacements of the A cations. Such anti-polar distortions are typically a consequence of the AFD modes [7] and would not exist in their absence; the ensuing AFE order can thus be regarded as improper in nature. In contrast, here we are interested in materials usually described as proper AFEs, in which a phase transition accompanied by a dielectric anomaly is supposedly driven by a primary anti-polar order parameter. (We adopt the most common definition of a proper AFE transition [4].) PbZrO$_3$ (PZO) displays such a striking behavior, and is usually presented as the prototypic AFE crystal [8–11]. However, the nature of PZO’s transition is far from being settled, as new experimental results and conflicting physical pictures have recently been reported [12, 13]. Hence, there is a need to clarify PZO’s behavior and status as a model AFE. Here we present a first-principles investigation to that end.

Main modes and their couplings.— We followed the usual first-principles approach to the investigation of a non-reconstructive phase transition, taking advantage of the experimental knowledge of the high-temperature (cubic Pm3m, with the elemental 5-atom unit cell) and low-temperature (orthorhombic Pbam, with a 40-atom unit cell) structures [14, 15]. The unit cell of the AFE Pbam phase can be viewed as a $\sqrt{2} \times 2\sqrt{2} \times 2$ multiple of the elemental unit, as sketched in Fig. 1(a). More precisely, if $a_1 = a(1,0,0)$, $a_2 = a(0,1,0)$, and $a_3 = a(0,0,1)$ define the ideal 5-atom cell in a Cartesian reference, the Pbam cell vectors are given by $b_1 = a_1 - a_2$, $b_2 = 2(a_1 + a_2)$, and $b_3 = 2a_3$. As shown in Fig. 1(b), PZO’s AFE distortion involves displacements of the Pb cations along the pseudo-cubic [110] direction, modulated according to the wave vector $q = q_\Sigma = 2\pi(1/4,1/4,0)/a$ of the first Brillouin Zone (BZ) of the 5-atom cell. (We give all vectors in the pseudo-cubic setting.)

We used standard methods based on density func-
tional theory (details in [16]) to relax the $Pm\bar{3}m$ and $Pbam$ phases, and got results [16] in good agreement with experiments [14, 15] and previous theoretical works [17, 18]. Then, we employed standard crystallographic tools [19] to identify the symmetry-adapted distortions connecting these two structures, and found three dominating ones [20]: (1) A $\Sigma_2$ component associated with the $q_\Sigma$ wave vector and which captures 36.0 % of the total distortion. This is the AFE\textsubscript{\Sigma} displacement pattern sketched in Fig. 1(b). Interestingly, this distortion also has certain AFD character, as oxygen displacements reminiscent of an in-phase rotation about the $b_3$ axis are clearly appreciated. (2) A $R_4^+$ component associated to $q_R = 2\pi(1/2, 1/2, 1/2)/a$ and involving anti-phase rotations of the $O_6$ octahedra about the $[110]$ axis; see sketch in Fig. 1(c). This AFD distortion amounts to 59.7 % of the total. (3) A $S_4$ distortion associated to $q_S = 2\pi(1/4, 1/4, 1/2)/a$ that captures 4.1 % of the total and is sketched in Fig. 1(d). This distortion too has a mixed character, combining AFE features with others that are reminiscent of AFD modes.

We then considered the simplest model that captures how the energy of PZO changes as a function of these three distortions of the cubic phase. Let $Q_\Sigma$, $Q_R$, and $Q_S$ denote the respective amplitudes, which we normalize so that $Q_\Sigma = Q_R = Q_S = 1$ describe the situation at the $Pbam$ ground state. To fourth order, the energy has the form [19]:

$$E = E_{\text{cubic}} + A_\Sigma Q_\Sigma^2 + B_\Sigma Q_\Sigma^4 + A_R Q_R^2 + B_R Q_R^4 + A_S Q_S^2 + B_S Q_S^4 + C_{\Sigma RS} Q_\Sigma Q_R Q_S + D_{ER} Q_\Sigma^2 Q_R^2 + D_{\Sigma S} Q_\Sigma^2 Q_S^2 + D_{RS} Q_R^2 Q_S^2. \tag{1}$$

Interestingly, we find a trilinear coupling $C_{\Sigma RS}$ involving all three modes under consideration. Such a coupling, whose existence had been noticed already [13, 21], is cooperative in nature and provides a mechanism for the simultaneous occurrence of the involved distortions. In order to get a quantitative estimate of the model parameters, we investigated various paths to transit between the $Q_\Sigma = Q_R = Q_S = 0$ and $Q_\Sigma = Q_R = Q_S = 1$ states. Figure 2 shows the results; the quality of the fit to Eq. (1) (parameters in caption) is excellent [22].

Several conclusions can be drawn from these results. First, all three $\Sigma_2$, $R_4^+$, and $S_4$ modes are instabilities of the cubic phase when considered individually. The AFD instability is the dominant and strongest one, closely followed by the AFE mode; in contrast, the energy gain associated with the $S_4$ mode is clearly smaller. Next, note that all the biquadratic couplings in Eq. (1) are competitive in nature, i.e., we have $D_{\Sigma R}, D_{\Sigma S}, D_{RS} > 0$. Interestingly, the AFE and AFD instabilities are strong enough to coexist in spite of their mutual repulsion; in contrast, condensation of either the AFE or AFD distortion results in the stabilization of the $S_4$ mode. Finally, and remarkably, the trilinear term has a considerable impact in the ground state energy: when going from $(1, 1, 0)$ to $(1, 1, 1)$ via relaxation of the $S_4$ distortion, the energy undergoes a considerable reduction, by about 27 meV per formula unit (fu). These three distortions together produce an energy gain of 392 meV/fu compared to the cubic phase. Full relaxation (via other structural modes not considered here) lead to a further energy decrease of only 3 meV/fu, which confirms the dominant character of $Q_\Sigma$, $Q_R$ and $Q_S$.

**Competing phases.**—Earlier studies suggest that the equilibrium $Pbam$ phase of PZO competes with other FE, AFE, and AFD structures [17, 21, 23–25]. We thus ran a series of computer experiments to shed some light on why PZO chooses such an unusual phase over more common alternatives.

We computed the energy of several hypothetical PZO phases displaying combinations of the most typical AFD and FE displacement patterns. We also considered a number of AFE patterns similar to AFE\textsubscript{\Sigma} but with different periodicities. To obtain the AFE\textsubscript{\Sigma} states, we first displaced the Pb cations by hand along the $[110]$ direction with the spatial modulation of the targeted wave vector, and then let the structure fully relax while preserving the initial symmetry. (In some cases the relaxed structures present more complex Pb displacements than initially expected.) From the results, which are summarized in Ta-
able I, a number of conclusions emerge. On one hand, the pure FE state $R3m$ is more stable than the purely AFD or AFE ones, although they all lie relatively far from the ground state (e.g., the $R3m$ solution lies at 58 meV/fu above). Combinations of FE and AFD distortions, on the other hand, can produce structures that are remarkably close to the ground state (the $R3c$ and $Ima2$ solutions lie at 7 meV/fu and 19 meV/fu, respectively). In fact, the energy difference between the $Pbam$ and $R3c$ or $Ima2$ phases is smaller than the energy associated with the trilinear term discussed above (27 meV/fu), which suggests that such a coupling is essential for the stabilization of the ground state. The central role played by the mutual interaction between modes is also corroborated by our results for the AFE$_4$ phases: $q_{c}$ is not the most favorable modulation, suggesting that, in absence of the $R^+_1$ and $S_4$ modes, there would be no reason for the crystal to favor it over, e.g., $q = 2\pi(1/8, 1/8, 0)/a$.

**Phonon mode analysis.**—The results discussed so far point to a crucial role played by the AFD distortions in stabilizing the observed antiferroelectric phase of PZO. It is therefore reasonable to speculate that condensation of the AFD modes may have an important impact on the unstable phonon branch associated with the polar (FE/AFE) modes. To verify this hypothesis, we calculated the phonon spectrum of PZO in two different configurations: first in the optimized cubic phase, and second in a phase where we optimized (by freezing it in) the ground state (the relevant AFD ($a^*a^*-c^0$) component, while keeping the other structural parameters identical to those of the cubic geometry.

The resulting phonon bands, calculated on a $\Gamma'Y'$ path in reciprocal space, are shown in Fig. 3. At $Q_R = 0$ [Fig. 3(a)] we recover the spectrum of the cubic reference, appropriately folded onto the smaller BZ of the $\sqrt{2} \times \sqrt{2} \times 2$ cell that we used to accommodate the AFD tilts. As previous authors noted [26], this phase presents multiple strong instabilities of both polar and AFD character, with the latter (particularly those at $q_R$) appearing to dominate over the former. As expected, we observe a whole band of unstable polar distortions, which includes the FE and AFE patterns associated with most of the phases of Table I. Within this band, the FE mode at $\Gamma'$ clearly dominates over the AFE modes.

The onset of the AFD distortions has a dramatic in-

**TABLE I.** Computed energies of PZO adopting several structures characterized by the presence of AFD (labeled using Glazer’s notation [1]) and polar distortions. For the polar distortions, we indicate whether they are FE or AFE and the (approximate in some cases) direction along which the dipoles lie. In cases in which there is more than one AFE component, we only indicate the dominant wave vector. The structures with asterisk have the same space group as the ground state (gs), but their corresponding cells are different.

| Structure | $E - E_{gs}$ (meV/fu) | AFD dist. | polar dist. |
|-----------|------------------------|-----------|-------------|
| $Pbam$ (gs) | 0 | $a^-a^-c^0$ | AFE [110] |
| $Pm3m$ | 375 | – | – |
| $I4/mcm$ | 113 | $a^-b^0b^0$ | – |
| $I\bar{m}cm$ | 52 | $a^-a^-c^0$ | AFE [110] |
| $R3c$ | 75 | $a^-a^-a^-$ | – |
| $Pnma$ | 35 | $a^-a^-c^+$ | AFE $\sim [110]$ |
| $P4mm$ | 124 | – | FE [100] |
| $Amm2$ | 91 | – | FE [110] |
| $R3m$ | 58 | – | FE [111] |
| $Ima2$ | 19 | $a^-a^-c^0$ | FE [110] |
| $R3c$ | 7 | $a^-a^-a^-$ | FE [111] |
| $Pbam^*$ | 217 | – | AFE [110] |
| $Pbam^*$ | 68 | – | AFE $\sim [100]$ |
| $Pbam^*$ | 60 | – | AFE $\sim [100]$ |

FIG. 3. (Color online) Phonon bands calculated along the $\Gamma'Y'$ line in the BZ of the 20-atom ($\sqrt{2} \times \sqrt{2} \times 2$) cell used to simulate the $Q_R$-distorted structure (see text). Primed labels denote wave vectors of this BZ. As a consequence of the folding, such a path encompasses four inequivalent segments in the BZ of the primitive cubic cell, each of which has been assigned a different color and symbol type: $\Gamma$-$\Sigma$ (black circles), $M$-$\Sigma$ (red squares), $Z$-$S$ (green crosses), and $R$-$S$ (blue stars), where $q_{\Sigma} = -q_{\bar{\Sigma}}$ and $q_{S} = -q_{\bar{S}}$. The size of each symbol corresponds to the decomposition (projection) of a given mode into the four components described above. (a): Cubic phase ($Q_R = 0$). (b): Distorted phase ($Q_R = 1.13$). The dashed lines in (b) indicate the hypothetical phonon spectrum obtained by suppressing the interaction (off-diagonal terms) between $q$-point pairs (see text). Only the low-energy part of the spectrum, including the unstable branches, is shown.
fluence on the unstable region of the phonon spectrum [Figure 3(b)]. Most of the formerly unstable modes have been stabilized — only five branches with imaginary frequency persist. At the $\Gamma'$ point of the folded BZ these are (from most to least unstable): (A) a $c^+$-type AFD mode that would lead to the $P\text{ma}$ structure of Table 1; (B) a FE mode with the polarization oriented along [110] that would lead to the $I\text{ma}2$ phase; (C) a $c^-$-type AFD mode leading to $R\text{Sc}3$; (D) an AFE mode with $q = 2\pi(1/2, 1/2, 0)/a$ and polar distortions aligned with [110]; (E) a similar AFE mode but with $q = 2/\pi(0, 0, 1/2)/a$ that is also present in the $P\text{ma}$ phase. All of these branches, except two, eventually become stable when moving away from $\Gamma'$. The surviving doublet (F) is predominantly of AFE-$c^+$ character (80%) with a smaller $S_1$ component (20%). This is, of course, the distortion that directly leads to the ground-state structure. Remarkably, the doublet is now more unstable than the FE mode at $\Gamma'$ [only AFD-$c^+$ appears to be stronger in panel (b)], confirming the crucial role played by $Q_R$ in selecting a specific AFE ground state [27].

To understand which couplings are primarily responsible for such an outcome, we performed a further computational experiment. Note that, to leading order, the effect of a certain $Q_R = Q_R$ distortion on the phonon spectrum is given by two types of terms: trilinear ones of the form $Q_{q_1,s}Q_{q_2,s'}Q_{R}$, where $s$ and $s'$ label atomic displacements and $q_1 + q_2 + q_R$ is a reciprocal lattice vector; biquadratic ones of the form $Q_{q,s}Q_{q,s'}Q_{R}^2$. Hence, we recalculated the phonon bands of the $Q_R$-distorted structure while suppressing the off-diagonal elements of the dynamical matrix that couple $(q_1, q_2)$ pairs. The result, shown as dashed lines in Fig. 3(b), clearly shows that the trilinear terms play a crucial role in pushing the zone-boundary doublet (F) to lower energies than the FE mode at $\Gamma'$, and effectively favors the occurrence of the former in the ground state.

Nature of PZO’s phase transition. — PZO’s AFE structure involves distortions of various symmetries, and it seems experimentally proved that all of them appear spontaneously at a single, strongly-discontinuous transformation upon cooling from the cubic phase [4, 11]. Our simulations do not incorporate thermal effects, which prevents us from discussing PZO’s transition in a conclusive way. Yet, they provide some hints that are useful in light of recent experimental measurements in which simultaneous softening of multiple phonon modes was observed [12, 13]. Based on the fact that the acoustic branch was also involved in the softening, theoretical models have been formulated where the phase transition is rationalized in terms of flexoelectric couplings [12]. Note that in this recent model the ferroelectric branch is believed to drive the transition and, in line with earlier works [10], the AFD distortions are assumed to play a secondary role.

Let us begin by noting that, in principle, a strongly first-order transition like PZO’s may or may not be accompanied by a significant mode softening. Our results are compatible with such a quasi-reconstructive transformation, of the sort that occurs in perovskite oxides sharing some of PZO peculiar features. A notable example is BiFeO$_3$ [28–31], which also presents stable phases lying far below the cubic phase, strong FE, AFE, and AFD instabilities, low-lying $R\text{Sc}$ and $P\text{ma}$ polymorphs, etc.

Notwithstanding these considerations, a particular soft mode might still drive the transformation. Let us assume that the AFD $R_T^+$ mode plays such a role. (Our argument remains valid if we swap the roles of the $R_T^+$ and $\Sigma_2$ modes.) Then, let us consider the harmonic part of a Landau potential for the $\Sigma_2$ and $S_1$ modes, at the AFD transition temperature ($T_R$) at which a $R_T^+$ distortion of amplitude $Q_R$ materializes. We would have:

$$F(Q_S, Q_S) \sim |\tilde{A}_c(T_R - T_S) + D_{\Sigma R} \tilde{Q}_R|^2 + |\tilde{A}_S(T_R - T_S) + D_{RS} \tilde{Q}_R|^2 + (C_{\Sigma RS} Q_R) Q_S Q_S,$$

where $T_S$ and $T_S$ are the critical temperatures for the corresponding instabilities, and all the $A$ and $D$ parameters are positive. Our calculations show that the AFD and AFE$_2$ instabilities are similarly strong; thus, we can tentatively assume $T_R \gtrsim T_S$. In such conditions, if $|\tilde{A}_c(T_R - T_S) + D_{\Sigma R} \tilde{Q}_R|$ is comparable in magnitude to $C_{\Sigma RS} Q_R$, then the above harmonic term would present a combined $\Sigma_2 + S_4$ instability. In other words, the occurrence of a discontinuous AFD transition could spark the $\Sigma_2$ and $S_4$ distortions, resulting in a single $P\text{m}3\text{m} \rightarrow P\text{ma}$ transformation. (Alternatively, if the conditions for the $\Sigma_2 + S_4$ instability occurred at $T_{\Sigma S} \lesssim T_R$, an intermediate phase could be observed between $T_{\Sigma S}$ and $T_R$.)

Regardless of whether we should view PZO’s transition as a quasi-reconstructive one or a soft-mode driven one, the central role of the AFD modes (to stabilize the $P\text{ma}$ phase over other alternatives or provide the induction mechanism through a trilinear coupling, respectively) is clear from our results. This is in line with the hypotheses made in [13] and questions the validity of models that treat the AFD distortions as a secondary effect [12].

In summary, our work has led to key insights concerning PZO’s AFE transition. Most importantly, our results suggest that the multi-mode character of the transformation is essential to its very occurrence. In particular, we have found that AFD modes associated to oxygen octahedra rotations play a key role in selecting the experimentally observed AFE structure, over competing structural variants, via a cooperative trilinear coupling. Consequently, it does not seem appropriate to think of a primary AFE order parameter driving PZO’s transition; rather, our results suggest a peculiar improper-like nature of the AFE order. PZO thus appears as a very
complex material, which poses the provocative question of whether its intricate behavior can be taken as representative of anti-ferroelectricity in perovskite oxides.
