Introduction

Sodium alginate [Alg-Na], an algal polysaccharide consisting of α-L-guluronate and β-D-mannuronate, is used as a food ingredient [1]. Some species of Alg-Na have been widely utilized as excipients in drug products and/or as impression materials in dentistry due to their polymeric properties and safe oral intake [2-4]. Alg-Na itself enacts a protective effect on the gastric mucosa; thus, it has been used as a medicine for the treatment of gastroesophageal reflux disease [5,6].

Rebamipide [RM] has been used as a gastroprotective drug against gastric ulcers [7,8]. RM is also used in patients with dry eye disease for its mucosal-protective effect, and its efficacy has been reviewed [9,10]. Recently, RM has been approved as a therapeutic agent for oral mucositis or ulcers by local application. For example, RM mouthwash has been used to treat oral mucositis induced by chemoradiotherapy and radiotherapy [11-13], and some attempts have been made to deliver RM to the local disease site [14,15]. A Film Dosage Form [FD] is a thin film containing active compounds. FDs prepared using water-soluble polymers can quickly swell and disintegrate in a small amount of liquid, such as saliva. Therefore, water-soluble polysaccharides, such as Alg-Na, have been studied as base materials to prepare FDs, through which drugs can be efficiently delivered to local disease sites. We have reported Alg-Na as a useful polymer for preparing FDs, because thin films can be formed using this polysaccharide as a film base by simple methods that do not require dissolution in organic solvents [16].

In the present study, FDs containing RM were prepared via the casting method using some species of Alg-Na as the film base. When FD is prepared with a water-soluble material such as Alg-Na, the disintegration profile of the film matrix is an important factor that characterizes the dosage form. Thus, the dissolution profiles of FDs were investigated using a colorimetric assay that measured the amount of Alg-Na in aqueous solutions [17]. The dissolution profiles of RM from the FDs were investigated in a limited amount of medium.
Experimental Materials

As the film base, we used two species of high-molecular-weight Alg-Na, Alg-A [300cps, Nacali Tesque Inc., Kyoto, Japan], Alg-B [500cps, Nacali Tesque Inc.] and two species of low-molecular-weight Alg-Na, Alg-C [I-1G, Kimica Co., Tokyo, Japan], Alg-D [II-1G, Kimica Co.]. RM was purchased from Tokyo Chemical Industry Co., Ltd. [Tokyo, Japan]. Chitin [Crab Shells, Nacali Tesque Inc.] and chitosan [fine powder, degree of deacetylation: 75-85%, Kimitsu Chemical Industries Co. Ltd., Tokyo, Japan] were used as additives to FD. Water-soluble carbodiimide, 1-Cyclohexyl-3-[2-morpholino ethyl] carbodiimide metho-p-toluenesulfonate [CMEC] were purchased from Aldrich Chemical Co. [Milwaukee, WI, USA]. All other chemicals were of reagent grade and were obtained from commercial sources.

FD preparation

FD was prepared as follows: 10ml of the base solution containing RM was dispersed in deionized water to prepare the film base solution. The mixture was thoroughly mixed by sonication and poured [3g each] into individual plastic Petri dishes [diameter, 54mm]. The dishes were kept at 40 °C for 24h after µm was added to the dish in the incubator to maintain a constant µm×3 was added. The dish was then shaken. The medium [0.3ml] was periodically removed using a plastic syringe and filtered through a syringe-driven filter unit [pore size: 0.45μm]. An equal volume [0.3ml] of physiological saline at 37 °C was used as film base solutions. For example, an approximately 0.45μm-thick film was formed in the case of 2% Alg-C. FD was also obtained by vortexing. Each mixture was incubated at 40 °C for 20min, after which 20mM FeCl3 in 0.1M HCl [3ml] was added. The absorbance of the solution in a quartz cell [1cm light path] was measured at 480nm using a spectrophotometer [UV-1200; Shimadzu, Kyoto, Japan]. The absorbance was normalized to that of the blank reagent. For each test, a calibration curve was constructed using a fresh set of Alg-Na standards.

RM dissolution test

The sample solution was obtained using the method described in the film disintegration test section. Next, 80μl aliquots of the filtered sample solution were placed in micro test tubes [1.5ml], to which 720μl of methanol was added to precipitate the polysaccharide dissolved from the dosage form. Samples were mixed and centrifuged [7,700×g, 5min; H-1300; Kokusan Co., Saitama, Japan]. The supernatant was then injected into the HPLC column. Each test was performed in triplicate.

RM assay

The HPLC system [Hitachi Co., Tokyo, Japan] consisted of a pump [L-2130], UV-detector [L-2400], autosampler [L-2200], and chromate-integrator [D-2500] connected to a packed column [150 mm×4.6mm, Cosmosil 5C18-MS-II, Nacalai Tesque Inc.]. To determine the RM concentration, the assay was performed at ambient temperature using a mobile phase consisting of 20mM potassium phosphate buffer [pH 6.8] and methanol [12:13] at a flow rate of 1.0mL/min [18]. The detector wavelength was set at 230nm.

Results and Discussion

As a base solution was poured onto a Petri dish to prepare FDs via the casting method, the viscosity of the solution was an important factor for casting [19]. Although both 1.5% high-molecular-weight Alg-Na and 2-4% low-molecular-weight Alg-Na could be cast, 2% high-molecular-weight Alg-Na solution could not be cast because of its high viscosity. The addition of RM to the base solution affected film formation by evaporating the solvent. As shown in Figure 1, FDs containing RM [0.75mg] were not obtained in all cases of 1.5% high-molecular-weight Alg-Na, such as Alg-A. Thin circular films containing RM formed when 2-4% low-molecular-weight Alg-Na was used as film base solutions. For example, an approximately 50μm-thick film was formed in the case of 2% Alg-C. FD was also obtained when 0.1-0.5% chitin or chitosan were added to 1.5% high-molecular-weight Alg-Na as an additive to the film base.

![Figure 1: Images of film dosage forms prepared using the base solution containing RM.](image-url)

[a] Alg-A, [b] 2% Alg-C, [c] 2% Alg-D, [d] 1.5% Alg-A containing 0.1% chitin, [e] 1.5% Alg-A containing 0.1% chitosan.
When the FD was soaked in physiological saline at 37 °C, it swelled and then disintegrated, resulting in the release of Alg-Na into the medium. In the disintegration test, the amount of dissolved Alg-Na was measured by a method that changed uronic acid within the polysaccharide to a hydroxamic acid derivative. The disintegration profiles differed between the Alg-Na species used for the preparation of FD. The FDs prepared with low-molecular-weight Alg-Na disintegrated quickly, as shown in Figure 2. For the FD prepared with 2% Alg-C, approximately 80% of the incorporated Alg-Na dissolved within 5 min, and the total amount of the film base dissolved into the test medium within 10 min. For the FD prepared with 2% Alg-D, 70% of the incorporated Alg-Na dissolved within 5 min, and 88% of the film base dissolved into the test medium within 10 min. In the case of FD prepared with 4% Alg-D, similar dissolution profiles were observed.

In contrast, the disintegration rate of FD prepared with high-molecular-weight Alg-Na was slower than that of low-molecular-weight Alg-Na. Figure 3 shows the disintegration profiles of FDs prepared with a high-molecular-weight Alg-Na-containing additive. For example, for the FD prepared with 1.5% Alg-A containing 0.1% chitin, 25% of the incorporated Alg-Na dissolved within 5 min, and 75% of the film base was dissolved into the test medium within 30 min. Similar dissolution profiles were observed for both 1.5% Alg-B containing 0.1% chitin and 1.5% Alg-A containing 0.1% chitosan.

As observed in the disintegration test, FDs prepared with Alg-Na swelled, which led to disintegration; therefore, RM incorporated in the FD was released from the preparation into the test solution. Figure 4 shows the drug dissolution profiles of FDs prepared with low-molecular-weight Alg-Na. The amount dissolved into the test solution at 5 min was 0.48 ± 0.05 mg of the drug incorporated in the FD prepared with 2% Alg-C. For the FD prepared with 2% Alg-D, 0.73 ± 0.01 mg of RM dissolved within 5 min, and similar RM dissolution profiles were obtained from the FDs prepared with 4% Alg-D. In the case of FDs prepared with high-molecular-weight Alg-Na containing chitin, RM immediately dissolved from the preparation. For example, RM (0.55 ± 0.06 mg) dissolved within 5 min from the FD prepared with 1.5% Alg-A containing 0.1% chitin, as shown in Figure 5. The same drug dissolution rates were also observed in the case of FD prepared with the base solution containing 0.1% chitosan. These results show that the disintegration of the FD film matrix did not affect the dissolution rate of RM, and 0.5–0.7 mg of RM dissolved in the medium within 10 min in all cases. Similar drug release profiles were observed for the FDs prepared with low-molecular-weight Alg-Na containing 0.1% chitin, as shown in Figure 6.
In this study, both the disintegration of FD prepared with Alg-Na and the drug release profiles from the dosage form were investigated. The film matrix immediately swelled, even in a restricted amount of media, and disintegrated during the release of RM. All materials used for the preparation of FD were selected according to their safety for oral administration; therefore, FDs may be an attractive dosage form for use in the oral cavity.
