Abstract

Background: The vaginal microflora is important for maintaining vaginal health and preventing infections of the reproductive tract. The rectum has been suggested as the major source for the colonisation of the vaginal econiche.

Methods: To establish whether the rectum can serve as a possible bacterial reservoir for colonisation of the vaginal econiche, we cultured vaginal and rectal specimens from pregnant women at 35-37 weeks of gestation, identified the isolates to the species level with tRNA intergenic length polymorphism analysis (tDNA-PCR) and genotyped the isolates for those subjects from which the same species was isolated simultaneously vaginally and rectally, by RAPD-analysis.

One vaginal and one rectal swab were collected from a total of each of 132 pregnant women at 35-37 weeks of gestation. Swabs were cultured on Columbia CNA agar and MRS agar. For each subject 4 colonies were selected for each of both sites, i.e. 8 colonies in total.

Results: Among the 844 isolates that could be identified by tDNA-PCR, a total of 63 bacterial species were present, 9 (14%) only vaginally, 26 (41%) only rectally, and 28 (44%) in both vagina and rectum. A total of 121 (91.6%) of 132 vaginal samples and 51 (38.6%) of 132 rectal samples were positive for lactobacilli. L. crispatus was the most frequently isolated Lactobacillus species from the vagina (40% of the subjects were positive), followed by L. jensenii (32%), L. gasseri (30%) and L. iners (11%). L. gasseri was the most frequently isolated Lactobacillus species from the rectum (15%), followed by L. jensenii (12%), L. crispatus (11%) and L. iners (2%).

A total of 47 pregnant women carried the same species vaginally and rectally. This resulted in 50 vaginal/rectal pairs of the same species, for a total of eight different species. For 34 of the 50 species...
pairs (68%), isolates with the same genotype were present vaginally and rectally and a high level of genotypic diversity within species per subject was also established.

**Conclusion:** It can be concluded that there is a certain degree of correspondence between the vaginal and rectal microflora, not only with regard to species composition but also with regard to strain identity between vaginal and rectal isolates.

These results support the hypothesis that the rectal microflora serves as a reservoir for colonisation of the vaginal econiche.

**Background**

The composition of the human vaginal microflora is affected by several host factors, including, among others, age, menarche, sexual activity, pregnancy and the use of contraceptives or spermicides, as well as individual habits such as douching [1]. Several bacterial species are known to colonize both the gastrointestinal and the reproductive tract, and the rectum has been suggested to play an important role as a source or reservoir for organisms that colonize the vagina [2,3]. It is important to establish to which degree this is also the case for lactobacilli, the predominant group of microorganisms of the normal vaginal microflora, because these bacteria are generally known to produce endogenous microbicides such as lactic acid, which acidifies the vagina, and hydrogen peroxide (H$_2$O$_2$), toxic to other bacteria and viruses, including HIV [4]. Studies of vaginal lactobacilli have demonstrated that *L. crispatus*, *L. jensenii*, *L. gasseri* and *L. vaginalis* are the most commonly recovered species of H$_2$O$_2$-producing lactobacilli [5-9] and the absence of H$_2$O$_2$-producing lactobacilli in the vagina has been associated with an increased risk for bacterial vaginosis (BV) [10,11]. BV has been linked to increased shedding of HIV in the female genital tract [12], increased acquisition of HIV [10] and herpes simplex virus type 2 [10,12] and with preterm birth [13].

In order to document in more detail a possible rectal origin of the vaginal microflora, this study was set up not only to compare the bacterial species present in vagina and rectum, but in addition, to compare the genotypes of those strains belonging to species that were present simultaneously at both sampling sites of the same subject.

**Methods**

**Patients**

The study was approved by the research ethics committee (IRB protocol nr 2007/096) of Ghent University Hospital, Belgium. All women attending the clinic were included and participating women gave a written informed consent. Between April and December 2007, 132 paired vaginal and rectal swabs were collected from pregnant women at 35 - 37 weeks of gestation.

**Sampling procedures**

All specimens were collected using nylon flocked swabs that were submerged into 1 ml of liquid Amies transport medium (eSwab, Copan Diagnostics, Brescia, It.). For rectal specimens, a swab was carefully inserted approximately 1.5 - 2 cm beyond the anal sphincter and then gently rotated to touch anal crypts.

Vaginal samples were collected by inserting a swab into the vagina. The swab was rolled round through 360 degrees against the vaginal wall at the midportion of the vault. At Ghent University Hospital, the routine screening for group B streptococci of pregnant women is always performed during the prenatal consultation at 35-37 weeks’ gestation according to the CDC guidelines for the prevention of perinatal Group B streptococcal disease [14]. All study samples were collected by midwives and transported to the Laboratory for Bacteriology Research of the University of Gent within 4 hours.

**Culture and Gram staining**

A total of 70 µl from the Amies liquid transport medium of each of the vaginal and rectal swabs was inoculated onto Columbia CNA agar with 5% sheep blood (Columbia CNA agar, Becton Dickinson, Erembodegem, Belgium) respectively De Mann Rogosa Sharp Agar (MRS, Oxoid, Hampshire, UK) and then incubated at 37°C in an anaerobic chamber (10% H$_2$, 10% CO$_2$, 80% N$_2$) (Bug-Box, LedTechno, Heusden-Zolder, B.) for 72 h. Another 50 µl of the vaginal swab suspension was taken for smear preparation for the Gram stain.

Gram stain based grading was carried out according to modified Ison & Hay criteria [15], as described by Verhelst et al. [16].

Grade Ia specimens contained mainly *Lactobacillus crispatus* cell types, i.e. plump, quite homogeneous lactobacilli, grade Ib contained non-*L. crispatus* cell types, i.e. long or short, thin lactobacilli, grade Ia contained mixtures of *L. crispatus* and non-*L. crispatus* cell types, grade I-like contained irregular-shaped Gram positive rods, grade II contained a mixture of *Lactobacillus* cell types and bacterial
vaginosis-associated bacteria (Gardnerella, Bacteroides-
Prevotella and Mobiluncus cell types), whereas samples
devoid of Lactobacillus cell types with the presence of only
Gardnerella, Bacteroides-Prevotella or Mobiluncus cell types
were classified as grade III. Finally, samples were classified
as grade IV when Gram positive cocci were predominantly
present and as grade 0 when no bacterial cells were
present [16].

**DNA-extraction from isolates**

DNA was extracted from cultured isolates by alkaline lysis
as follows: One bacterial colony was suspended in 20 µl
of lysis buffer (0.25% sodium dodecyl sulfate, 0.05 N
NaOH) and heated at 95°C for 15 min. The cell lysate was
diluted by adding 180 µl of distilled water. The cell debris
was spun down by centrifugation at 16,000 g for 5 min.
Supernatants were used for PCR or frozen at -20°C until
further use.

**Identification of isolates**

From all 132 women, 8 colonies per subject, i.e., one colo-
yony of each of the two most abundant colony types from
both Columbia CNA and MR5 agar plates and for both
rectal and vaginal swabs were picked, i.e. a total of 1056
isolates. Isolates were identified by 16S rRNA intergenic
length polymorphism analysis (tDNA-PCR) as described before
[8,17-19]. Briefly, the 16S rRNA-intergenic spacer regions
were amplified by PCR using consensus primers, applicable to
most bacterial species, and the resulting fingerprints,
obtained by separation of the amplified spacers by capil-
lar electrophoresis on an ABI310, were compared with
those of a large library of reference strains of the different
species, shown in previous studies to be part of the vaginal
microflora. Isolates with fingerprints that did not match
fingerprints already present in the library were considered
as not identifiable.

**Genotyping of isolates**

Isolates of species present in both vagina and rectum of
the same subject were genotyped using RAPD-analysis
with RAPD Ready-to-Go beads (GE Healthcare, Bucking-
amshire, UK) as described previously [20] with primer
OPM1 (5’ GIT GGT GGC T) at a final concentration of 2
µM, including 0.2 µM of fluorescent TET-labeled OPM1
primer. After 5 min at 94°C, 5 min at 35°C and 5 min at
72°C, reaction mixtures were cycled 30 times in a Veriti™
Thermal Cycler (Applied Biosystems, Foster City, Ca.),
with the following conditions: 30 s at 94°C, 1 min at
35°C, and 1 min at 72°C, with a final extension period of
5 min at 72°C. Reaction vials were then cooled to 10°C
until electrophoresis.

**Capillary electrophoresis**

A volume of 11.9 µl of deionized formamide (ACE forma-
mide, Lucron, De Pinte) was mixed with 0.6 µl of an inter-
nal size standard mixture containing 0.3 µl of the ROX-
400 high-density size standard (Applied Biosystems, Fos-
ter City, Ca.) and 0.3 µl of Map marker 1000 size standard
(BioVentures, Murfreesboro, Tn.). One µl of RAPD-PCR
product was added. The mixtures were denatured by heat-
ing at 95°C for 3 min and placed directly on ice for at least
10 min. Capillary electrophoresis was carried out using an
ABI-Prism 310 genetic analyzer (Applied Biosystems) at
60°C, at a constant voltage of 1.5 kV, and at a more or less
constant current of approximately 10 mA. Capillaries with
a length of 47 cm and diameter of 50 µm were filled with
performance-optimized polymer 4. Electropherograms
were normalized using Genescan Analysis software, ver-
sion 2.1 (Applied Biosystems).

**Data analysis**

tDNA-PCR and RAPD fingerprints were obtained as table
files from the GeneScan Analysis software (Applied Bio-
systems) and analyzed with BaseHopper, an in house soft-
ware program [17]. The obtained tDNA fingerprints were
compared with those of a library of tDNA fingerprints
obtained from reference strains, representing most vaginal
species isolated in previous studies and previously identi-
fied by 16S rRNA gene sequencing [8].

Similarity between RAPD fingerprints was calculated
using the Dice algorithm. Clustering analysis was done
with the Neighbor module of the Phylip software http://
evolution.genetics.washington.edu/phylip.html, using
the Neighbour joining algorithm. Isolates of which the
RAPD fingerprints were clustered together, were inspected
visually to confirm similarity.

**Results**

**Categorization of vaginal microflora**

Samples were categorized as grade Ia for 55 subjects
(41.6%), grade Ib for 37 (28.0%), grade lab for 13
(9.8%), grade I-like for 5 (3.8%), grade II for 14 (10.6%),
grade III for 6 (4.5%) and grade 0 for 2 (1.5%).

The most common genus recovered from grade Ia, Ib and
lab specimens was Lactobacillus. Grade Ia samples con-
tained predominantly L. crispatus (75.0%) and L. jensenii
(43.6%), whereas L. gasseri (40.5%) and L. iners (27%)
were the most frequently present species in grade Ib spec-
imens. The five grade I-like specimens were found to con-
tain respectively Bifidobacterium bifidum and Enterococcus
faecalis, L. gasseri and E. faecalis, L. jensenii, L. gasseri and
Gardnerella vaginalis or L. rhamnosus.

The most characteristic cultured organisms in grade II and
grade III specimens were G. vaginalis (28% and 33%,
respectively), Actinomyces neuii, Aerococcus chrisstenii,
Atopobium vaginae and Finegoldia magna. The lactobacilli
cultured from the six grade III specimens were respectively
L. iners, L. gasseri, L. jensenii, L. crispatus, L. rhamnosus and a combination of L. gasseri and L. vaginalis.

Rectal and vaginal prevalence of different bacterial species

For a total of 132 women, 4 colonies each were picked from the vaginal and rectal sites, i.e. a total of 1056 colonies were picked and subjected to identification by tDNA-PCR. Of these, 844 could be identified.

A total of 103 isolates gave no amplification or tDNA-PCR patterns composed of only a few and short tRNA intergenic spacers. Most of the isolates for which no amplification or only a few fragments could be obtained, are probably corynebacteria, which yield poor tDNA-PCR fingerprints (unpublished data).

Finally, 109 isolates gave uninterpretable patterns, due to mixed cultures, as was confirmed by 16S rRNA gene sequencing for 20 of these, whereby the sequences could not be interpreted because of ambiguities, pointing to mixtures.

The frequency of vaginal and rectal colonization by lactobacilli and the other most prominent bacterial species is shown in Table 1. A total of 63 bacterial species were identified, 9 (14%) occurring only vaginally, 26 (41%) only rectally and 28 (44%) in both vagina and rectum, with 8 species that could be isolated simultaneously from rectum and vagina of 47 subjects.

Overall, 121 of 132 pregnant women (92%) were colonized vaginally by lactobacilli and 52 (39%) carried rectal lactobacilli. Seventy two pregnant women (54.5%) carried lactobacilli from the rectum, at a frequency of \(\frac{121}{132}\) subjects positive, whereas 7% of them carried lactobacilli only vaginally, and 20% were colonized by lactobacilli only rectally, followed by L. gasseri (11%) and L. iners (10%).

Besides these five Lactobacillus species, all other species were encountered in no more than five subjects, except for G. vaginalis (8% of subjects positive).

L. gasseri was the most frequently isolated Lactobacillus species from the rectum (20/132 subjects positive), followed by L. jensenii (16) and L. crispatus (14). L. iners was isolated rectally from only 2 subjects. L. vaginalis was isolated only from the vagina, whereas L. fermentum, L. coleohominis and L. fermentum were only isolated from the rectum, at a frequency of \(\leq 1\%\). Rectally, the most abundant species that could be cultured, were Streptococcus anginosus group (47/132 subjects positive), Finegoldia magna (40), Peptoniphilus indolicus (25) and E. faecalis (21).

Forty six pregnant women (35%) were colonized by at least 2 different Lactobacillus species, with 42 of them only vaginally, two only rectally and another two both in the vagina and rectum. Taking into account vaginal and rectal colonization by more than one Lactobacillus species, 18 women (13.6%) were colonized by both L. crispatus and L. jensenii, of which 17 vaginally and one rectally, five (4%) by L. jensenii and L. gasseri of which 3 vaginally and 2 rectally and another 18 (13.6%) with other combinations of Lactobacillus species. Seven subjects (5.3%) were colonized vaginally by more than two Lactobacillus species. In total, of the 121 women colonized vaginally by lactobacilli, 42 (32%) were colonized by two or more Lactobacillus species and of the 52 women colonized by lactobacilli rectally, two (1.5%) were colonized by two Lactobacillus species. A total of 47 (35%) of 132 pregnant women were colonized both vaginally and rectally with the same species and 3 of these 47 women carried two species both vaginally and rectally. The species found to be simultaneously present in the same subject both rectally and vaginally were L. crispatus (n = 10 subjects), L. jensenii (14), L. gasseri (16), S. anginosus (3), S. agalactiae (3), S. salivarius (1), E. faecalis (2) and Bifidobacterium species (1).

In summary, 50 vaginal/rectal pairs of the same species were observed in 47 subjects, for a total of eight different species.

Genotyping of bacterial isolates from the vagina and the rectum

For 34 of the 50 vaginal/rectal species pairs, isolates with the same genotype were present vaginally and rectally.

Table 2 presents the genotyping results for each of the 50 vaginal/rectal species pairs. We found the same genotype for both rectal and vaginal L. crispatus isolates in 7/10 subjects, for L. gasseri in 14/16, for L. jensenii in 7/14, for Bifidobacterium species in 1/1, for E. faecalis in 1/2, for S. agalactiae in 2/3, and for S. anginosus in 2/3.

Figure 1 shows the genotyping results for four pregnant women for which rectal and vaginal isolates belonged to a single genotype, for L. gasseri (Figure 1), L. crispatus (Figure 2), L. jensenii (Figure 3) and E. faecalis (Figure 4).

Genotyping results: variability among multiple isolates per subject

For only 2 of the 9 vaginal samples of which more than one L. crispatus isolate was picked, all the isolates belonged to the same genotype. For the 7 other vaginal samples, 2 to 3 genotypes of L. crispatus were present. In 7 of the 10 cases for which rectal/vaginal pairs of L. crispatus
| Species                                      | Only vaginala | Only rectal | Vaginal + rectal | Overall |

a: Number of pregnant women carrying this species.
were observed, the one or two rectal *L. crispatus* isolates had the same genotype of at least one of the one to four vaginal isolates. For only two of the 11 women for which more than one vaginal *L. jensenii* isolate was present, the genotype of all isolates was identical. For another two of these 11 women, all four isolates were genotypically different. For half (7/14) of the subjects with *L. jensenii*, the presence of identical rectal and vaginal isolates could be established.

For the other species, a similar pattern of large heterogeneity among the vaginal strains of the same species was also observed and about half of the women were found to carry at least one vaginal isolate genotypically identical to at least one rectal isolate.

**Discussion**

During the last decade, the composition of the vaginal microflora has been well characterised, using culture based and culture independent methods [8,21-27]. However, the origin of lactobacilli and BV associated bacteria remains less well-understood and different opinions exist as to whether the vaginal bacteria are largely endogenous or whether there is continuous recolonization from the rectum. Few studies have addressed the species composition of both vagina and rectum in the same subjects [2,3,5] and only the study of Marrazzo et al. [3] genotyped paired rectal/vaginal isolates, from lesbian women. To our knowledge, this is the first study among pregnant women to address the relatedness of vaginal and rectal strains to the degree of clonal identity of the strains.

**Rectal and vaginal occurrence of lactobacilli**

Table 3 compares the findings of this study with those of two other groups with respect to rectal and vaginal colonization by lactobacilli. The four species predominant in the vagina, as established in this study, i.e. *L. crispatus, L. jensenii, L. gasseri* and *L. iners* are in correspondence with previous studies [2,3,6,16,28-30].

Both Antonio et al. [2] and Marrazzo et al. [3] reported *L. crispatus* and *L. jensenii* twice as much vaginally compared to their rectal occurrence, whereas we report four, respectively three times higher abundance of these species vaginally. Both groups also found approximately equal abundance for *L. gasseri* in rectum and vagina, whereas we could isolate twice as much *L. gasseri* from the vagina. *L. iners* was found ten times more often vaginally than rectally in this study and 20 times more vaginally than rectally in that of Antonio et al. [2], while this species was virtually absent from the study of Marrazzo et al. [3]. *L. vaginalis* was not found by Marrazzo et al. [3] and virtually absent in the study of Antonio et al. [2], whereas we found a vaginal carriage rate of approximately 10%.

The differences in *Lactobacillus* vaginal microflora between studies may be attributed to several factors. One suggestion is that the intestinal lactobacilli differ geographically [5], and the same may be true for the vaginal lactobacilli [31]. Also the populations studied differ, e.g. pregnant women in our study vs. nonpregnant women in the study of Antonio et al. [2] and lesbian women in the study of Marrazzo et al. [3]. Strong differences may exist between women, e.g. on average only 30% of the women carry *L. crispatus*, differences between Caucasian and black women have been reported [32], and differences may be present for each woman because samples can be taken during different phases of the menstrual cycle. More technically related factors concern variations in the way that samples are taken, transported and treated, the fact that culture media and incubation methods may strongly influence the outcome, e.g. incubation in an anaerobic chamber yields more *L. vaginalis* than incubation in an anaerobic jar (see below) and the use of MRS agar precludes isolation of *L. iners*, and that identification has often been based on phenotypic methods [33,34].

In addition, Kim et al. [35], reported that the vaginal microflora is not homogeneous throughout the vaginal tract but differs significantly within an individual with regard to anatomical site and sampling method used.

Apparently, when based on culture, the vaginal carriage rate for *L. crispatus* ranges between 20 and 40% (Antonio et al. [6], Kiss et al. [28], this study), although Marrazzo et al. [3] report a carriage rate of approximately 65%. The high percentage reported by the latter group could be related to the study of a different population (lesbian women), to the use of culture methods better suited for *L. crispatus* and corresponds better with results obtained by non culture based methods, as reported previously [16,22,26,27,32,36-38].

Interestingly, in a previous study of our group [8], we isolated almost no *L. vaginalis*, using anaerobic jars and GasPak (Becton Dickinson), yielding an atmosphere of 15% CO₂, 80% N₂, and less than 1% O₂. Since we started using an anaerobic chamber, with an atmosphere of 10% H₂, 10% CO₂, and 80% N₂, the number of *L. vaginalis* isolations has increased significantly and this species is now among the five most abundant vaginal species. Possibly, the virtual absence of *L. vaginalis* in the studies of Antonio et al. [2] and Marrazzo et al. [3] might be explained by the use of anaerobic culture in jars.

Comparing the reported culture results for *L. iners* remains also problematic, because this species does not grow on MRS agar, specifically designed to culture lactobacilli, and the small colonies it forms on most media may be more easily overlooked.
Table 2: Genotyping results for the 50 cases in which the same species could be isolated from vagina and rectum of the same subject

| Subjects, arranged per species | V1 | V2 | V3 | V4 | R1 | R2 | R3 | R4 | V = R |

a: V: vaginal isolates 1-4, R: rectal isolates 1-4.
b: Different genotypes are designated A, B, C, D or E per subject. Genotypic similarity/difference only relates to the other isolates of the same subject, i.e. genotype A of subject 1 does not indicate similarity to genotype A of subject 2.
c: Women for which the genotype of at least one vaginal isolate was identical to that of at least one rectal isolate.
The rectal occurrence of lactobacilli in culture-based studies may be underreported. Because lactobacilli are the predominant species vaginally, they can be easily overgrown by the predominant rectal bacteria as they represent about 0.01% of the overall cultivable bacterial intestinal population [39,40]. However, high occurrence of intestinal lactobacilli has been reported [41,42]. The difference with our study might be explained by the fact that these studies used fecal samples, whereas we started from rectal swabbing.

The virtual absence of *L. iners* from the rectum in this culture-based study is in correspondence with the findings of the other culture-based studies [2,3]. However, preliminary data, obtained by analyzing the same samples using *L. iners* specific realtime PCR, indicate that for most women for which this species could be isolated by culture from the vagina, also the rectal sample is *L. iners* PCR positive (data not reported).

In this population of pregnant women, we isolated lactobacilli more frequently from the vagina (121 subjects, 91.6%) than from the rectum (52 subjects, 39.3%), which is in correspondence with the findings of Antonio et al. [2], who reported vaginal recovery of lactobacilli in 74% and rectal recovery in 51% of a total of 531 nonpregnant females.

Although for many women from which lactobacilli could be isolated from the vagina, no lactobacilli were isolated rectally, most of the women that carried lactobacilli rectally, also had vaginal lactobacilli, i.e. few women carried lactobacilli only rectally.
Number of Lactobacillus species per individual

In our study, a total of 46 (35%) of 132 pregnant women carried two or more Lactobacillus species vaginally and/or rectally. Marrazzo et al. [3] reported 72% of 237 participants to be colonized overall by lactobacilli and 24% to be overall colonized with more than one Lactobacillus species. Antonio et al. [6] reported that 8% carried more than one Lactobacillus species in the vagina.

A total of 18 women in this study were colonized by both L. crispatus and L. jensenii (17 vaginally and one rectally). Vaginal colonization of women with L. crispatus and L. jensenii has been suggested to be advantageous in the maintenance of a normal microflora and the prevention of sexually transmitted diseases [2,6].

Genotyping results: clonal identity between vaginal and rectal isolates

RAPD was used in this study to detect genotypic similarity of vaginal and rectal strains of the same bacterial species. We could show that for 34 of the 50 pairs (68%) for which several isolates of the same species were present both in vagina and rectum, genotypic identity could be observed between at least one of the vaginal and at least one of the rectal isolates. In another study, on the same population of women, we compared the genotypes of rectal and vaginal Streptococcus agalactiae (group B streptococci: GBS) isolates and found clonal identity between isolates from both sites in 18 of the 19 subjects [43], confirming that also for GBS the rectally occurring strains are frequently identical to their vaginal counterparts. Because of the close proximity of the rectum to the vagina, the isolation of H2O2-producing vaginal Lactobacillus species from the...
rectum suggests that it may play a role as a reservoir for these microorganisms [2].

Vaginal colonization by Lactobacillus species was found to be transient in many females [7], and the rectum may be a source for vaginal recolonisation by lactobacilli after a disturbance of the ecology that follows douching, menses or sexual intercourse. Studies conducted between 1960 and 1980 indicated that while most Lactobacillus strains found in the human intestinal tract are allochthonous, L. acidophilus, L. fermentum (now L. reuteri) and L. salivarius can be isolated from individuals over longer periods [44-48]. Since on the basis of current taxonomy L. crispatus [49], L. gasseri [50] and L. iners [51] belong to the L. acidophilus complex the rectum may be a source for vaginal recolonization by these Lactobacillus species.

Genotyping results: variability among multiple isolates per subject

We found a surprising high genotypic heterogeneity within species. For the 50 species for which isolates were available from both vagina and rectum of a total of 47 pregnant women, on average of 2.2 vaginal respectively 1.3 rectal isolates were genotyped and on average 1.6 vaginal genotypes and 1.1 rectal genotypes were found for these species. It can be expected that more species pairs, more intraspecies genotypic diversity and more identical genotypes in rectum and vagina will be found, when more isolates would be picked. Although we did not sample the same subjects at different time intervals, this finding suggests the occurrence of changes in the composition of the vaginal microflora, whereby different strains of a limited number of species may replace each other, and are may be exchanged between vagina and rectum.
The high transmissibility of strains was also established in the study of Marrazzo et al. [3] by the observation that many sexual partners carried genotypically identical strains. This hypothesis may be confirmed by long term follow up of individual women, e.g. during subsequent menstrual cycles, and by picking more isolates per subject and per site at multiple time points.

**Conclusion**

Although it has been claimed that the vaginal microflora originates from the rectal microflora, this is to our knowledge only the second study, besides the recent study of Marrazzo et al. [3] to address this in detail at the strain level. Several of the total of 63 species identified were found only vaginally (9, i.e. 14.3%) or only rectally (26, i.e. 41.3%), but 29 species (44.4%) were isolated from both sites, indicating that many species can colonize the vagina from the rectum or migrate to the rectum from the vagina. For the 8 species for which isolates were present simultaneously in the same subject in vagina and rectum, we found considerable genotypic diversity within the species (i.e. on average 1.36 genotypes for on average 1.79 isolates per subject), both in rectum and vagina, as well as identical genotypes present simultaneously in rectum and vagina for 70% of the 50 species pairs studied. All these data indicate a strong correlation between vaginal and rectal microflora, not only at the species level but also at the strain level.

It is possible that the rectal colonization by lactobacilli may function as a reservoir for the maintenance of a normal vaginal flora and that this may be associated with a
decreased incidence of BV-associated adverse effects, as has been suggested [3].
