Abstract

Limestone reservoir plays a vital role in global oil and gas distribution. Many studies on limestone dissolution have been reported, which mainly emphasize on the main controlling factors of limestone dissolution and reservoir formation mechanism. However, few studies have been conducted on limestone dissolution laws, and a general understanding of limestone dissolution under supergene and burial conditions is lacking. A water-rock simulation experiment was conducted by using five typical Lower Paleozoic limestones in Zhubanghai area of Jiyang depression of China to study limestone dissolution laws under supergene and burial conditions. Sample characteristics were observed by scanning electron microscopy, and limestone dissolution was investigated by inductively coupled plasma optical emission spectrometer (ICP-OES). Results show that the erosion rate of limestone is higher than that of dolomite under supergene condition (22 °C and 1.0 MPa). Limestone has selective corrosion in structure and components. Calcite is generally manifested as a “corroded crystalline cone,” and dolomite generally presents “honeycomb-shaped” corrosion. Under burial conditions, the erosion rate of limestone first increases, decreases, and finally increases in the range of [80 °C, 18 MPa–160 °C, 42 MPa]. In the range of [120 °C, 30 MPa–160 °C, 42 MPa], the erosion rate of dolomite generally becomes higher than that of calcite, and the erosion of dolomite dominates. Dolomite easily forms secondary pores and high-quality reservoirs than limestone. In this study, the general laws of limestone dissolution were investigated, and conclusions provide references to evaluate high-quality limestone reservoirs.

Keywords: Limestone dissolution, Supergene condition, Burial condition

1. Introduction

Research on limestone reservoirs has recently attracted wide attention. Limestone reservoirs play an important role in oil and gas distribution in the world. Oil and gas reservoirs in limestone reservoir strata account for approximately 50% of total global oil and gas reservoirs. Oil and gas output in limestone reservoirs strata has exceeded 60% of total global oil and gas output [1, 2]. Universal developments of limestone paleo crust of weathering and ancient dissolution reservoirs, which are related to the plane of unconformity, have been made [3]. Supergene karstification and buried karstification are the most important diagenesis for the development of limestone reservoirs [4]. Secondary pores and large cavities formed by supergene karstification and buried karstification are among the important characteristics of high-quality limestone reservoirs [5, 6]. The development of high-quality weathering crust reservoirs is believed to be the consequence of supergene atmospheric fresh water reconstruction [7–10]. Corrosion in the buried diagenetic environment is important to the formation of pores in limestone reservoirs, thereby forming high-porosity oil and gas reservoirs [11]. Two perceptions on the corrosion rates of limestone under supergene conditions have been reported by Chinese scholars. One is limestone>dolomite limestone>lime-dolomite>dolomite [12], and the other is dolomite limestone>dolomite>lime-dolomite>dolomite [13]. For the corrosion rate of limestone under burial conditions, most scholars have deemed that the corrosion rate of dolomite is higher than that of limestone [12, 14–16]. Many experimental studies on limestone dissolution have been performed via the kinetic theory of limestone dissolution [14, 17], an open-system pH-free drift method [17], water–rock reaction experiment, and scanning electron microscopy (SEM) observations, and major achievements have been made. These achievements contribute to the study of limestone corrosion and evaluation of high-quality reservoirs. However, previous studies mainly focused on the controlling factors of limestone dissolution and the formation mechanism of limestone reservoirs. Only few studies discussed the corrosion laws of limestone, and a general understanding on limestone dissolution under supergene and burial conditions is lacking. In this study, a series of studies on the corrosion laws of the Lower Paleozoic limestone in Zhubanghai area under supergene and burial conditions was conducted. The basic corrosion laws of limestone were summarized, which provide references for the quality of high-quality limestone reservoirs.

2. State of the art

Supergene karstification and buried dissolution are important diageneses of limestone dissolution. With large-scale detection of limestone reservoirs in recent years,
research on limestone reservoirs is attracting increasing attention. A series of studies on the main controlling factors of limestone dissolution has been reported. Gledhill et al. studied the dissolution kinetics of calcite in saline by using an open-system pH-free drift method; they found that the temperature and partial pressure of CO$_2$ rather than salinity are the main influencing factors of the dissolution rate [17]. Elkhoury et al. proposed a reactive transport model to explore the effects of fluid properties and flow rate on dissolution [18]. Ellis et al. studied fractured limestone by X-ray diffraction (XRD) imaging and disclosed a nonintuitive inverse relationship between cover dissolution of fractured limestone and permeability evolution [19]. Garing et al. measured the changes in fracture volume induced by calcite dissolution and gypsum precipitation through X-ray computer microtomography and water chemistry. They found that changes in the permeability of fractures depend highly on flow rate and dissolution mode [20]. Smith et al. investigated low-permeability limestone dissolution induced by CO$_2$ through in situ observation and concluded that the constant of calcite reaction rate is about 17 times that of dolomite [21, 22]. Menke et al. analyzed the effects of pores on limestone dissolution through in situ observation and found that limestone dissolution is restricted by pore-scale transmission of reactants [23]. Ghommem et al. proposed a 3D core-scale prediction model for the acidification of limestone [24]. Fan et al. discussed the differences between the dissolution of limestone and dolomite through a differential dissolution simulation experiment and found that the mineral composition of limestone is the main influencing factor for the differential dissolution of limestone [25]. She et al. studied the dissolution laws and pore evolutions of limestone in a limestone dissolution experiment in acetic acid. They determined that the dissolution volume of limestone is inversely proportional to temperature but proportional to pressure. Temperature influences the dissolution volume of limestone more considerably than pressure [26]. Peng et al. discussed the limestone dissolution mechanism through a dissolution simulation experiment and controlled selective dissolution by mineral composition and reservoir space types of limestone. The limestone dissolution capability of acid fluid initially increases and then decreases, thereby exhibiting an optimal temperature and pressure range for limestone dissolution [27]. Shou et al. studied the reconstruction effect of limestone dissolution under strata conditions and relevant controlling factors through a simulation experiment of seepage and reaction of fluids in pores–fractures of rocks. The dissolution capacity of limestone was found to decrease gradually rather than increase with the increase in strata temperature. Pressure presented a weak positive correlation with the dissolution capacity of limestone [28]. All of these previous studies focused on the main controlling factors of limestone dissolution. However, the effects of the main controlling factors on the dissolution behavior of different types of limestone have not been discussed in detail. Existing studies mainly reported the effects of a single main controlling factor on the dissolution of two types of limestone. The dissolution of different types of limestone under collaborative controlling conditions of multiple factors has yet to be explored.

A series of studies on limestone dissolution under supergene and burial conditions was performed to disclose limestone dissolution characteristics and mechanism and limestone dissolution conditions under different temperatures and pressures. Pokrovsky et al. discussed the activation energy of limestone dissolution under different temperatures and pCO$_2$, and found that high temperature and pCO$_2$ might decrease the reactivity of carbonate minerals in aqueous solution [29, 30]. Alkattan et al. determined the dissolution rates of single calcite crystal, limestone, and compressed calcite powder following the mass loss of samples by using the free drifting rotary disk technology. Test results indicated that the dissolution rates of single calcite crystal, limestone, and compressed calcite powder are the same under acid conditions [31]. Zhu et al. observed the surface characteristics and mechanism of limestone dissolution through a dissolution experiment in acetic acid and hydrochloric acid; calcite and dolomite exhibit a unique dissolution phenomenon, and limestone presents a small content of dolomite that can accelerate dissolution [32]. Yang et al. performed a simulation experiment on the dissolution-induced diagenetic processes of limestone with different compositions under supergene and burial conditions and identified that the dissolution rate of limestone is related to mineral composition. Under near-surface conditions, the dissolution rate is positively related to calcite content. The dissolution rate of calcite is significantly lower than that of dolomite when temperature is higher than 75°C and pressure exceeds 20 MPa [12]. She et al. analyzed the reconstruction mechanism of organic acid to limestone reservoirs from supergene to deep buried environments by a dissolution kinetic experiment. They reported that the types and connectivity of pores formed by limestone dissolution are closely related to the formation of favorable limestone reservoirs [14, 15]. Tan et al. conducted a dissolution simulation experiment based on CO$_2$ solution and acetic acid solution to discuss the influences of temperature, pressure, and fluid on the karstification of different minerals and limestones under burial conditions. The dissolution rate of limestone was found to increase with the increase in calcite content. Under deep burial conditions, the influences of mineral composition on dissolution rate are weak [33]. Jiang et al. performed a dissolution simulation experiment by using CO$_2$, acetic acid, and H$_2$S solution to investigate the dissolution of calcite and dolomite under single controlling factors of temperature or pressure. Given the same pressure, limestone is the easiest to be dissolved, whereas dolomite is the most difficult to be dissolved. The solubility of transition rock is between those of limestone and dolomite. Under the same temperature, limestone is the easiest to be dissolved in the pressure range of 0.2–30 MPa, but dolomite is easily dissolved after 50 MPa [11]. These studies discussed the dissolution characteristics and mechanism of limestone under supergene and burial conditions and achieved outstanding findings. However, none of these studies explored the basic dissolution laws of different limestones, thereby failing to acquire a universal understanding in limestone dissolution laws under supergene and burial conditions.

To address the shortcomings of existing studies, this study summarizes the general dissolution laws of limestone under supergene and burial conditions intuitively through SEM images, water sample test, mass loss rate, and changes in Ca$^{2+}$ and Mg$^{2+}$ concentrations before and after the dissolution. Research conclusions provide references to assess limestone dissolution and high-quality limestone reservoirs.
The remainder of this study is organized as follows. Section 3 introduces the research methods. Section 4 analyzes the experimental results and summarizes the general laws of limestone dissolution under supergene and burial conditions. Section 5 concludes the study.

3. Methodology

3.1 Experimental samples

Experimental samples were drilling cores collected from CB302 (drilling depth=3543.8 m), CB302-2 (drilling depth=3537.95 m), CB304 (drilling depths=3367.46 and 3375.8 m), and CB306 (drilling depth=4398 m) at approximately 3000–4000 m deep Cambria and Ordovician strata in Zhuanghai area. Samples were named based on sheet observation and full-rock XRD analysis. The XRD analysis results showed that calcite and dolomite were the main mineral components of experimental samples. Few feldspars, quartz, and clay minerals were determined. Therefore, experimental samples were named as dolomite, lime-dolomite, limestone, dolomite limestone, and ooid-limestone.

The sheet pictures show that dolomite from CB304 was highly developed with intergranular pores (Fig. 1a). However, few pores were observed in lime-dolomite (Fig. 1b) and limestone from CB302-2 (Fig. 1c). Many cracks were noted in dolomite limestone from CB302, which were expanded by karstification in the late period (Fig. 1d). Stylolites were developed in ooid-limestone samples from CB306, with asphaltenes. Dolomite was developed at stylolites (Fig. 1e).

Table 1. XRD analyses of carbonate rocks

| Well number | Depth/m | Lithology           | Quartz | Feldspar | Calcite | Dolomite | Pyrite | Clay minerals |
|-------------|---------|---------------------|--------|----------|---------|----------|--------|---------------|
| CB304       | 3367.46 | Dolomite            | 2      | 1        | 1       | 95       | —      | 1             |
| CB304       | 3375.8  | Lime-dolomite       | 7      | —        | 15      | 76       | —      | 2             |
| CB302-2     | 3537.95 | Limestone           | 3      | 93       | —       | 2        | —      | 2             |
| CB302       | 3543.8  | Dolomite limestone  | 2      | 80       | —       | 17       | —      | 1             |
| CB306       | 4398    | Ooid-limestone      | 1      | 80       | —       | 17       | —      | 2             |

Note: The horizontal line indicates that it has not been detected or is below the detection limit.

3.2 Experimental process

3.2.1 Supergene experimental process

In this experiment, 10 mL (3.6 g) of concentrated hydrochloric acid (36%) was diluted to 1 L of water, with a concentration of 3.6 g/L and pH 1.0. Subsequently, 100 mL of diluents was collected and further diluted to 1 L and pH 2.0 [32]. Samples were ground to small pieces with similar size (approximately 2.5–2.8 g). Some samples were slightly lighter than 2.5 g due to limited samples. All samples were weighed and placed in 100 mL of prepared acid solution to react for 24 h under normal pressure and temperature (1 MPa and 22 °C). Samples were collected, dried for 24 h at the end of experiment, and weighed. The reacted rock samples were observed by an S4800 cold field emission SEM.

3.2.2 Buried experimental process

In this experiment, 2.9 mL of formic acid was diluted to 1 L of water, and 10 mL of diluents was collected for later use. Subsequently, 4 mL of acetic acid was diluted to 1 L of water, and 10 mL of diluents was collected for later use. The prepared 10 mL of formic acid diluents and 10 mL of acetic acid diluents were mixed and then diluted to 1 L, and 10 mL of diluents was collected. Approximately 3 g of oxalic acid was weighed by an electronic balance and prepared into 1 L
of solution, in which 10 mL of diluents was collected. The mixture of formic and acetic acid solutions (10 mL) was added with 10 mL of oxalic acid diluents and diluted to 1 L. The mixture (500 mL) was used as the acid solution in each buried simulation experiment. The pH of the mixture was measured as 3.71 by a pH meter.

Samples were weighed. The ground test samples and prepared 500 mL of mixture were placed in a high-temperature and high-pressure reactor. The reactor was closed, and the temperature was adjusted. Nitrogen was supplied to make the pressure in the reactor slightly lower than the target pressure. When the temperature was stabilized after 3 h, nitrogen was supplied or discharged to make the pressure in the reactor equal to the target pressure. The samples and solution were collected at 48 h. The samples were dried in a drying oven for 24 h and weighed. The solution was tested by ICP-OES instrument. Reacted rock samples were observed by an S4800 cold field emission SEM.

4. Result Analysis and Discussion

Rock samples after the reaction were observed by an S4800 cold field emission SEM. Limestone samples developed different degrees of karstification under supergene and burial conditions (Fig. 2). The sample surface was uneven, with dissolution pores (Figs. 2 d, a, c, and e) and fractures (Fig. 2 e). Some samples dissolved out a single crystal form (Figs. 2 a, b, c, and d). Some samples showed mild karstification, with surface dissolution (Fig. 2 b).

4.1 Dissolution simulation experiment of supergene conditions

4.1.1 Analysis of dissolution degree and ion concentration

The experimental results (Tables 2 and 3) show that the dissolution rates of limestone under normal pressure and temperature were dolomite limestone>ooid-limestone>limestone>dolomite. For dolomite and Lime-dolomite, the change rate of mass and the releasing amounts of Ca$^{2+}$ and Mg$^{2+}$ revealed some errors. The total dissolution law indicates that the dissolution rate of limestone is considerably higher than that of dolomite under supergene conditions. This result implied that the dissolution rate of calcite was higher than that of dolomite under supergene conditions, which conformed to previous research conclusions. The dissolution rate of dolomite limestone (dolomite content=17%) was higher than that of limestone, which indicated that few dolomite in limestone could accelerate karstification. This phenomenon may be because Mg$^{2+}$ enters into calcite crystals to combine with lattices, thereby increasing the dissolubility of calcite [34]. The limit of the Mg$^{2+}$ content is Mg: Ca=0.045 (mass fraction) [35]. This phenomenon is called the “salting-in effect” [13].
Selective dissolution occurs on the basis of previous studies. Under supergene conditions, calcite and dolomite show selective dissolution [6, 32]. The micro dissolution characteristics of experimental samples were observed by an S4800 cold field emission SEM. Under supergene conditions, calcite and dolomite become “crystalline cone” (Fig. 3a) or dissolution along edges. Edges of mineral crystals are favorable positions for selective dissolution because mineral crystallization extends from the center (crystallization directions. Edges of mineral crystals are favorable positions for selective dissolution because mineral crystallization extends from the center (crystallization nucleus) to outside. It often leads to incomplete crystals at edges due to lattice distortions. Factors that cause lattice distortion may facilitate the easy dissolution of the lattice [37]. In the study area, the dissolution of calcite is mainly manifested by a “dissolution crystalline cone” (Fig. 3a) or dissolution along edges. Edges become “crystalline cone” caused by dissolution (Figs. 3b and 3c). Dolomite is mainly manifested by “stair-shaped”...

Note: (a1 – d1): Carbonate sample before reaction; (a2 – e1): Carbonate samples under epigenetic conditions; a1 – c1: Dissolved sample appears as a single crystal; d2: Eroded holes and deeper dissolution; e2: Corrosion cracks are relatively developed; (a2 – e1): Carbonate samples under burial conditions; a1: 140 °C, 36 MPa, Corrosion is comparatively serious, the surface is covered by residual clay minerals, and corrosion holes are relatively developed; b2: 120 °C, 30 MPa, Low degree of dissolution, a small dissolved hole can be seen on the surface; c1: 160 °C, 42 MPa, Corrosion is comparatively serious, and deep dissolved holes appear; d1: 100 °C, 24 MPa, Mainly manifested as surface erosion, revealing internal crystal morphology; e1: 80 °C, 18 MPa, Corrosion is serious, and caves appear; (a2 – a1): Dolomite; b2 – b1: Lime-dolomite; c2 – c1: Limestone; d2 – d1: Cloudy limestone; e2 – e1: Ooid-limestone

### 4.1.2 Dissolution characteristics of limestone

The micro dissolution characteristics of experimental samples were observed by an S4800 cold field emission SEM. Under supergene conditions, calcite and dolomite have selective dissolution [6, 32]. On the basis of previous studies, selective dissolution refers to the dissolution of acid fluid at positions with weak ion and molecular binding force, such as lattice defects, dislocation, cleavage plane, and intersections [36]. This phenomenon is caused by limitations on mineral crystallization trends and crystallization conditions. Moreover, the dissolution rate varies on different crystallization directions. Edges of mineral crystals are favorable positions for selective dissolution because mineral crystallization extends from the center (crystal nucleus) to outside. It often leads to incomplete crystals at edges due to limited material sources and crystallization spaces, thereby leaving many lattice vacancies or lattice distortions. Factors that cause lattice distortion may facilitate the easy dissolution of the lattice [37]. In the study area, the dissolution of calcite is mainly manifested by a “dissolution crystalline cone” (Fig. 3a) or dissolution along edges. Edges become “crystalline cone” caused by dissolution (Figs. 3b and 3c). Dolomite is mainly manifested by “stair-shaped”
The major dissolution characteristics of limestone are summarized as follows:

(1) Surface dissolution: Hydrochloric acid dissolves limestone crystal surfaces gradually, forming pits and fractures on limestone crystal surfaces. The dissolution intensity of experimental samples is very high due to the low pH of hydrochloric acid. Dissolution pores in some samples are hollowed out, and some samples have evident internal dissolution of single crystal. Local dissolution occurs in some crystals, and only partial crystalline forms are left. Serious dissolution occurs on the dolomite surface, which shows “honeycomb” dissolution (Fig. 3g). The “stair-shaped” dissolution (Fig. 3d) is also evident.

(2) Dissolution along cleavage: This dissolution phenomenon is observed in calcite and dolomite. Calcite mainly occurs as a “dissolution crystal cone” (Fig. 3a). The dissolution of dolomite along the cleavage direction is mainly manifested as “cutting strips” [32] (Fig. 3e), and some are dissolved into pieces (Fig. 3f).

(3) Dissolution along particle edges: This dissolution is common in SEM images. Calcite is mainly “sharp-edged” dissolution along particle edges (Figs. 3b and 3c), and dolomite also presents a similar phenomenon. However, the angle of crystalline cone in dolomite is generally larger than that of calcite, and it is approximately a right angle (Fig. 3i). When the dissolution intensity is sufficient, edge dissolution may form single dolomite particles (Fig. 3g). This phenomenon is extremely common in SEM images of experimental samples.

4.2 Dissolution simulation experiment under burial conditions

The experimental results (Fig. 4) show that the mass change rate of limestone dissolution presents an N-shaped variation law with the increase in temperature and pressure. In the studied ranges of temperature and pressure, the mass change rate of limestone dissolution peaks at approximately 120 °C and 30 MPa, but it reaches the valley at approximately 140 °C and 36 MPa. This law is reflected in the changes in the concentration sum of Ca$^{2+}$ and Mg$^{2+}$ (Table 4). In previous studies, the limestone dissolution capability of acid fluid first increases and then decreases [5, 27]. Therefore, the range of [80 °C, 18 MPa–120 °C, 30 MPa] is the best temperature and pressure range for organic acid dissolution. This range is known as the limestone dissolution window [27, 38, 39]. In the range of [80 °C, 18 MPa–160 °C, 42 MPa], the mass change rate and Ca$^{2+}$ and Mg$^{2+}$ concentrations in dolomite and lime-dolomite are generally higher than those in ooid-limestone, limestone, and dolomite limestone. This finding indicates that the dissolution rate of dolomite is higher than that of limestone in this range. After 140 °C and 36 MPa, the Ca$^{2+}$ and Mg$^{2+}$ concentrations...
dissolve from dolomite, and the increase trend is considerably higher than that of limestone. With the continuous increase in temperature and pressure, dolomite is easier to be dissolved than limestone. In the range of [85 °C, 20 MPa–160 °C, 42 MPa], the dissolution rate of lime-dolomite is higher than those of the rest of the mineral components. According to previous studies, involving a certain amount of calcite in dolomite can greatly increase the dissolution intensity of dolomite, which is beneficial to high-quality dolomite reservoirs [5, 28]. Lime-dolomite is an important material basis to form high-quality limestone reservoirs [25].

The curve of the \( \text{Ca}^{2+} - \text{Mg}^{2+} \) concentration ratio (Fig. 5) depicts that the \( \text{Ca}^{2+} - \text{Mg}^{2+} \) concentration ratio of dolomite and lime-dolomite approaches 1 (chemometric of dolomite) in the studied range of temperature and pressure. In the range of [80 °C, 18 MPa–120 °C, 30 MPa], the \( \text{Ca}^{2+} - \text{Mg}^{2+} \) concentration ratio of limestone, dolomite limestone, and ooid-limestone increases generally. The optimal dissolution temperature range for calcite in acetic acid is 80 °C–120 °C, which is basically the same as previous conclusions [40].

The \( \text{Ca}^{2+} - \text{Mg}^{2+} \) concentration ratio begins to decrease in the range of [120 °C, 30 MPa–140 °C, 36 MPa]. The \( \text{Ca}^{2+} - \text{Mg}^{2+} \) concentration ratio is much higher than 1 under 140 °C and 36 MPa. The \( \text{Ca}^{2+} - \text{Mg}^{2+} \) concentration ratio approaches 1 in the range of [140 °C, 36 MPa–160 °C, 42 MPa]. Hence, calcite dissolution assumes the dominant role in the three types of limestone in the range of [80 °C, 18 MPa–140 °C, 36 MPa]. The dissolution rate of calcite in all three types of limestone is higher than that of dolomite in the range of [80 °C, 18 MPa–120 °C, 30 MPa]. Nevertheless, the dissolution rate of dolomite approaches that of calcite in the range of [120 °C, 30 MPa–140 °C, 36 MPa]. After 140 °C and 36 MPa, the dissolution of dolomite takes the dominant role. Dolomite is easier to form secondary pores and high-quality limestone reservoirs than limestone under deep burial conditions.

### Table 4. Changes in calcium and magnesium ions after the dissolution of carbonate rocks under burial conditions

5. Conclusions

The dissolution characteristics of limestone under supergene conditions are discussed, and the relevant dissolution rate order is made through SEM observations and ICP-OES test to summarize the general laws of supergene and buried dissolution of limestone. The dissolution of limestone under burial conditions is also studied. The major conclusions are as follows:

1. Under supergene conditions, the dissolution rate order of limestone > dolomite limestone > ooid-limestone > lime-dolomite > dolomite. The dissolution rate of limestone is higher than that of dolomite. The dissolution rates of dolomite limestone and ooid-limestone are higher than that of limestone. A small dolomite content in limestone can accelerate dissolution due to the “salting-in effect.”

2. Under supergene conditions, selective dissolution in the composition of limestone occurs. Specifically, limestone mainly forms a “dissolution crystal cone,” and dolomite mainly presents “honeycomb” dissolution, accompanied with “cutting strip” and “stair-shaped” dissolution.

3. The dissolution rate of lime-dolomite peaks in the studied range of temperature and pressure. In the range of [80 °C, 18 MPa–160 °C, 42 MPa], the mass change rate of dolomite and the Ca^{2+} and Mg^{2+} concentrations in solution are higher than those of limestone. The dissolution rate of dolomite is also higher than that of limestone. After 140 °C and 36 MPa, the dissolution of dolomite and limestone is mainly the dissolution of dolomite components. Dolomite is easier to form secondary pores and high-quality limestone reservoirs than limestone under deep burial conditions.

In this study, the general law of limestone dissolution is concluded by analyzing SEM images and Ca^{2+} and Mg^{2+} concentrations in limestone samples. This study provides references to assess high-quality limestone reservoirs. Limited by types of core samples, the dissolution law of other types of limestone in CO₂ solution will be studied in future work.
