Functional outcomes by age after inpatient stroke rehabilitation in Saudi Arabia

Background: Among various risk factors, age has been identified as a nonmodifiable risk factor for stroke that influences functional outcomes after inpatient stroke rehabilitation in the developed world as well as in Saudi Arabia (SA). The demand for inpatient stroke rehabilitation services increases with population aging and stroke incidence; however, these services are limited in SA.

Objective: To examine functional outcomes by age after inpatient stroke rehabilitation in SA.

Patients and methods: Data from 418 patients with stroke who underwent inpatient stroke rehabilitation at the King Fahad Medical City-Rehabilitation Hospital, Riyadh, SA, between November 2008 and December 2014 were collected from electronic medical records. According to the patients’ age, we classified participants into two groups: adults, aged <65 years (n=255), and older adults, aged ≥65 years (n=163). All patients’ functional statuses at admission and discharge from inpatient stroke rehabilitation were assessed using the functional independence measure (FIM) scale.

Results: The mean age was 59.9 years (SD = 9.4). Older adults had significantly smaller changes in functional outcome from admission to discharge on both the total FIM (23 [SD = 15.9]) and the motor FIM (21 [SD = 15.4]), and they were significantly less independent (36%) compared to adults. In the adjusted models, older adults had significantly lower scores than adults, by 11 points (p < 0.0001) for the total FIM score and by 10 points (p < 0.0001) for the motor FIM subscale score. There was no significant change with age in the cognitive FIM subscale score.

Conclusion: After inpatient stroke rehabilitation, older adults had limited functional outcomes or were less independent than adults. However, the clinical relevance of this finding is questionable, so there is currently no justification to deny patients access to intensive stroke rehabilitation solely because of advanced age. Future large-scale research is needed to confirm rehabilitation outcomes by including confounders such as social support, socioeconomic conditions, comorbidities, and the patient’s opinion after rehabilitation.

Keywords: adult, older adult, FIM

Introduction

Age has been identified as a nonmodifiable risk factor for stroke, and among the various risk factors, it has effects on functional outcomes after inpatient stroke rehabilitation in the developed world as well as in Saudi Arabia (SA). The risk increases with increasing age, doubling every decade after age 55 years. Studies from SA have also reported that stroke occurs with a higher incidence in the 61–70 age group, compared to the 20–40 age group. Therefore, one of the key elements in minimizing stroke and its functional limitations in the both general and elderly populations is inpatient stroke rehabilitation.
Demand for inpatient stroke rehabilitation services has increased with aging of the population, and stroke incidence has substantially and steadily increased over the years. 

Unfortunately, inpatient stroke rehabilitation services are limited in SA; in particular, only 2 hospitals of 350 were found to have a specialized stroke team in our recent call-for-action review about stroke rehabilitation in SA. 

These hospitals provide comprehensive rehabilitation services for patients of all ages who need rehabilitation treatment services. A recent literature review on stroke in SA also demonstrated that stroke care in SA has yet to reach the levels observed in developed countries, which requires establishing stroke units, increasing public awareness, training health care providers, and enhancing collaboration. More recent studies have also reported that there is a high demand for more inpatient stroke rehabilitation services and relevant teams of professionals in SA. 

Among several previous studies, few early studies examined the effects of age on the functional independence measure (FIM) gain as an outcome after inpatient stroke rehabilitation. The authors of these studies found that the changes in the total FIM and in subscores did not differ between young patients and the oldest patients. In SA, a prospective study was conducted on 180 patients with stroke who were referred to an active rehabilitation program between February 2008 and October 2010, with the goal of identifying the factors that possibly influence functional outcomes after inpatient rehabilitation. The study results showed that rehabilitation could be effective in elderly patients with stroke and that age predicts the outcome to a lesser extent than other clinical covariates, such as the FIM score at admission. The results of studies have varied, however, regarding the methodological differences in participant type, participant age (often treated as continuous), and the length of rehabilitation.

The available literature from SA supports the idea that stroke risk and related functional limitation increase with age. Thus, we wanted to examine functional outcomes by age, apart from the effect of functional status at admission. To this end, we evaluated two patient subgroups: those aged <65 years, treated as adults, and those aged ≥65 years, treated as older adults.

Objective

The aim of this study was to examine functional outcomes by age after inpatient stroke rehabilitation in SA. We hypothesized that functional outcomes would differ by age after inpatient stroke rehabilitation.

Patients and methods

Study design

Between November 2008 and December 2014, a review of the electronic medical record database at the King Fahad Medical City-Rehabilitation Hospital (KFMC-RH) was conducted by two of the investigators. The time frame was determined based on the availability of medical records for patients with stroke diagnosed according to the International Classification of Diseases, Ninth Revision, codes 348–438 and 799.3. Differences of opinion regarding medical records were resolved by discussion between the investigators until consensus was reached.

Setting

The KFMC-RH is the largest Ministry of Health tertiary inpatient stroke rehabilitation center in Riyadh, SA, providing free rehabilitation services to referred patients. The average duration of rehabilitation care in SA is 45 days, with the duration of care determined by age and gender. Data on the frequency and type of rehabilitation care were not available in the KFMC-RH database at the time of record review. However, the database also includes FIM instrument scores, which are obtained in a standardized way for all admissions and discharges.

Participants

All patients (N=418) aged 18 years or older who were admitted for inpatient stroke rehabilitation between November 2008 and December 2014 were considered for inclusion in this retrospective study. According to the patients’ age, we classified participants into two groups: adults, aged <65 years (n=255), and older adults, aged ≥65 years (n=163). This study was approved by the Committee on Human Research and the Institutional Review Board for the KFMC-RH (approval number: 14–273). The requirement for informed consent was waived because the retrospective record review was performed without contact with the subjects. Additionally, the privacy and confidentiality of individually identifiable patient health information are well established and respected by the Ministry of Health.

Measurements

Functional outcomes were evaluated with the FIM. This instrument is administered using the Uniform Data System for Medical Rehabilitation protocol, and it provides indices for the level of assistance required for a patient to accomplish activities of daily living. The FIM comprises 18 items: 13 motor items (motor FIM subscale) and 5 cognitive items.
(cognitive FIM subscale). Each item is given an ordinal score from 1 to 7. The minimum score of 1 represents complete dependence on others for that task, and the maximum score of 7 represents full independence. The total, motor, and cognitive FIM score ranges are 18–126, 13–91, and 5–35, respectively; higher scores reflect greater independence. FIM scores were sequentially measured at admission and discharge to determine the effects of therapy. The reliability and validity of the FIM for stroke patients are well established.19–21

Patient demographics included age and gender. Clinical data included stroke type (hemorrhagic and other stroke), body involvement (left, right, and bilateral), and discharge disposition (to home and not to home). Baseline functional status, complications of stroke, comorbidities, social support, and socioeconomics were not included as potential confounders because we wanted to focus on age as a predictor of functional outcomes using data available at the rehabilitation unit.

Statistical analysis

Descriptive statistics are shown as percentages for categorical measures and means with SDs for continuous measures. The chi-square test was used to analyze categorical variables, and two-sample independent t-tests were used to assess continuous variables to identify significant differences between the two groups. Functional category outcome changes between admission and discharge are presented as counts (percentages). Significant differences were calculated using chi-square statistics.

Individual linear regression analyses for the total FIM and its subscores (motor and cognitive FIM) were used to examine functional outcomes in older adults compared to adults. Each analysis consisted of two models: an unadjusted model (Model 1) and a model adjusted for age, gender, stroke type, body involvement, and discharge disposition (Model 2). Adults aged <65 years were used as the reference for all models. All analyses were performed with SAS version 9.2 (SAS Institute, Inc., Cary, NC, USA).

Results

Of the 418 patients, 255 patients were younger than 65 years (61%) and 163 patients were aged 65 or above (39%). All identifying characteristics of the patients are summarized in Table 1. The mean age of older adults was 72.4 years (SD =5.9), and the average length of stay in inpatient stroke rehabilitation was 48 days (SD =36.3). The majority of patients were men (58%) with hemorrhagic stroke (87%) and left hemiparesis (62%). Older adults were on an average of 25 years older than the adults. Older adults had a significantly lower total FIM score (mean: 91 vs 80, p<0.0001) and motor FIM subscale score (mean: 63 vs 52, p<0.0001) at discharge. The average changes from admission to discharge in the total FIM score (27 vs 23, p=0.005) and motor FIM score (25 vs 21, p=0.011) significantly differed by age.

Figure 1 shows the outcomes according to the FIM score by functional category, stratified by age group. There were significant increases in the functional level in all three categories. From admission to discharge, older adults exhibited a 33% decrease in the maximum assistance category, a 3% reduction in the moderate assistance category, and a 36% increase in the minimal-to-no-assistance category (p=0.001) compared to adults, who respectively showed 32%, 13%, and 45% decreases (p=0.005). Overall, all stroke rehabilitation participants exhibited a 33% decrease in the maximum assistance category, a 9% reduction in the moderate assistance category, and a 42% increase in the minimal-to-no-assistance category (p<0.0001) from admission to discharge.

Table 1 Descriptive characteristics of the study participants

| Characteristics                      | Total N=418 | Adults 255 (61%) | Older adults 163 (39%) | p-value |
|--------------------------------------|-------------|------------------|------------------------|---------|
| Age in years, mean ± SD              | 59.9±9.4    | 47.5±12.9        | 72.4±5.9               | <0.0001 |
| Gender                               |             |                  |                        |         |
| Male                                 | 237 (57%)   | 143 (56%)        | 94 (58%)               | 0.75    |
| Female                               | 181 (43%)   | 112 (44%)        | 69 (42%)               |         |
| Stroke type                          |             |                  |                        |         |
| Hemorrhagic                          | 347 (83%)   | 205 (80%)        | 142 (87%)              | 0.07    |
| Other stroke                         | 71 (17%)    | 50 (20%)         | 21 (13%)               |         |
| Body involvement                     |             |                  |                        |         |
| Left                                 | 202 (54%)   | 110 (49%)        | 92 (62%)               | 0.024   |
| Right                                | 151 (40%)   | 98 (44%)         | 53 (35%)               |         |
| Bilateral                            | 20 (5%)     | 16 (7%)          | 4 (3%)                 |         |
| Discharge setting                    |             |                  |                        |         |
| To home                              | 406 (97%)   | 250 (98%)        | 156 (96%)              | 0.16    |
| Not to home                          | 12 (3%)     | 5 (2%)           | 7 (4%)                 |         |
| LOS, mean ± SD                       | 47.5±31.1   | 47.0±25.9        | 48.0±36.3              | 0.94    |

Dovepress
Outcomes confirmed by regression analyses of the total FIM (Table 2), motor FIM (Table 3), and cognitive FIM (Table 4) are presented for older adults compared to adults. In the unadjusted model, older adults had significantly lower scores, which were 11.5 points \((p<0.0001)\) lower for the total FIM score and 11 points \((p<0.0001)\) lower for the motor FIM subscale score. In the adjusted model, older adults had significantly lower scores, which were 11 points \((p<0.0001)\) lower for the total FIM score and 10 points \((p<0.0001)\) lower for the motor FIM subscale score. There was no significant change by age in the cognitive FIM subscale score.

### Discussion

This study aimed to examine the functional outcomes by age after inpatient stroke rehabilitation in SA. After inpatient stroke rehabilitation, older adults were significantly less independent than adults. Furthermore, regression analyses revealed that older age was significantly associated with lower scores on the total FIM and motor FIM after discharge from inpatient stroke rehabilitation, even after adjusting for gender, stroke type, body involvement, and discharge disposition.

Among other factors, age is an important nonmodifiable prognostic factor, and several previous studies have accordingly shown that younger patients had better outcomes.\(^{22-29}\) In this study, older adults had significantly lower scores on the total FIM and the motor FIM alone. In contrast, there was no significant association for the cognitive FIM. This result may be due to the fact that predicting rehabilitation outcomes in older adults with stroke can be difficult due to several clinical modifiers, such as comorbidity, medical complications, neuropsychologic impairment appropriate to the aging brain, and social concern.\(^{30}\) Successful inpatient stroke rehabilitation for older adults may require more comprehensive programs over a longer period.\(^{31}\)

In contrast to the effect of age, the confounder gender (male vs female) was related to significant improvement in the total FIM score and motor FIM subscale score at discharge, as has been reported in previous studies.\(^{32,33}\) Additionally, the confounder body involvement was related to less

### Table 2 Regression analysis of the total FIM scores of older adults with stroke after discharge from an inpatient rehabilitation unit

**Abbreviations:** FIM, functional independence measure; SE, standard error.
improvement in the cognitive FIM subscale score, similar to the findings of other studies, which revealed that cognitive recovery is more limited with increasing age.\(^{33,34}\) Another confounder, discharge disposition, was related to significantly less improvement in the total FIM and its domains (motor and cognitive) in patients who were not discharged to home, perhaps because of predictive factors such as pre-stroke living arrangement (lived alone vs lived not alone), as previously hypothesized by other authors.\(^{35}\)

The study findings were similar to those of previous studies.\(^{10,22,23,36–38}\) The results of these studies confirmed that older adults had lower FIM scores. Additionally, the findings of these studies confirmed that a higher FIM score on admission is associated with higher scores on discharge. One example is an early prospective study performed in Canada, which demonstrated that age alone was a significant predictor of the total FIM score and motor FIM score at discharge.\(^{10}\) However, this study’s methodology, such as the participant type and the composition of the inpatient rehabilitation program, differed from that of our study. A recent systematic literature review that was performed between January 2000 and October 2015 in the Netherlands demonstrated that young age was significantly associated with better functional outcomes at discharge.\(^{22}\) Another study that was performed in Istanbul showed that age was a significant predictor of the total FIM score and motor FIM score at discharge.\(^{36}\) However, apart from the effect of functional status at admission, functional outcomes according to age categories after inpatient stroke rehabilitation in SA have not been examined.

The findings of this study have significant implications for developing stroke rehabilitation services in SA to achieve better functional outcomes among older adults with stroke. In SA, Al-Jadid and Robert reported that stroke occurred at a higher frequency in the 61–70 age group and had lower rates in the 20–30 and 31–40 age groups.\(^{6}\) Another study from SA also reported that stroke most often occurred in the 61–70 age group, whereas the 30–40 age group was least affected.\(^{7}\) Additionally, a survey was conducted in SA to assess the level of stroke awareness in the Saudi adult population.\(^{39}\) The findings of that study suggest that there is an alarming deficit in the standard of stroke knowledge among Saudi adults.

### Study limitations and strengths
Our study had certain limitations. First, the findings cannot be generalized to all people because this was a single-center study. Second, causality cannot be determined because the study was retrospective. Third, the data were limited because they did not include potential confounders, such as marital status, education, living status, race, social support, functional status at admission, stroke severity, comorbidity, depressive symptoms, and body mass index. Finally, as this was a retrospective study, patients were preselected for admission because they were regarded as likely to benefit from stroke rehabilitation. The strength of the study is that the KFMC-RH is a large tertiary inpatient stroke rehabilitation hospital in Riyadh, SA, with a license to use the FIM scale, which has the highest reliability and validity among the methods of evaluating activities of daily living and is widely used in rehabilitation settings.\(^{8,26,40–42}\)

### Conclusion
After inpatient stroke rehabilitation, older adults had limited functional outcomes or were less independent than adults. However, the clinical relevance of this finding is questionable, so there is currently no justification to deny patients access to intensive stroke rehabilitation solely because of advanced age. Future large-scale research is needed to confirm rehabilitation outcomes by including confounders such as social support, socioeconomics, comorbidities, and the patient’s opinion after rehabilitation. In any case, the knowledge obtained in this study may be applied to establish new comprehensive rehabilitation centers in SA for older adults with stroke.

### Acknowledgments
The authors extend their appreciation to the Research Centre, College of Applied Medical Sciences, and the Deanship of Scientific Research at King Saud University for funding this research.
