ABSTRACT

Background: GNAO1 is an emerging disorder characterized with hypotonia, developmental delay, epilepsy, and movement disorder, which can be potentially life threatening during acute exacerbation. In the USA, deep brain stimulation (DBS) has been licensed for treating children with chronic, treatment-resistant primary dystonia, who are 7 years old or older.

Case Description: A 4-year-old girl diagnosed to have GNAO1-related dyskinesia and severe global developmental delay. She had severe dyskinesia precipitated by intercurrent infection, requiring prolonged intensive care for heavy sedation and related complications. Her dyskinesia improved dramatically after DBS implantation. Technical difficulties and precautions of DBS in preschool children were discussed.

Conclusion: DBS should be considered early in the treatment of drug-resistant movement disorders in young children with GNAO1, especially after dyskinetic crisis, as they tend to recur. Presurgical counseling to parents and close monitoring of complications is also important in the process.

Keywords: Deep brain stimulation, Dyskinesia, GNAO1, Preschool child

INTRODUCTION

GNAO1 is an emerging disorder characterized with developmental delay, early onset epilepsy, and movement disorder.¹,² Life-threatening dystonic or hyperkinetic crisis is common.³ There are increasing reports in using deep brain stimulation (DBS) to ameliorate the associated movement disorders.⁴⁻⁵⁻⁶ The Food and Drug Administration in the USA has approved DBS for the treatment of dystonia in 2003 for children older than 7 years with humanitarian device exemption.⁶ However, National Health Service of England do not put forward an age limit for DBS in children.⁷ A meta-analysis of DBS in more than 300 children with dystonia from various causes showed that two-thirds of them had clinically significant (>20%) improvement in Burke–Fahn–Marsden Dystonia Rating Scale (BFMDRS), but few received DBS at age younger than 7 years old.⁸ Here, we reported
our experience of using DBS in a young child with severe GNAO1-related dyskinesia.

**CASE ILLUSTRATION**

A 4-year-old girl has background history of global developmental delay and dyskinesia, caused by *de novo* pathogenic mutation in *GNAO1* (c.709G>A, p.Glu237Lys). She could not sit independently, and she did not have any verbal expression. She was admitted with worsening of hyperkinetic movement with near continuous choreoathetoid movement involving the whole body, triggered by enterovirus infection. It was further complicated by pneumonia and rhabdomyolysis. She stayed in intensive care unit (ICU) for 7 weeks and required heavy sedation/anesthesia to control her movement, with a combination of midazolam, fentanyl, and propofol. Oral medications were also maximized [Table 1].

She still had significant choreoathetoid movement after discharge from ICU, which severely affected her daily activities such as posturing and feeding. Parents eventually agreed for DBS as rescue therapy. She underwent preoperative magnetic resonant imaging (MRI) under general anesthesia (GA). The target of DBS was bilateral posterolateral ventral portion of the globus pallidus internus (GPI). She was kept sedated and intubated after MRI. The next day, frame-based stereotactic surgery for DBS was performed under GA. Leksell® Vantage™ Head Frame was fixed to the head, and computed tomography (CT) of brain was performed together with the frame. Afterward, the preoperative MRI with targeting plan was fused to the CT images. Directional leads (Vercise™ Cartesia™ Model DB-2202-45) were implanted on both sides and a rechargeable pulse generator (Vercise Gevia™ Model DB-1200) was implanted over the left subclavian subcutaneous pocket.

On postoperative day 1, sedation was stopped and the pulse generator was switched on. The initial setting of stimulation was monopolar configuration contact 1 and 9 which were the distalmost (ventral) pair of contact, with 3 mA, pulse width 60 µs, and frequency of 130 Hz. There was significant decrease in the hyperkinetic movement in early postoperative days. The patient was discharged home on postoperative day 8. Her choreoathetoid movement continued to improve with further DBS programming. There was no further exacerbation of dyskinesia at 24 months follow-up after DBS, even with intercurrent infection. The BFMDRS was 106.5/120 before DBS and 64.5/120 by 10 months follow-up [Table 2]. The latest DBS parameters remained the same monopolar configuration 1–9, while the amplitude was increased to 3.9 mA and 4.0 mA, respectively. The frequency and pulse width remained 130 Hz and 60 µs, respectively. We were able to step down her oral drugs [Table 1]. She was also making some progress in neurodevelopment that she could now sit independently and reach out for objects.

**DISCUSSION**

*GNAO1* – Guanosine nucleotide-binding protein G (o) subunit α is a gene that is associated with neurodevelopmental problems, including early-onset epilepsy, mild-to-severe developmental delay, and various movement disorders, from hyperkinesia to lack of spontaneous movement.[13,16] The mutation is our patient has been reported in at least three patients[17,18] and its functional effect is still unknown.[19] The genotype-phenotype correlation is still unclear. The movement disorders may include variable combination of dystonia, choreoathetosis, and dyskinetic movement. Tetrabenazine appears most effective in certain patients, but response to medical treatment is often suboptimal.[17] Kelly et al., in 2019, have proposed that identification of genetic variant in *GNAO1* gene with movement disorder should prompt earlier evaluation and counseling for DBS for the treatment of movement disorder because of frequent occurrence of potentially life-threatening dystonic/dyskinetic crisis.[12]

Up to date, there were 17 published DBS implantations in patients with *GNAO1*-associated movement disorders and all reported “positive” results, usually with dramatic improvement of the hyperkinetic movement and decrease in the recurrence of status dystonicus.[3,4,8,9,13,14,18–20] These reports could certainly be limited by reporting bias.

**Table 1:** Drug regime.

| Region                  | Preoperative | 2 years follow-up |
|-------------------------|--------------|-------------------|
| Clonazepam              | 1.25 mg      | 1.5 mg            |
| Trihexyphenidyl         | 9 mg         | Stopped           |
| Baclofen                | 3 mg         | Stopped           |
| Tetrabenazine           | 50 ng        | 37.5 mg           |
| Clonidine               | 0.3 mg       | Stopped           |
| Chloral hydrate (for sleep disturbance) | 500 mg       | Stopped           |
| Body weight             | 11 kg        | 15 kg             |

**Table 2:** Scores of Burke–Fahn–Marsden Dystonia Rating Scale.

| Region                  | Preoperative | 10 months follow-up |
|-------------------------|--------------|---------------------|
| Eyes                    | 0            | 0                   |
| Mouth                   | 0            | 0                   |
| Speech and swallowing   | 4.5          | 9                   |
| Neck                    | 16           | 4.5                 |
| Right arm               | 6            | 12                  |
| Left arm                | 16           | 9                   |
| Right leg               | 16           | 12                  |
| Left leg                | 16           | 9                   |
| Trunk                   | 16           | 9                   |
| Total                   | 106.5        | 64.5                |
However, the response of DBS in these cases was dramatic as shown in video recordings with on and off stimulation.\textsuperscript{[13]} Many patients improved within days and weeks with DBS stimulation.\textsuperscript{[12]} Recently, there were also reports of long-term response of DBS in GNAO1-associated movement disorders with persistent benefit up to 10 years.\textsuperscript{[2,13]} Ten out of 17 reported cases received the implantation in ICU with dystonic/hyperkinetic crisis, which reflected the severity of the movement disorder and potentially “life-saving effect” of DBS in these patients.\textsuperscript{[1,8,11,20]}

All DBS implantations with GNAO1 mutations were targeted at GPi.\textsuperscript{[1,3,6,19]} The optimal stimulation setting is still unknown. A range of settings has been reported: with amplitude, pulse width, and frequency ranging from 1 to 4 V, 50 to 450 μs, and 130 to 210 Hz, respectively.\textsuperscript{[2,19]}

Recharging devices have been used in the series reported by Kaminska et al., in 2017. It reduces frequency of battery replacement. Yet, the DBS team needs continuous support to carers for using harness or belt for recharging. Loss of recharger and difficulty in maintaining connection between recharger and battery were common.\textsuperscript{[11]}

Radiological studies from patients with DBS suggested a projected increase in distance between entry point and target of 5–10 mm from brain growth from 4 to 18 years of age, with most occurring before 7 years of age.\textsuperscript{[1]} Younger age of implantation would necessitate need for future revision of leads as the child grows. Among 17 reported DBS implantations with GNAO1 mutations, five of them were younger than 7 years of age when they received surgery. Our patient is the second youngest patient with GNAO1 mutation who received DBS implantation.\textsuperscript{[14]} Long-term clinical follow-up plus minor rescan for the DBS lead location is needed for our patient. Implantations in young children may be associated with more technical challenges, especially if they are malnourished and/or have severe dyskinetic movement. Complications with infections, skin erosions, and/or cerebrospinal fluid leakage may be increased. Different teams have proposed various remedial strategies, such as implanting stimulators in abdomen in malnourished children\textsuperscript{[2]} or performing staged operations of electrode and stimulator placement.\textsuperscript{[15]}

In the large pediatric cohort of DBS for dystonia reported by Kaminska et al., 26 out of 126 patients were 7 years or younger when they received the implantation. The youngest one was only 3.3 years of age. Surgical site infections were the most significant adverse events and occurred in 10.3%. They concluded that medical and surgical experience of the DBS team might also be an important factor for treatment success. Safe and early DBS implantation might mitigate functional skeletal deformities and adverse effects from drugs. It might also optimize developmental potential by activity-dependent plasticity.\textsuperscript{[11]}

Families should be counseled on the risks of deterioration of hyperkinetic movement or even “dystonic storm” on sudden cessation of DBS, for example, system switch off unexpectedly, battery failure, or electrode malfunction. They should also be reminded about possible electrode contact point migration as the child grows and hence need for revision. Although movement disorder may improve, DBS may not help the neurodevelopment dramatically. Parents need to be realistic in developmental outcome of the patients.

CONCLUSION

DBS can be an effective treatment for severe hyperkinetic movement disorder in patients with pathogenic GNAO1 mutation. Age alone should not be a limitation in consideration of DBS. The risk and potential benefit of the procedure should be thoroughly discussed with the families.

Acknowledgment

The authors thanked Ms. Rosanna Wong, our occupational therapist, in the functional assessment of the patient.

Declaration of patient consent

The authors certify that they have obtained all appropriate patient consent.
