This paper presents the status of the APEmille project, which is essentially completed, as far as machine development and construction are concerned. Several large installations of APEmille are in use for physics production runs leading to many new results presented at this conference. This paper briefly summarizes the APEmille architecture, reviews the status of the installations and presents some performance figures for physics codes.

1. OVERVIEW

The APEmille project was started with the goal of developing and commissioning a massively parallel computer optimized for lattice gauge theory (LGT), with a peak performance close to the 1 TFlops threshold \cite{1}. APEmille is the third generation of APE machines \cite{2}. The project is now completed, as far as hardware development and construction are concerned: several APEmille systems have been installed at various sites, providing an overall processing power close to 1.5 TFlops. These systems have become the main workhorse for doing LGT simulations for several research groups \cite{3}. In this paper, we briefly recall the features of APEmille, present the status of the project, describe the final shape of the software environment and discuss the performance achieved by physics programs.

2. APEmille ARCHITECTURE

APEmille is based on a three dimensional mesh of nodes connected by a synchronous communication network linking first neighbours. All nodes in the mesh operate in Single Instruction Multiple
Data (SIMD) mode. Each node consists of a 0.5 GFlops custom developed floating point processor and 32 MB data memory. At each clock cycle the processor is able to complete the operation $a \times b + c$ following the IEEE standard, where $a, b, c$ are single precision complex or double precision real operands. APEmille is a highly modular and scalable system. The basic building block and smallest independently running entity is a processing board (PB) with $2 \times 2 \times 2$ nodes. Up to 16 PBs are interconnected via a single backplane to form an APEmille crate. One crate has 128 processors, approximately 65 GFlops peak performance and 4 GB data memory. Larger systems, which can be re-partitioned by software, are assembled by connecting $n$ crates together. The corresponding topology is $2^n \times 8 \times 8$.

APEmille systems are connected to a network of host PCs with a Linux operating system, each hosting 4 PBs. The network contains one or more master PCs on which users log in to start their application programs. Input/output is usually performed onto disks belonging to the master. This I/O setup is limited by the performance of the network connecting the PCs (typically FastEthernet). The measured bandwidth is of the order of 6 MBytes/sec. Higher I/O rates can be achieved by hooking 'local' disks directly to the host PCs with Ultra2 SCSI channels. In this setup the bandwidth scales with the size of the system. Typically it is of the order of 100 MBytes/sec per crate.

Power consumption of APEmille systems is very low (less than 30 W/GFlops) and the footprint of a two-crate rack is about 0.7m$^2$. For these reasons, APEmille machines are simply air cooled and do not need complex infrastructure.

### Table 1

| Key parameters of APEmille:          |
|-------------------------------------|
| Peak performance | 528 MFlops/proc   |
| Clock frequency   | 66 MHz            |
| FP registers      | 512 (32-bit)      |
| Data memory       | 32 MByte/proc     |
| Communication BW  | 66 MByte/s/direction |
| I/O BW per master | 6 MByte/s         |
| Power consumption | 28 W/GFlops       |
| Price              | 2.5 Euro/MFlops peak |

3. PROJECT STATUS

After prototypes were assembled and tested in late 1999, a first round of production was carried out in the year 2000. A second and final round of production was started in spring 2001. APEmille systems have been installed at several sites belonging to the APEmille collaboration and also at a few more universities and research labs (see Tab. 1). The presently installed peak processing power is about 1460 GFlops and will grow to about 2.2 TFlops once the final round of construction is completed.

APEmille is a very stable system: up-times of 1-2 months or more are routinely achieved. Hardware maintenance is typically limited to simple replacement of ageing modules and is therefore cheap, both in terms of hardware costs and manpower.

4. SOFTWARE AND PERFORMANCE

APEmille systems use the familiar TAO programming language, already used in all previous APE machines. The language has been extended by very few elements to exploit the new
features of APEmille, like double precision and local integer data types, and the increased number of registers. Old APE100 programs can be re-compiled for the new machine with almost no changes. High performance, however, is achieved only after some tuning of the codes. To this end the TAO programmer still has to follow only a few optimisation guidelines.

Typically, the efficiency is limited by latencies in local memory accesses and by both latencies and bandwidth in remote data transfers. Good performance requires therefore some care to hide the latencies and to have data already available in registers when they are needed by the floating-point unit.

The steps to boost efficiency include:

- Intensive use of registers to prefetch data.
- Memory accesses which are known to be always local are flagged to the compiler, so that a more aggressive scheduling can be employed.
- Memory accesses are made in large bursts of data (say up to 36–96 complex numbers in a single burst) and complex conjugation is performed "on the fly" when loading the data.
- Use of APEmille intrinsic 64-bit floating-point format in precision critical parts of the code.

Using the steps described above to optimize a bi-conjugate gradient solver for the improved Wilson-Dirac operator, the following performance numbers have been obtained:

- The main loop in the most time consuming kernel of the code achieves a pipeline filling of more than 80%.
- Computations with SU(3) matrices (clover term) run at 380 MFlops per node.
- The full inverter runs at 200 MFlops sustained (distributed lattice with local volume $6 \times 3 \times 3 \times 64$ on each node).

5. CONCLUSIONS

With the completion of the last APEmille systems at various sites by end of this year, an other 2 TFlops of overall compute power will be available to the LGT community. APEmille has become a main and reliable workhorse for many groups. System and compiler software are very stable, but further adjustments may bring additional improvements in performance and user-friendliness. While the APEmille project has basically been finished, the development of a next generation of APE machines is in progress.

ACKNOWLEDGMENTS

We would like to thank F. Aglietti, M. Cosini, I. D’Auria, A. Hoferichter, A. Menchikov, A. Michelotti, E. Panizzi, B. Proietti, G. Sacco and K.-H. Sulanke for important contributions in the early phases of the project.
